In this section, computer simulations are presented to demonstrate the effect of matched filtering and the Diophantine inverse filtering method. A room ($20 \times 16 \times 5$ m in size) was simulated using the image model [10]. The source was located at (14,9.5,1.7)m. 5th order images were assumed and wall reflectivity was assumed to be $\alpha = 0.1$. Sensor spacing was considered to be 40 cm. A large spacing between sensors was chosen to make the impulse responses as dissimilar as possible.

The SNR of the output was calculated using the formula:

$$SNR(dB) = 10 \log_{10} \frac{\sum s(n)^2}{\sum (y(n) - s(n))^2} \quad (32.35)$$

where $s(n)$ is the input speech signal and $y(n)$ is the output speech signal. The two signals are sufficiently staggered to account for the delay in the processing.

The signal-to-noise-ratios were calculated as follows:

No. of mics	SNR
2	15 dB
3	27 dB
4	37 dB

FIGURE 32.8: Rate of convergence of RAP for calculating the exact inverse filters.

For comparison, the SNR gains of a single beamforming, multiple beamforming, and matched filter linear arrays using five microphones are presented below. The multiple beamformer has one beam directed at each image of the source.

Method	SNR
Single beamformer	-1 dB
Multiple beamformer	11 dB
Matched filter	13 dB

Figure 32.9 shows the impulse response of the room using an unsteered array system consisting of four microphones. Figures 32.10 and 32.11 are the system responses of a single beamformer and the matched filter. The matched filter system response is a much better approximation of an ideal impulse than the single beamformer. But the tail of the response is still significant compared to the exact inverse system (Fig. 32.12) whose final response is very close to an ideal impulse.

FIGURE 32.9: Impulse response of a room (images up to 5th order are used).

For obtaining the same SNR gain, the exact inverse requires a lesser number of microphones than either the matched filter or the multiple beamformer. The Diophantine inverse filtering method does not suffer from the effects of spatial aliasing that may affect traditional beamformers using periodically spaced microphones. Finding the exact inverse is also more computationally intensive than matched filtering or multiple beamforming.

32.5.1 Speaker Identification

A simple speaker identification experiment was done to test the acoustic fidelity of the exact inverse system. The dimensions of the simulated room, the location of the source and the other conditions was assumed to be identical to the experiment reported in the previous section. A part of the TIMIT database with 38 speakers, all from the New England area, was used. Five sentences were used for

FIGURE 32.10: Response of a single beamformer for a source located on the axis.

training and five were used for testing. Twelve cepstral vectors were used and a Learning Vector Quantizer (LVQ) was used for identification [25].

Speaker identification accuracy for the exact inverse system:			
Testing data			
Training data	CLS (%)	One mic (%)	Array output (%)
CLS	91.6	36.3	90
Array output			92.6

Speaker identification accuracy for the exact inverse system when an interfering Gaussian noise source at 15 dB signal-to-competing noise ratio is present:			
Testing data			
Training data	CLS (%)	One mic (%)	Array output (%)
CLS	91.6	14.2	9.5
Array output			49

The identification accuracy when trained and tested on clean speech recorded through a close talking microphone (CLS) was 91.6%. The performance dropped to 36.3% when the same system was tested on a single microphone located at the center of the array. Once the Diophantine inverse filtering was used to clean up the speech, the performance jumped back to 90%. The identification accuracy when the system was trained and tested on the Diophantine inverse filtered output was 92.6%.

But the performance was poor even in the presence of modest interference. When a Gaussian noise source at 15 dB signal-to-competing noise ratio levels was introduced at (3.0,5.0,1.0)m, the performance on the output of the exact inverse filtering system (9.5%) was worse than the single

FIGURE 32.11: Response of a matched filtering system for a source located at the focus.

microphone (14.2%). Under matched training and testing conditions, the performance of the exact inverse system was significantly lower (49%).

Recently, speaker identification results were reported on the output of a matched-filtered system [26]. The room dimensions and conditions were similar to the ones in this report and the data sets used for training and testing were the same. The performance under matched conditions for close talking microphone was 94.7% and for the matched filtered output was 88.4%. In the presence of an interfering source producing Gaussian noise at 15 dB signal-to-competing noise ratio levels, the performance when trained on close talking microphone and tested on the matched filtered output was 80%; the performance when trained and tested on the matched filtered output in the presence of noise was approximately 88% [26].

From these results, it is clear that though the exact inverse filtering outperforms the matched filter under clean conditions, it performs significantly poorer when there are interfering noise sources. This can be attributed to the fact that the exact inverse system attempts to maximize the signal-to-reverberant noise ratio (SRNR) for a source at the focus. Though it maximizes the SRNR for a source at the focus and lowers the SRNR for any source located away from the focus, it does not guarantee that the contribution of interfering source to the output power will also be lowered. Figure 32.13 shows the impulse response of the exact inverse system for the location of the interfering noise source. It is clear that the SNR of the source at this location would be poor (the effective response does not look like an ideal impulse). But the signal is effectively amplified. On the other hand, the matched filter *maximizes the output power for a source located at the focus and minimizes the output power for all other sources* thus providing lower signal-to-noise ratio improvement, but higher levels of spatial discrimination.

FIGURE 32.12: Response of the Diophantine inverse filtering system (the delay involved is not shown).

FIGURE 32.13: Response of the Diophantine inverse filtering system for a source located away from the focus.

32.6 Summary

Microphone arrays can be successfully used in “inverting” room acoustics. A simple single beam-former is not effective in combating room reverberation, especially in the presence of interfering noise sources. Adaptive algorithms that project a null in the direction of the interferer can be used, but they introduce significant distortion in the main signal. Constrained adaptive arrays mitigate this problem but they are of limited capability in severely reverberant environments. Processing algorithms such as multiple beamforming and matched filtering, combined with three-dimensional array of sensors, though only providing an approximation to the inverse, give robust dereverberant systems that provide selectivity in a spatial volume and thus immunity from interfering noise sources. An exact inverse using Diophantine inverse filtering using the MINT model can be found. Though this method provides a higher signal-to-noise ratio for a source at the focus, it does not provide immunity from noise interference that the matched filtering can offer. Speaker identification results are provided that substantiate the performance analysis of these systems.

33.1 Introduction

A synthetic aperture radar (SAR) is a radar sensor that provides azimuth resolution superior to that achievable with its real beam by synthesizing a long aperture using platform motion. The geometry for the production of the SAR image is shown in Fig. 33.1. The SAR is used to generate an electromagnetic map of the surface of the earth from an airborne or spaceborne platform. This electromagnetic map of the surface contains information that can be used to distinguish different types of objects that make up the surface. The sensor is called a synthetic aperture radar because a synthetic aperture is used to achieve the narrow beamwidth necessary to get a high cross-range resolution. In SAR imagery the two dimensions are range (perpendicular to the sensor) and cross-range (parallel to the sensor). The range resolution is achieved using a high bandwidth pulsed waveform. The cross-range resolution is achieved by making use of the forward motion of the radar platform to synthesize a long aperture giving a narrow beamwidth and high cross-range resolution. The pulse returns collected along this synthetic aperture are coherently combined to create the high cross-range resolution image. A SAR sensor is advantageous compared to an optical sensor because it can operate day and night through clouds, fog, and rain, as well as at very long ranges. At very low nominal operating frequencies, less than 1 GHz, the radar even penetrates foliage and can image objects below the tree canopy. The resolution of a SAR ground map is also not fundamentally limited by the range from the sensor to the ground. If a given resolution is desired at a longer range, the synthetic aperture can simply be made longer to achieve the desired cross-range resolution.

A SAR image may contain “speckle” or coherent noise because it results from coherent processing of the data. This speckle noise is a common characteristic of high frequency SAR imagery and reducing speckle, or building algorithms that minimize speckle, is a major part of processing SAR imagery beyond the image formation stage. Traditional techniques averaged the intensity of adjacent pixels, resulting in a smoother but lower resolution image. Advanced SAR sensors can collect multiple polarimetric and/or frequency channels where each channel contains unique information about the

FIGURE 33.1: SAR imaging geometry.

surface. Recent systems have also used elevation angle diversity to produce 3-D SAR images using interferometric techniques. In all of these techniques, some sort of averaging is employed to reduce the speckle.

The largest consumers of SAR sensors and products are the defense and intelligence communities. These communities use SAR to locate and target relocatable and fixed objects. Manmade objects, especially ones with sharp corners, have very bright signals in SAR imagery, making these objects particularly easy to locate with a SAR sensor. A technology similar to SAR is inverse synthetic aperture radar (ISAR) which employs motion of the platform to image the target in cross-range. The ISAR data can be collected from a fixed radar platform since the target motion creates the viewing angle diversity necessary to achieve a given cross-range resolution. ISAR systems have been used to image ships, aircraft, and ground vehicles.

In addition to the defense and intelligence applications of SAR, there are several commercial remote sensing applications. Because a SAR sensor can operate day and night and in all weather, it provides the ability to collect data at regular intervals uninterrupted by natural influences. This stable source of ground mapping information is invaluable in tracking agriculture and other natural resources. SAR sensors have also been used to track oil spills (oil-coated water has a different backscatter than natural water), image underground rock formations (at some frequencies the radar will penetrate some soils), track ice conditions in the Arctic, and collect digital terrain elevation data.

Radar is an abbreviation for RAdio Detection And Ranging. Radar was developed in the 1930s and 1940s to detect and track ships and aircraft. These surveillance and tracking radars were designed so that a target was contained in a single resolution cell. The size of the resolution cell was a critical design parameter. Smaller resolution cells allowed one to determine the location of a target more accurately and increased the target-to-clutter ratio, improving the ability to detect a target. In the

1950s it was observed that one could map the ground (an extended target that takes up more than one resolution cell) by mounting the radar on the side of an aircraft and building a surface map from the radar returns. High range resolution was achieved by using a short pulse or high bandwidth waveform. The cross-range resolution was limited by the size of the antenna, with the cross-range resolution roughly proportional to R/L_a where R is the range from the sensor to the ground and L_a is the length of the antenna. The physical length of the antenna was constrained, limiting the resolution. In 1951, Carl Wiley of the Goodyear Aircraft Corporation noted that the reflections from two fixed targets in the antenna beam, but at different angular positions relative to the velocity vector of the platform, could be resolved by frequency analysis of the along track (or cross-range) signal spectrum. Wiley simply observed that each target had different Doppler characteristics because of its relative position to the radar platform and that one could exploit the Doppler to separate the targets. The Doppler effect is, of course, the change in frequency of a signal transmitted or received from a moving platform discovered by Christian J. Doppler in 1853:

$$f_d = v/\lambda$$

where f_d is the Doppler shift, v is the radial velocity between the radar and target, and λ is the radar wavelength. While the Doppler effect had been used in radar processing before the 1950s to separate moving targets from stationary ground clutter, Wiley's contribution was to discover that with a side looking airborne radar (SLAR), Doppler could be used to improve the cross-range spatial resolution of the radar. Other early work on SAR was done independently of Wiley at the University of Illinois and the University of Michigan during the 1950s. The first demonstration of SAR mapping was done in 1953 by the University of Illinois by performing frequency analysis of data collected by a radar operating at a 3-cm wavelength from a C-46 aircraft. Much work has been accomplished perfecting SAR hardware and processing algorithms since the first demonstration. For a much more detailed description of the history of SAR including the development of focused SAR, phase compensation techniques, calibration techniques, and autofocus, see the recent book by Curlander and McDonough [1].

Before offering a brief description of some processing approaches for forming, enhancing, and interpreting SAR imagery, we give two examples of existing SAR systems and their applications. The first system is the Shuttle Imaging Radar (SIR) developed by the NASA Jet Propulsion Laboratory (JPL) and flown on several space shuttle missions. This system was designed for non-military collection of geographic data. The second example is the Advanced Detection Technology Sensor (ADTS) built by the Loral Corporation for the MIT Lincoln Laboratory. The ADTS sensor was designed to demonstrate the capability of a SAR to detect and classify military targets. Table 33.1 contains the basic parameters for the ADTS and SIR SAR systems along with details on several other SAR systems.

Figure 33.2 shows an example image formed from data collected by the SIR SAR. The JPL engineers describe this image as follows:

This is a radar image of Mount Rainier in Washington state... This image was acquired by the Spaceborne Imaging Radar-C and X-band Synthetic Aperture Radar (SIR-C/X-SAR) aboard the space shuttle Endeavor on its 20th orbit on October 1, 1994. The area shown in the image is approximately 59 kilometers by 60 kilometers (36.5 miles by 37 miles). North is toward the top left of the image, which was composed by assigning red and green colors to the L-band, horizontally transmitted and vertically received, and the L-band, horizontally transmitted and vertically received. Blue indicates the C-band, horizontally transmitted and vertically received. In addition to highlighting topographic slopes facing the space shuttle, SIR-C records rugged areas as brighter and smooth areas as darker. The scene was illuminated by the shuttle's radar from the northwest so that northwest-facing slopes are brighter and southeast-facing slopes are dark. Forested regions are pale green in color; clear cuts and bare ground are bluish or purple; ice is

TABLE 33.1 Example SAR Systems

Platform	Bands polarization	Resolution (m)	Swath width	Interferometry
JPL AIRSAR	C, L, P-Full	4	10–18 km	Cross track L,C Along track L,C
SIR-C/X-SAR	C, L-Full, X - VV	30×30	15–90	Multi-pass

dark green and white. The round cone at the center of the image is the 14,435-foot (4,399-meter) active volcano, Mount Rainier. On the lower slopes is a zone of rock ridges and rubble (purple to reddish) above coniferous forests (in yellow/green). The western boundary of Mount Rainier National Park is seen as a transition from protected, old-growth forest to heavily logged private land, a mosaic of recent clear cuts (bright purple/blue) and partially regrown timber plantations (pale blue).

Figure 33.3 is an example image collected by the ADTS system. The ADTS system operates at a nominal frequency of 33 GHz and collects fully polarimetric, 1-ft resolution data. This image was formed using the polarimetric whitening filter (PWF) combination of three polarimetric channels to reduce the speckle noise. The output of the PWF is an estimate of radar backscatter intensity. The image displayed in Fig. 33.3 is based on a false color map which maps low intensity to black followed by green, yellow, and finally white. The color map simply gives the non-color radar sensor output false colors that make the low intensity shadows look black, the grass look green, the trees look yellow, and bright objects look white. This sample image was collected near Stockbridge, New York, and is of a house with an above ground swimming pool and several junked cars in the backyard. The radar is at the top of the image looking down at a 20° depression angle. The scene contains large areas of grass or crops and some foliage. Note the bright returns from the manmade objects, including the circular above-ground swimming pool, and strong corner reflector scattering from some of the cars in the backyard. Also note the relatively strong return from the foliage canopy. At this frequency the radar does not penetrate the foliage canopy. Note the shadows behind the trees where there is no radar illumination.

In this chapter on SAR algorithms, we give a brief introduction to the image formation process in Section 33.2. We review a few simple algorithms for reducing speckle noise in SAR imagery and automatic detection of manmade objects in Section 33.3. We review a few simple automatic object classification algorithms for SAR imagery in Section 33.4. This brief introduction to SAR only contains a few example algorithms. In the Section “Further Reading”, we recommend some starting

FIGURE 33.2: SAR image of Mt. Rainier in Washington State taken from shuttle imaging radar.

points for further reading on SAR algorithms, and discuss several open issues under current research in the SAR community.

33.2 Image Formation

In this section, we discuss some basic principles of SAR image formation. For more detailed information about SAR image formation, the reader is directed to the references given at the end of this chapter. One fundamental scenario under which SAR data is collected is shown in Fig. 33.1. An aircraft flies in a straight path at a constant velocity and collects radar data at a boresight of 90° . In practice it is impossible for an aircraft to fly in a perfectly straight line at a constant velocity (at least within a wavelength), so motion (phase) compensation of the received radar signal is needed to account for aircraft perturbations. The radar on the aircraft transmits a short pulsed waveform or uses frequency modulation to achieve high range resolution imaging of the surface. The pulses collected from several positions along the trajectory of the aircraft are coherently combined to synthesize a long synthetic aperture in order to achieve a high cross-range resolution on the surface. In this section, we first discuss SLAR where only range processing is performed. Next, we discuss unfocused SAR where both range and cross-range processing are executed. Finally, we discuss focused SAR where “focusing” is performed in addition to range and cross-range processing to achieve the highest resolution and best image quality. At the end of this section we briefly mention several other important

FIGURE 33.3: SAR image near Stockbridge, New York, collected by the ADTS.

SAR image formation topics such as phase compensation, clutter-lock, autofocus, spotlight SAR, and ISAR. The details of these topics can be found in [1]–[3].

33.2.1 Side-Looking Airborne Radar (SLAR)

SLAR is the earliest radar system for remote surveillance of a surface. These radar systems could only perform range processing to form the 2-D reflectivity map of the surface, so the cross-range resolution is limited by the real antenna beamwidth. These SLAR systems typically operated at high frequencies (microwave or millimeter-wave) to maximize the cross-range resolution. We cover SLAR systems because SLAR performs the same range processing as SAR, and the limitations of a SLAR motivate the need for SAR processing.

The resolution of a SLAR system is limited by the radar pulse width in the range dimension, and the beamwidth and slant range in the cross-range dimension:

$$\begin{aligned}\delta_r &= cT/2 \cos \eta \\ \delta_{cr} &= R\lambda/L_a\end{aligned}$$

where we represent the approximate 3-dB beamwidth of the antenna by λ/L_a , δ_r is the range resolution, δ_{cr} is the cross-range resolution, c is the speed of wave propagation, T is the compressed pulse width, η is the angle between the radar beam and the surface, R is the slant range to the surface, λ is the wavelength, and L_a is the length of the antenna.

The goal is to design the SLAR with a narrow beamwidth, short slant range, and a short pulsewidth to achieve high resolution. In practice, the pulsewidth of the radar is limited by hardware constraints and the amount of “energy on target” required to get sufficient signal-to-noise ratio to obtain a good

image. To achieve a high range resolution without a short pulse, frequency modulation can be used to synthesize an effectively short pulse. This process of generating a narrow synthetic pulsewidth is called pulse compression. The approach is to introduce a modulation on the transmitted pulse, and then pass the received signal through a filter matched to the transmit signal modulation. The most common transmit waveforms used for pulse compression are linear FM (or chirp) and phase coded. Some radars use a digital version of linear FM called a stepped frequency waveform.

We illustrate pulse compression with the ideal application of the linear FM waveform. The square pulse is modulated by a linear FM signal, and the resulting transmit signal is

$$s(t) = \begin{cases} \cos\left(\omega_0 t - \frac{1}{2}\mu t^2\right) & |t| \leq T/2 \\ 0 & |t| > T/2 \end{cases}$$

where the bandwidth (frequency deviation) introduced by the linear FM is

$$\Delta f = T\mu/2\pi$$

If this transmit pulse is perfectly reflected from a stationary point target, range losses are ignored, and we shift in time to remove the two-way delay; the received signal is exactly the same as the transmitted signal. The matched filter response for the transmitted signal is

$$h(t) = \left(\frac{2\mu}{\pi}\right)^{1/2} \cos\left(\omega_0 t + \frac{1}{2}\mu t^2\right)$$

The output of the received signal applied to the matched filter is:

$$\Psi(t) = \left(\frac{\mu T^2}{2\pi}\right)^{1/2} \frac{\sin(\mu T t/2)}{(\mu T t/2)} \operatorname{Re} \left[e^{j\left(\omega_0 t + \frac{1}{2}\mu t^2 + \pi/4\right)} \right]$$

This output has a mainlobe that has a 4-dB beamwidth of $1/\Delta f$. The resulting compressed pulse can be significantly narrower than the width of the transmitted pulse with a pulse compression ratio of $T\Delta f$. The range resolution of the radar has been increased by this pulse compression factor and is now given by:

$$\delta_r \approx c/2\Delta f \cos \eta$$

Note that the range resolution in the ideal case is now completely independent of the physical width of the transmitted pulse. Performing range compression against real radar targets that Doppler shift the frequency of the receive signal introduces ambiguities resulting in additional signal processing issues that must be addressed. There is a trade-off between the ability of a radar waveform to resolve a target in range and frequency. The performance of a waveform in range-frequency space is given by its ambiguity. The ambiguity function is the output of the matched filter for the signal for which it is matched and for frequency shifted versions of that signal. The references contain a much more detailed description of ambiguity functions and radar waveform design.

Using pulse compression, a SLAR system can achieve a very high range resolution on the order of 1 ft or less, but the cross-range resolution of the SLAR is limited by the physical beamwidth of the antenna, the operating frequency, and the slant range. This cross-range resolution limitation of SLAR motivates the use of a synthetic array antenna to increase the cross-range resolution.

33.2.2 Unfocused Synthetic Aperture Radar

Figure 33.1 provides a good geometric description of SAR. As with SLAR, the radar platform moves along a straight line collecting radar data from the surface. The SAR system goes one step further than

SLAR by coherently combining pulses collected along the flight path to synthesize a long synthetic array. The beamwidth of this synthetic aperture is significantly narrower than the physical beamwidth (real beam) of the real antenna. The ideal synthetic beamwidth of this synthetic aperture is

$$\theta_B = \lambda/2L_\theta$$

The factor of two results from the two-way propagation from the moving platform. The unfocused SAR can be implemented by performing FFT processing in the cross-range dimension for the samples in each range bin. This is simply the conventional beamformer for an array antenna. The difference between SAR and real beam radar is that the aperture samples that comprise the SAR are collected at different times by a moving platform. There are several design constraints on a SAR system, including:

- The speed of the platform and pulse repetition rate (PRF) of the radar must be mutually selected so that the sample points of the synthetic array are separated by less than $\lambda/2$ to avoid grating lobes.
- The PRF must be selected so that the swath width is unambiguously sampled.
- A point on the ground must be visible to the radar real beam across the entire length of the synthetic array. This limits the size of the real beam antenna. This constraint leads to the observation that with SAR, the smaller the real-beam antenna, the better the resolution, whereas with SLAR the larger the real-beam antenna, the better the resolution.
- The SAR assumes that a ground target has an isotropic signal across the collection angle of the radar platform as it flies along the synthetic array.

The resolution of the unfocused SAR is limited because the slant range to a scatterer at a fixed location on the surface changes along the synthetic aperture. If we limit the synthetic aperture to a length so that the range from every array point in the aperture to a fixed surface location differs by less than $\lambda/8$, then the cross-range resolution of the unfocused SAR is limited to:

$$\delta_{cr} = \sqrt{R\lambda/2}$$

33.2.3 Focused Synthetic Aperture Radar

The cross-range limitation of an unfocused SAR can be removed by focusing the data, as in optics. The focusing procedure for the SAR involves adjusting the phase of the received signal for every range sample in the image so that all of the points processed in cross-range through the synthetic beamformer appear to be at the same range. The phase error at each range sample used to form the SAR image is

$$\Delta\phi = \frac{2\pi}{\lambda} \left(\frac{d_n^2}{R} \right) \text{ radian}$$

where d_n is the cross-range distance from the beam center, R is the slant range to the point on the ground from the beam center, and λ is the wavelength. The range samples can be focused before cross-range processing by removing this phase error from the phase history data. Note that each data point has a different phase correction based on the along-track position of the sensor and the point's range from the sensor.

When focusing is performed, the resulting SAR image resolution is independent of the slant range between the sensor and ground. This can be shown as follows:

$$\delta_{cr} = R\theta_s$$

where,

$$\theta_s \approx \frac{\lambda}{2L_e} \text{ and } L_e \approx \frac{R\lambda}{L_a}$$

therefore,

$$\delta_{cr} \approx L_a/2$$

The effective beamwidth of the synthetic aperture is approximately $\lambda/2L_e$ where the factor of two comes from the two-way propagation of the energy (the exact effective beamwidth depends on the synthetic array taper used to control sidelobes). The length of the effective aperture (L_e) is limited by the fact that a given scatterer on the surface must be in the mainbeam of the real radar beam for every position along the synthetic aperture. The result is that the resolution of the SAR when the data is focused is approximately $L_a/2$.

SAR processing can also be developed by considering the Doppler of the radar signal from the surface as first done by Wiley in 1951. When the real beamwidth of the SAR is small, a point on the surface has an approximately linearly decreasing Doppler frequency as it passes through the main beam of the real SAR beamwidth. This time varying Doppler frequency has been shown to be approximately:

$$f_d(t) = \frac{2v^2|t - t_0|}{\lambda R}$$

where v is the velocity of the platform and t_0 is the time that the point scatterer is in the center of the main beam. The change in Doppler frequency as the point passes through the main beam is $2v^2T_d/\lambda R$, and T_d is the time that the point is in the main beam. As with linear FM pulse compression, covered in Section 33.2.1, this Doppler signal can be processed through a filter to produce a higher cross-range resolution signal which is limited by the size of the real aperture just as with the synthetic antenna interpretation ($\delta_{cr} = L_a/2$). In a modern SAR system, typically both pulse compression (synthetic range processing) and a synthetic aperture (synthetic cross-range processing) are employed. In most cases, these transformations are separable where the range processing is referred to as “fast time” processing and the cross-range processing is referred to as “slow-time” processing.

A modern SAR system requires several additional signal processing algorithms to achieve high resolution imagery. In practice, the platform does not fly a straight and level path, so the phase of the raw receive signal must be adjusted to account for aircraft perturbations, a procedure called motion compensation. In addition, since it is difficult to exactly estimate the platform parameters necessary to focus the SAR image, an autofocus algorithm is used. This algorithm derives the platform parameters from the raw SAR data to focus the imagery. There is also an interpolation algorithm that converts from polar to rectangular formats for the imagery display. Most modern SAR systems form imagery digitally using either an FFT or a bank of matched filters. Typically, a SAR will operate in either a stripmap or spotlight mode. In the stripmap mode, the SAR antenna is typically pointed perpendicular to the flight path (although it may be squinted slightly to one side). A stripmap SAR keeps its antenna position fixed and collects SAR imagery along a swath to one side of the platform. A spotlight SAR can move its antenna to point at a position on the ground for a longer period of time (thus actually achieving cross-range resolutions even greater than the aperture length over two). Many SAR systems support both stripmap and spotlight modes, using the stripmap mode to cover large areas of the surface in a slightly lower resolution mode, and spotlight modes to perform very high resolution imaging of areas of high interest.

33.3 SAR Image Enhancement

In this section we review a few techniques for removing speckle noise from SAR imagery. Removing the speckle can make it easier to extract information from SAR imagery and improves the visual quality.

Coherent noise or speckle can be a major distortion in high resolution, high frequency SAR imagery. The speckle is caused when the intensity of a resolution cell results from the coherent combination of many wavefronts resulting from randomly oriented clutter surfaces within a resolution cell. These wavefronts can combine constructively or destructively resulting in intensity variations across the image. When the number of wavefronts approaches infinity (i.e., large resolution cell collected by a high frequency radar) the Rayleigh clutter model can be used to represent the speckle under the right statistical assumptions. When the number of wavefronts is less than infinity, the K -distribution and other product models do a better job of theoretically and empirically modeling the clutter.

When the combination of the radar system design and clutter properties results in images that contain large amounts of speckle, it is desirable to perform additional processing to reduce the speckle. One approach for speckle reduction is to noncoherently spatially average adjacent resolution cells, sacrificing resolution for the speckle reduction. This spatial averaging can be performed as a part of the image formation analogous to the Bartlett method of spectral estimation. Another approach for reducing speckle is to average across polarimetric channels if multiple polarimetric channels are available.

The *polarimetric whitening filter* (PWF) reduces the speckle content while preserving the image resolution. The PWF was derived by Novak et al. [5] as a quadratic filter that minimizes a specific speckle metric (defined as the ratio of the clutter standard deviation to its mean). The PWF first whitens the polarimetric data with respect to the clutter's polarimetric covariance, and then noncoherently averages across the polarimetric channels. This whitening filter essentially diagonalizes the covariance matrix of the complex backscatter vector $[HH, HV, VV]^T$, such that the resulting new linear polarization basis $[HH', HV', VV']^T$ has equal power in each component, where:

$$\begin{bmatrix} HH' \\ HV' \\ VV' \end{bmatrix} = \begin{bmatrix} HH \\ \frac{HV}{\sqrt{\varepsilon}} \\ \frac{VV - \rho^* \sqrt{\gamma} HH}{\sqrt{\gamma(1-|\rho|^2)}} \end{bmatrix} \quad (33.1)$$

where

$$\varepsilon = \frac{E(|HV|^2)}{E(|HH|^2)}, \gamma = \frac{E(|W|^2)}{E(|HH|^2)}, \rho = \frac{E(HH \cdot W^*)}{\sqrt{E(|HH|^2) \cdot E(|W|^2)}} \quad (33.2)$$

The polarization scattering matrix (using a linear-polarization basis) can then be expressed as

$$\sum = \sigma_{HH} \begin{bmatrix} 1 & 0 & \rho\sqrt{\gamma} \\ 0 & \varepsilon & 0 \\ \rho^*\sqrt{\gamma} & 0 & \gamma \end{bmatrix} \quad (33.3)$$

The pixel intensity (power) is then derived through non-coherent averaging of the power in each of the new polarization components,

$$Y = |HH|^2 + \left| \frac{HV}{\sqrt{\varepsilon}} \right|^2 + \left| \frac{W - \rho^* \sqrt{\gamma} HH}{\sqrt{\gamma(1-|\rho|^2)}} \right|^2 \quad (33.4)$$

yielding a minimal speckle image at the original image resolution. Novak et al. [5] have shown that on the ADTS SAR data, the PWF reduces the clutter standard deviation by 2.0 to 2.7 dB compared with the standard deviation of single-polarimetric-channel data. The PWF has a dramatic effect on the visual quality of the SAR imagery and the performance of automatic detection and classification

algorithms applied to SAR images. The PWF does not take into account the effect of the speckle reduction operation on target signals. It only minimizes the clutter. There has been recent work on polarimetric speckle reduction filters that both reduce the clutter speckle while preserving the target signal. Fig. 33.4 shows the three polarimetric channels and the resulting PWF image for an ADTS SAR chip of a target-like object.

FIGURE 33.4: Polarimetric processing of SAR data to reduce speckle.

33.4 Automatic Object Detection and Classification in SAR Imagery

SAR algorithmic tasks of high interest to the defense and intelligence communities include automatic target detection and recognition (ATD/R). Since SAR imagery has very different target and clutter characteristics as compared with visual and infrared imagery, uniquely designed ATD/R algorithms are required for SAR data. In this section, we describe a few basic ATD/R algorithms that have been developed for high resolution, high frequency SAR imagery (10 GHz or above) [6, 7, 8].

Performing target detection and classification against remote sensing imagery and, in particular, SAR imagery is very different from the classical pattern recognition problem. In the classical pattern recognition problem, we have models defining N classes, and the goal is to design a classifier to separate sensor data into one of the N classes. In SAR target classification, the imagery contains regions of diffuse clutter which can be represented to some degree by models, but the imagery also contains a possibly uncountable set of target-like discrete unknown and unmodelable objects. The goal is to reject both the diffuse clutter and the unknown discrete objects and to classify the target

objects. This need to handle the unknown object means that the classifier must have the unknown class as a possible outcome of the classifier. Since the unknown class cannot be modeled, most SAR ATR systems solve the problem by employing a distance metric to compare the sensor data with models for each target of interest, and if the distance is too great, the data is classified as an unknown object.

Another design issue for a SAR ATD/R system is the need to process hundreds of square kilometers of data in near real-time to be of practical benefit. One widely used approach for solving this computational problem is to use a simple focus-of-attention or pre-detection algorithm to reject most of the diffuse clutter and pass only regions of interest (ROI), including all of the targets. These ROIs are then processed through a set of computationally more complicated classifiers which classify objects in the ROIs as one of the targets or as an unknown object.

In high frequency SAR imagery most target signatures have extremely bright peaks caused by physical corners on the target. One effective pre-detection technique involves applying a single pixel detector to find the bright pixels caused by corner reflectors on the targets. Since the background clutter power is unknown and varies across the image, we cannot simply use a thresholding operation to find these bright pixels. One approach for handling the unknown clutter power is to estimate it from clutter samples surrounding a test pixel. This approach for target detection is referred to as a constant false alarm rate (CFAR) detector because with the proper clutter and target models, it can be shown that the output of the detector has a constant false alarm rate in the presence of unknown clutter parameters. Fig. 33.5 depicts one design for a CFAR template. The clutter parameters are estimated using the auxiliary samples along a box with a test sample in the center. This test sample may or may not be on a target. The size of the box containing the auxiliary samples is sized so that the auxiliary samples do not overlap a target when the test sample is on the target. We also need to keep the size of the box containing the auxiliary samples as small as possible, so that we get a good local estimate of the clutter parameters. With these design constraints, a good choice for the CFAR template is just over twice the maximum dimension of the targets of interest.

FIGURE 33.5: CFAR template.

One of these CFAR algorithms, first developed by Goldstein [9], is referred to as the two parameter CFAR or the log- t test:

$$\frac{\log x - \frac{1}{N} \sum_{i=1}^N \log y_i}{\sqrt{\frac{1}{N-1} \sum_{i=1}^N \left(\log y_i - \frac{1}{N} \sum_{i=1}^N \log y_i \right)^2}} \begin{matrix} H_1 \\ > \\ < \\ H_0 \end{matrix} t$$

where x is the test sample, and y_1, \dots, y_N are the auxiliary samples. This test is performed for

every pixel in the SAR scene and the output is thresholded with the threshold t . When N is large, the test statistic is approximately Gaussian if the SAR data is log normally distributed. In this case, Gaussian statistics can be used to determine the threshold for a given probability of false alarm. In practice, it is much more accurate to determine the threshold with a set of training data. This is primarily a corner reflector detector, and the output will almost always get more than one detection per target. In practice, a simple clustering algorithm can be used based on the size of the targets and the expected spacing of targets to get one detection per target and reduce the number of false alarms which are usually also clustered. The two-parameter CFAR test is one example of a simple SAR target detector. Researchers have also developed more sophisticated ordered statistic detectors, multi-polarimetric channel detectors, and feature-based discriminators to get improved SAR target detector performance [6, 7, 8].

This simple pre-detector gets a large number of false alarms (hundreds per square kilometer in single polarimetric channel, one foot resolution imagery) [5]. In order to further reduce the false alarm rate and classify the targets, further processing is necessary on the output of the pre-detector. One widely used approach for performing this classification operation is to apply a linear filter bank classifier to the ROIs identified by the pre-detector. Researchers have developed a large number of approaches for designing these linear filter bank classifiers including spatial matched filters [7], synthetic discriminant functions [7], and vector quantization/learning vector quantization [8]. The simplest approach is to build the spatial matched filters by breaking the target into angle subclasses, and averaging the training signatures in a given angle subclass to represent that subclass. In practice, the templates must be normalized because the absolute energy of a given target signature is unknown. The exact location of a target in the ROI is also unknown, so the matched filter must be applied for every possible spatial position of the target. This is performed more efficiently in the frequency domain as follows:

$$\rho_{ij} = \max \left\{ FFT^{-1} \left[FFT(\mathbf{t}_{ij}) \cdot FFT(\mathbf{x})^* \right] \right\}$$

where \mathbf{x} is a ROI and \mathbf{t}_{ij} is the spatial matched filter representing the i th target and the j th angle subclass of that target. The ρ_{ij} is computed for every angle subclass of every target, and the maximum represents the estimate of the correct target and angle subclass. The output can be thresholded to reject false alarms. In practice the level of the threshold is determined by testing on both target and false alarm data.

In this section, we have reviewed a few basic concepts in SAR ATD/R. For a much more detailed treatment of this topic, consult the references and the recommended further reading given below.

Further Reading and Open Research Issues

A very brief overview of SAR with a few example algorithms is given here. The items in the reference list give a more detailed treatment of the topics covered in this chapter. SAR is a very active research topic. Articles on SAR algorithms are regularly published in many journals and conferences, including:

Journals

IEEE Transactions on Aerospace and Electronic Systems, *IEEE Transactions on Geoscience and Remote Sensing*, *IEEE Transactions on Antennas and Propagation*, *IEEE Transactions on Signal Processing*, and *IEEE Transactions on Image Processing*.

Conferences

IEEE National Radar Conference, *IEEE International Radar Conference*, and the International Society for Optical Engineering (SPIE) has several SAR Conferences.

There are numerous open areas of research on SAR signal processing algorithms including:

- Still developing an understanding of the utility and applications of multi-polarimetric, multi-frequency, and 3-D SAR.
- Performance/robustness of model-based image formation not completely understood.
- Performance/robustness of different detection, discrimination, and classification algorithms given radar, clutter, and target parameters not completely understood.
- No fundamental theoretical understanding of performance limitations given radar, clutter, and target parameters (i.e., no Shannon theory).

34.1 Introduction

In this chapter we consider a class of iterative restoration algorithms. If y is the observed noisy and blurred signal, D the operator describing the degradation system, x the input to the system, and n the noise added to the output signal, the input-output relation is described by [3, 51]

$$y = Dx + n. \quad (34.1)$$

Henceforth, boldface lower-case letters represent vectors and boldface upper-case letters represent a general operator or a matrix. The problem, therefore, to be solved is the inverse problem of recovering x from knowledge of y , D , and n . Although the presentation will refer to and apply to signals of any dimensionality, the restoration of greyscale images is the main application of interest.

There are numerous imaging applications which are described by Eq. (34.1) [3, 5, 28, 36, 52]. D , for example, might represent a model of the turbulent atmosphere in astronomical observations with ground-based telescopes, or a model of the degradation introduced by an out-of-focus imaging device. D might also represent the quantization performed on a signal, or a transformation of it, for reducing the number of bits required to represent the signal (compression application).

The success in solving any recovery problem depends on the amount of the available prior information. This information refers to properties of the original signal, the degradation system (which is in general only partially known), and the noise process. Such prior information can, for example, be represented by the fact that the original signal is a sample of a stochastic field, or that the signal is “smooth,” or that the signal takes only nonnegative values. Besides defining the amount of prior information, the ease of incorporating it into the recovery algorithm is equally critical.

After the degradation model is established, the next step is the formulation of a solution approach. This might involve the stochastic modeling of the input signal (and the noise), the determination of the model parameters, and the formulation of a criterion to be optimized. Alternatively it might involve the formulation of a functional to be optimized subject to constraints imposed by the prior information. In the simplest possible case, the degradation equation defines directly the solution approach. For example, if D is a square invertible matrix, and the noise is ignored in Eq. (34.1), $x = D^{-1}y$ is the desired unique solution. In most cases, however, the solution of Eq. (34.1) represents an ill-posed problem [56]. Application of regularization theory transforms it to a well-posed problem which provides meaningful solutions to the original problem.

There are a large number of approaches providing solutions to the image restoration problem. For recent reviews of such approaches refer, for example, to [5, 28]. The intention of this chapter is to concentrate only on a specific type of iterative algorithm, the successive approximation algorithm, and its application to the signal and image restoration problem. The basic form of such an algorithm is presented and analyzed first in detail to introduce the reader to the topic and address the issues involved. More advanced forms of the algorithm are presented in subsequent sections.

34.2 Iterative Recovery Algorithms

Iterative algorithms form an important part of optimization theory and numerical analysis. They date back at least to the Gauss years, but they also represent a topic of active research. A large part of any textbook on optimization theory or numerical analysis deals with iterative optimization techniques or algorithms [43, 44]. In this chapter we review certain iterative algorithms which have been applied to solving specific signal recovery problems in the last 15 to 20 years. We will briefly present some of the more basic algorithms and also review some of the recent advances.

A very comprehensive paper describing the various signal processing inverse problems which can be solved by the successive approximations iterative algorithm is the paper by Schafer et al. [49]. The basic idea behind such an algorithm is that the solution to the problem of recovering a signal which satisfies certain constraints from its degraded observation can be found by the alternate implementation of the degradation and the constraint operator. Problems reported in [49] which can be solved with such an iterative algorithm are the phase-only recovery problem, the magnitude-only recovery problem, the bandlimited extrapolation problem, the image restoration problem, and the filter design problem [10]. Reviews of iterative restoration algorithms are also presented in [7, 25]. There are certain advantages associated with iterative restoration techniques, such as [25, 49]: (1) there is no need to determine or implement the inverse of an operator; (2) knowledge about the solution can be incorporated into the restoration process in a relatively straightforward manner; (3) the solution process can be monitored as it progresses; and (4) the partially restored signal can be utilized in determining unknown parameters pertaining to the solution.

In the following we first present the development and analysis of two simple iterative restoration algorithms. Such algorithms are based on a simpler degradation model, when the degradation is linear and spatially invariant, and the noise is ignored. The description of such algorithms is intended to provide a good understanding of the various issues involved in dealing with iterative algorithms. We then proceed to work with the matrix-vector representation of the degradation model and the iterative algorithms. The degradation systems described now are linear but not necessarily spatially

invariant. The relation between the matrix-vector and scalar representation of the degradation equation and the iterative solution is also presented. Various forms of regularized solutions and the resulting iterations are briefly presented. As it will become clear, the basic iteration is the basis for any of the iterations to be presented.

34.3 Spatially Invariant Degradation

34.3.1 Degradation Model

Let us consider the following degradation model

$$y(i, j) = d(i, j) * x(i, j) , \quad (34.2)$$

where $y(i, j)$ and $x(i, j)$ represent, respectively, the observed degraded and original image, $d(i, j)$ the impulse response of the degradation system, and $*$ denotes two-dimensional (2D) convolution. We rewrite Eq. (34.2) as follows

$$\Phi(x(i, j)) = y(i, j) - d(i, j) * x(i, j) = 0. \quad (34.3)$$

The restoration problem, therefore, of finding an estimate of $x(i, j)$ given $y(i, j)$ and $d(i, j)$ becomes the problem of finding a root of $\Phi(x(i, j)) = 0$.

34.3.2 Basic Iterative Restoration Algorithm

The following identity holds for any value of the parameter β

$$x(i, j) = x(i, j) + \beta \Phi(x(i, j)) . \quad (34.4)$$

Equation (34.4) forms the basis of the successive approximation iteration by interpreting $x(i, j)$ on the left-hand side as the solution at the current iteration step and $x(i, j)$ on the right-hand side as the solution at the previous iteration step. That is,

$$\begin{aligned} x_0(i, j) &= 0 \\ x_{k+1}(i, j) &= x_k(i, j) + \beta \Phi(x_k(i, j)) \\ &= \beta y(i, j) + (\delta(i, j) - \beta d(i, j)) * x_k(i, j) , \end{aligned} \quad (34.5)$$

where $\delta(i, j)$ denotes the discrete delta function and β the relaxation parameter which controls the convergence as well as the rate of convergence of the iteration. Iteration (34.5) is the basis of a large number of iterative recovery algorithms, some of which will be presented in the subsequent sections [1, 14, 17, 31, 32, 38]. This is the reason it will be analyzed in quite some detail. What differentiates the various iterative algorithms is the form of the function $\Phi(x(i, j))$. Perhaps the earliest reference to iteration (34.5) was by Van Cittert [61] in the 1930s. In this case the gain β was equal to one. Jansson et al. [17] modified the Van Cittert algorithm by replacing β with a relaxation parameter that depends on the signal. Also Kawata et al. [31, 32] used Eq. (34.5) for image restoration with a fixed or a varying parameter β .

34.3.3 Convergence

Clearly if a root of $\Phi(x(i, j))$ exists, this root is a *fixed point* of iteration (34.5), that is $x_{k+1}(i, j) = x_k(i, j)$. It is not guaranteed, however, that iteration (34.5) will converge even if Eq. (34.3) has one or more solutions. Let us, therefore, examine under what conditions (sufficient conditions) iteration (34.5) converges. Let us first rewrite it in the discrete frequency domain, by taking the 2D discrete Fourier transform (DFT) of both sides. It should be mentioned here that the arrays involved in iteration (34.5) are appropriately padded with zeros so that the result of 2D circular convolution equals the result of 2D linear convolution in Eq. (34.2). The required padding by zeros determines the size of the 2D DFT. Iteration (34.5) then becomes

$$\begin{aligned} X_0(u, v) &= 0 \\ X_{k+1}(u, v) &= \beta Y(u, v) + (1 - \beta D(u, v)) X_k(u, v), \end{aligned} \quad (34.6)$$

where $X_k(u, v)$, $Y(u, v)$, and $D(u, v)$ represent respectively the 2D DFT of $x_k(i, j)$, $y(i, j)$, and $d(i, j)$, and (u, v) the discrete 2D frequency lattice. We express next $X_k(u, v)$ in terms of $X_0(u, v)$. Clearly,

$$\begin{aligned} X_1(u, v) &= \beta Y(u, v) \\ X_2(u, v) &= \beta Y(u, v) + (1 - \beta D(u, v)) \beta Y(u, v) \\ &= \sum_{\ell=0}^1 (1 - \beta D(u, v))^\ell \beta Y(u, v) \\ &\dots \dots \dots \\ X_k(u, v) &= \sum_{\ell=0}^{k-1} (1 - \beta D(u, v))^\ell \beta Y(u, v) \\ &= \frac{1 - (1 - \beta D(u, v))^k}{1 - (1 - \beta D(u, v))} \beta Y(u, v) \\ &= (1 - (1 - \beta D(u, v))^k) X(u, v) \end{aligned} \quad (34.7)$$

if $D(u, v) \neq 0$. For $D(u, v) = 0$,

$$X_k(u, v) = k \cdot \beta Y(u, v) = 0, \quad (34.8)$$

since $Y(u, v) = 0$ at the discrete frequencies (u, v) for which $D(u, v) = 0$. Clearly, from Eq. (34.7) if

$$|1 - \beta D(u, v)| < 1, \quad (34.9)$$

then

$$\lim_{k \rightarrow \infty} X_k(u, v) = X(u, v). \quad (34.10)$$

Having a closer look at the sufficient condition for convergence, Eq. (34.9), it can be rewritten as

$$\begin{aligned} |1 - \beta \operatorname{Re}\{D(u, v)\} - \beta \operatorname{Im}\{D(u, v)\}|^2 &< 1 \\ \Rightarrow (1 - \beta \operatorname{Re}\{D(u, v)\})^2 + (\beta \operatorname{Im}\{D(u, v)\})^2 &< 1. \end{aligned} \quad (34.11)$$

Inequality (34.11) defines the region inside a circle of radius $1/\beta$ centered at $c = (1/\beta, 0)$ in the $(\operatorname{Re}\{D(u, v)\}, \operatorname{Im}\{D(u, v)\})$ domain, as shown in Fig. 34.1. From this figure it is clear that the left half-plane is not included in the region of convergence. That is, even though by decreasing β the size

FIGURE 34.1: Geometric interpretation of the sufficient condition for convergence of the basic iteration, where $c = (1/\beta, 0)$.

of the region of convergence increases, if the real part of $D(u, v)$ is negative, the sufficient condition for convergence cannot be satisfied. Therefore, for the class of degradations that this is the case, such as the degradation due to motion, iteration (34.5) is not guaranteed to converge.

The following form of (34.11) results when $\text{Im}\{D(u, v)\} = 0$, which means that $d(i, j)$ is symmetric

$$0 < \beta < \frac{2}{D_{\max}(u, v)}, \quad (34.12)$$

where $D_{\max}(u, v)$ denotes the maximum value of $D(u, v)$ over all frequencies (u, v) . If we now also take into account that $d(i, j)$ is typically normalized, i.e., $\sum_{i,j} d(i, j) = 1$, and represents a low pass degradation, then $D(0, 0) = D_{\max}(u, v) = 1$. In this case (34.11) becomes

$$0 < \beta < 2. \quad (34.13)$$

From the above analysis, when the sufficient condition for convergence is satisfied, the iteration converges to the original signal. This is also the inverse solution obtained directly from the degradation equation. That is, by rewriting Eq. (34.2) in the discrete frequency domain

$$Y(u, v) = D(u, v) \cdot X(u, v), \quad (34.14)$$

we obtain, for $D(u, v) \neq 0$,

$$X(u, v) = \frac{Y(u, v)}{D(u, v)}. \quad (34.15)$$

An important point to be made here is that, unlike the iterative solution, the inverse solution (34.15) can be obtained without imposing any requirements on $D(u, v)$. That is, even if Eq. (34.2) or (34.14) has a unique solution, that is, $D(u, v) \neq 0$ for all (u, v) , iteration (34.5) may not converge if the sufficient condition for convergence is not satisfied. It is not, therefore, the appropriate iteration to solve the problem. Actually iteration (34.5) may not offer any advantages over the direct implementation of the inverse filter of Eq. (34.15) if no other features of the iterative algorithms are used, as will be explained later. The only possible advantage of iteration (34.5) over Eq. (34.15) is that the noise amplification in the restored image can be controlled by terminating the iteration before convergence, which represents another form of regularization. The effect of noise on the quality of the restoration has been studied experimentally in [47]. An iteration which will converge to the inverse solution of Eq. (34.2) for any $d(i, j)$ is described in the next section.

34.3.4 Reblurring

The degradation Eq. (34.2) can be modified so that the successive approximations iteration converges for a larger class of degradations. That is, the observed data $y(i, j)$ are first filtered (reblurred) by a system with impulse response $d^*(-i, -j)$, where $*$ denotes complex conjugation [33]. The degradation Eq. (34.2), therefore, becomes

$$\begin{aligned}\tilde{y}(i, j) &= y(i, j) * d^*(-i, -j) = d^*(-i, -j) * d(i, j) * x(i, j) \\ &= \tilde{d}(i, j) * x(i, j) .\end{aligned}\quad (34.16)$$

If we follow the same steps as in the previous section substituting $y(i, j)$ by $\tilde{y}(i, j)$ and $d(i, j)$ by $\tilde{d}(i, j)$ the iteration providing a solution to Eq. (34.16) becomes

$$\begin{aligned}x_0(i, j) &= 0 \\ x_{k+1}(i, j) &= x_k(i, j) + \beta d^*(-i, -j) * (y(i, j) - d(i, j) * x_k(i, j)) \\ &= \beta d^*(-i, -j) * y(i, j) + (\delta(i, j) \\ &\quad - \beta d^*(-i, -j) * d(i, j)) * x_k(i, j) .\end{aligned}\quad (34.17)$$

Now, the sufficient condition for convergence, corresponding to condition (34.9), becomes

$$|1 - \beta |D(u, v)|^2| < 1 , \quad (34.18)$$

which can be always satisfied for

$$0 < \beta < \frac{2}{\max_{u,v} |D(u, v)|^2} . \quad (34.19)$$

The presentation so far has followed a rather simple and intuitive path, hopefully demonstrating some of the issues involved in developing and implementing an iterative algorithm. We move next to the matrix-vector formulation of the degradation process and the restoration iteration. We borrow results from numerical analysis in obtaining the convergence results of the previous section but also more general results.

34.4 Matrix-Vector Formulation

What became clear from the previous sections is that in applying the successive approximations iteration the restoration problem to be solved is brought first into the form of finding the root of a function (see Eq. (34.3)). In other words, a solution to the restoration problem is sought which satisfies

$$\Phi(\mathbf{x}) = 0 , \quad (34.20)$$

where $\mathbf{x} \in \mathcal{R}^N$ is the vector representation of the signal resulting from the stacking or ordering of the original signal, and $\Phi(\mathbf{x})$ represents a nonlinear in general function. The row-by-row from left-to-right stacking of an image $x(i, j)$ is typically referred to as *lexicographic ordering*.

Then the successive approximations iteration which might provide us with a solution to Eq. (34.20) is given by

$$\begin{aligned}\mathbf{x}_0 &= 0 \\ \mathbf{x}_{k+1} &= \mathbf{x}_k + \beta \Phi(\mathbf{x}_k) \\ &= \Psi(\mathbf{x}_k) .\end{aligned}\quad (34.21)$$

Clearly if \mathbf{x}^* is a solution to $\Phi(\mathbf{x}) = 0$, i.e., $\Phi(\mathbf{x}^*) = 0$, then \mathbf{x}^* is also a fixed point to the above iteration since $\mathbf{x}_{k+1} = \mathbf{x}_k = \mathbf{x}^*$. However, as was discussed in the previous section, even if \mathbf{x}^* is the unique solution to Eq. (34.20), this does not imply that iteration (34.21) will converge. This again underlines the importance of convergence when dealing with iterative algorithms. The form iteration (34.21) takes for various forms of the function $\Phi(\mathbf{x})$ will be examined in the following sections.

34.4.1 Basic Iteration

From the degradation Eq. (34.1), the simplest possible form $\Phi(\mathbf{x})$ can take, when the noise is ignored, is

$$\Phi(\mathbf{x}) = \mathbf{y} - \mathbf{D}\mathbf{x} . \quad (34.22)$$

Then Eq. (34.21) becomes

$$\begin{aligned} \mathbf{x}_0 &= \mathbf{0} \\ \mathbf{x}_{k+1} &= \mathbf{x}_k + \beta(\mathbf{y} - \mathbf{D}\mathbf{x}_k) \\ &= \beta\mathbf{y} + (\mathbf{I} - \beta\mathbf{D})\mathbf{x}_k \\ &= \beta\mathbf{y} + \mathbf{G}_1\mathbf{x}_k , \end{aligned} \quad (34.23)$$

where \mathbf{I} is the identity operator.

34.4.2 Least-Squares Iteration

A least-squares approach can be followed in solving Eq. (34.1). That is, a solution is sought which minimizes

$$M(\mathbf{x}) = \|\mathbf{y} - \mathbf{D}\mathbf{x}\|^2 . \quad (34.24)$$

A necessary condition for $M(\mathbf{x})$ to have a minimum is that its gradient with respect to \mathbf{x} is equal to zero, which results in the *normal equations*

$$\mathbf{D}^T \mathbf{D}\mathbf{x} = \mathbf{D}^T \mathbf{y} \quad (34.25)$$

or

$$\Phi(\mathbf{x}) = \mathbf{D}^T (\mathbf{y} - \mathbf{D}\mathbf{x}) = \mathbf{0} , \quad (34.26)$$

where T denotes the transpose of a matrix or vector. Application of iteration (34.21) then results in

$$\begin{aligned} \mathbf{x}_0 &= \mathbf{0} \\ \mathbf{x}_{k+1} &= \mathbf{x}_k + \beta\mathbf{D}^T (\mathbf{y} - \mathbf{D}\mathbf{x}_k) \\ &= \beta\mathbf{D}^T \mathbf{y} + (\mathbf{I} - \beta\mathbf{D}^T \mathbf{D})\mathbf{x}_k \\ &= \beta\mathbf{D}^T \mathbf{y} + \mathbf{G}_2\mathbf{x}_k . \end{aligned} \quad (34.27)$$

It is mentioned here that the matrix-vector representation of an iteration does not necessarily determine the way the iteration is implemented. In other words, the pointwise version of the iteration may be more efficient from the implementation point of view than the matrix-vector form of the iteration.

34.5 Matrix-Vector and Discrete Frequency Representations

When Eqs. (34.22) and (34.26) are obtained from Eq. (34.2), the resulting iterations (34.23) and (34.27), should be identical to iterations (34.5) and (34.17), respectively, and their frequency domain counterparts. This issue, of representing a matrix-vector equation in the discrete frequency domain is addressed next.

Any matrix can be diagonalized using its singular value decomposition. Finding, in general, the singular values of a matrix with no special structure is a formidable task, given also the size of the matrices involved in image restoration. For example, for a 256×256 image, \mathbf{D} is of size $64K \times 64K$. The situation is simplified, however, if the degradation model of Eq. (34.2), which represents a special case of the degradation model of Eq. (34.1), is applicable. In this case, the degradation matrix \mathbf{D} is block-circulant [3]. This implies that the singular values of \mathbf{D} are the DFT values of $d(i, j)$, and the eigenvectors are the complex exponential basis functions of the DFT. In matrix form, this relationship can be expressed by

$$\mathbf{D} = \mathbf{W} \tilde{\mathbf{D}} \mathbf{W}^{-1}, \quad (34.28)$$

where $\tilde{\mathbf{D}}$ is a diagonal matrix with entries the DFT values of $d(i, j)$ and \mathbf{W} the matrix formed by the eigenvectors of \mathbf{D} . The product $\mathbf{W}^{-1} \mathbf{z}$, where \mathbf{z} is any vector, provides us with a vector which is formed by lexicographically ordering the DFT values of $z(i, j)$, the unstacked version of \mathbf{z} . Substituting \mathbf{D} from Eq. (34.28) into iteration (34.23) and premultiplying both sides by \mathbf{W}^{-1} , iteration (34.5) results. The same way iteration (34.17) results from iteration (34.27). In this case, *reblurring*, as was named when initially proposed, is nothing else than the least squares solution to the inverse problem. In general, if in a matrix-vector equation all matrices involved are block circulant, a 2D discrete frequency domain equivalent expression can be obtained. Clearly, a matrix-vector representation encompasses a considerably larger class of degradations than the linear spatially-invariant degradation.

34.6 Convergence

In dealing with iterative algorithms, their convergence, as well as their rate of convergence, are very important issues. Some general convergence results will be presented in this section. These results will be presented for general operators, but also equivalent representations in the discrete frequency domain can be obtained if all matrices involved are block circulant.

The *contraction mapping theorem* usually serves as a basis for establishing convergence of iterative algorithms. According to it, iteration (34.21) converges to a unique fixed point \mathbf{x}^* , that is, a point such that $\Psi(\mathbf{x}^*) = \mathbf{x}^*$ for any initial vector if the operator or transformation $\Psi(\mathbf{x})$ is a contraction. This means that for any two vectors \mathbf{z}_1 and \mathbf{z}_2 in the domain of $\Psi(\mathbf{x})$ the following relation holds

$$\|\Psi(\mathbf{z}_1) - \Psi(\mathbf{z}_2)\| \leq \eta \|\mathbf{z}_1 - \mathbf{z}_2\|, \quad (34.29)$$

where η is strictly less than one, and $\|\cdot\|$ denotes any norm. It is mentioned here that condition (34.29) is norm dependent, that is, a mapping may be contractive according to one norm, but not according to another.

34.6.1 Basic Iteration

For iteration (34.23) the sufficient condition for convergence (34.29) results in

$$\|\mathbf{I} - \beta \mathbf{D}\| < 1, \quad \text{or} \quad \|\mathbf{G}_1\| < 1. \quad (34.30)$$

If the l_2 norm is used, then condition (34.30) is equivalent to the requirement that

$$\max_i |\sigma_i(\mathbf{G}_1)| < 1, \quad (34.31)$$

where $|\sigma_i(\mathbf{G}_1)|$ is the absolute value of the i -th singular value of \mathbf{G}_1 [54].

The necessary and sufficient condition for iteration (34.23) to converge to a unique fixed point is that

$$\max_i |\lambda_i(\mathbf{G}_1)| < 1, \quad \text{or} \quad \max_i |1 - \beta \lambda_i(\mathbf{D})| < 1, \quad (34.32)$$

where $|\lambda_i(A)|$ represents the magnitude of the i -th eigenvalue of the matrix A . Clearly for a symmetric matrix \mathbf{D} conditions (34.30) and (34.32) are equivalent. Conditions (34.29) to (34.32) are used in defining the range of values of β for which convergence of iteration (34.23) is guaranteed.

Of special interest is the case when matrix \mathbf{D} is singular (\mathbf{D} has at least one zero eigenvalue), since it represents a number of typical distortions of interest (for example, distortions due to motion, defocusing, etc). Then there is no value of β for which conditions (34.31) or (34.32) are satisfied. In this case \mathbf{G}_1 is a *nonexpansive mapping* (η in (34.29) is equal to one). Such a mapping may have any number of fixed points (zero to infinitely many). However, a very useful result is obtained if we further restrict the properties of \mathbf{D} (this results in no loss of generality, as it will become clear in the following sections). That is, if \mathbf{D} is a symmetric, semi-positive definite matrix (all its eigenvalues are nonnegative), then according to *Bialy's theorem* [6], iteration (34.23) will converge to the minimum norm solution of Eq. (34.1), if this solution exists, plus the projection of \mathbf{x}_0 onto the null space of \mathbf{D} for $0 < \beta < 2 \cdot \|\mathbf{D}\|^{-1}$. The theorem provides us with the means of incorporating information about the original signal into the final solution with the use of the initial condition.

Clearly, when \mathbf{D} is block circulant the conditions for convergence shown above can be written in the discrete frequency domain. More specifically, conditions (34.31) and (34.9) are identical in this case.

34.6.2 Iteration with Reblurring

The convergence results presented above also holds for iteration (34.27), by replacing \mathbf{G}_1 by \mathbf{G}_2 in expressions (34.30) to (34.32). If $\mathbf{D}^T \mathbf{D}$ is singular, according to Bialy's theorem, iteration (34.27) will converge to the minimum norm least squares solution of (34.1), denoted by \mathbf{x}^+ , for $0 < \beta < 2 \cdot \|\mathbf{D}\|^{-2}$, since $\mathbf{D}^T \mathbf{y}$ is in the range of $\mathbf{D}^T \mathbf{D}$.

The rate of convergence of iteration (34.27) is linear. If we denote by \mathbf{D}^+ the *generalized inverse* of \mathbf{D} , that is, $\mathbf{x}^+ = \mathbf{D}^+ \mathbf{y}$, then the rate of convergence of (34.27) is described by the relation [26]

$$\frac{\|\mathbf{x}_k - \mathbf{x}^+\|}{\|\mathbf{x}^+\|} \leq c^{k+1}, \quad (34.33)$$

where

$$c = \max\{ |1 - \beta \|\mathbf{D}\|^2|, |1 - \beta \|\mathbf{D}^+\|^{-2}| \}. \quad (34.34)$$

The expression for c in (34.34) will also be used in Section 34.8, where higher order iterative algorithms are presented.

34.7 Use of Constraints

Iterative signal restoration algorithms regained popularity in the 1970s due to the realization that improved solutions can be obtained by incorporating prior knowledge about the solution into the restoration process. For example, we may know in advance that \mathbf{x} is bandlimited or space-limited, or we may know on physical grounds that \mathbf{x} can only have nonnegative values. A convenient way of expressing such prior knowledge is to define a constraint operator \mathcal{C} , such that

$$\mathbf{x} = \mathcal{C}\mathbf{x}, \quad (34.35)$$

if and only if x satisfies the constraint. In general, \mathcal{C} represents the concatenation of constraint operators. With the use of constraints, iteration (34.21) becomes [49]

$$\begin{aligned} x_0 &= 0, \\ \tilde{x}_k &= \mathcal{C}x_k, \\ x_{k+1} &= \Psi(\tilde{x}_k). \end{aligned} \tag{34.36}$$

The already mentioned recent popularity of constrained iterative restoration algorithms is also due to the fact that solutions to a number of recovery problems, such as the bandlimited extrapolation problem [48, 49] and the reconstruction from phase or magnitude problem [49, 57], were provided with the use of algorithms of the form (34.36) by appropriately describing the distortion and constraint operators. These operators are defined in the discrete spatial or frequency domains. A review of the problems which can be solved by an algorithm of the form of (34.36) is presented by Schafer et al. [49].

The contraction mapping theorem can again be used as a basis for establishing convergence of constrained iterative algorithms. The resulting sufficient condition for convergence is that at least one of the operators \mathcal{C} and Ψ is contractive while the other is nonexpansive. Usually it is harder to prove convergence and determine the convergence rate of the constrained iterative algorithm, taking also into account that some of the constraint operators are nonlinear, such as the positivity constraint operator.

34.7.1 The Method of Projecting Onto Convex Sets (POCS)

The method of POCS describes an alternative approach in incorporating prior knowledge about the solution into the restoration process. It reappears in the engineering literature in the early 1980s [64], and since then it has been successfully applied to the solution of different restoration problems (from the reconstruction from phase or magnitude [52] to the removal of blocking artifacts [62, 63], for example). According to the method of POCS the incorporation of prior knowledge into the solution can be interpreted as the restriction of the solution to be a member of a closed convex set that is defined as the set of vectors which satisfy a particular property. If the constraint sets have a nonempty intersection, then a solution that belongs to the intersection set can be found by the method of POCS. Indeed, any solution in the intersection set is consistent with the *a priori* constraints and, therefore, it is a feasible solution.

More specifically, let Q_1, Q_2, \dots, Q_m be closed convex sets in a finite dimensional vector space, with P_1, P_2, \dots, P_m their respective projectors. Then, the iterative procedure,

$$x_{k+1} = P_1 P_2 \cdots P_m x_k, \tag{34.37}$$

converges to a vector which belongs to the intersection of the sets $Q_i, i = 1, 2, \dots, m$, for any starting vector x_0 . It is interesting to note that the resulting set intersection is also a closed convex set.

Clearly, the application of a projection operator P and the constraint \mathcal{C} , discussed in the previous section, express the same idea. Projection operators represent nonexpansive mappings.

34.8 Class of Higher Order Iterative Algorithms

One of the drawbacks of the iterative algorithms presented in the previous sections is their linear rate of convergence. In [26] a unified approach is presented in obtaining a class of iterative algorithms with different rates of convergence, based on a representation of the generalized inverse of a matrix. That is, the algorithm,

$$x_0 = \beta D^T y$$

$$\begin{aligned}
\mathbf{D}_0 &= \beta \mathbf{D}^T \mathbf{D} \\
\Omega_{k+1} &= \sum_{i=0}^{p-1} (\mathbf{I} - \mathbf{D}_k)^i \\
\mathbf{D}_{k+1} &= \Omega_k \mathbf{D}_k \\
\mathbf{x}_{k+1} &= \Omega_k \mathbf{x}_k,
\end{aligned} \tag{34.38}$$

converges to the minimum norm least squares solution of Eq. (34.1), with $n = 0$. If iteration (34.38) is thought of as corresponding to iteration (34.27), then an iteration similar to (34.38) which corresponds to iteration (34.23) has also been derived [26, 41].

Algorithm (34.38) exhibits a p -th order of convergence. That is, the following relation holds [26]

$$\frac{\|\mathbf{x}_k - \mathbf{x}^+\|}{\|\mathbf{x}^+\|} \leq c^{p^k}, \tag{34.39}$$

where the convergence factor c is described by Eq. (34.34).

It is observed that the matrix sequences $\{\Omega_k\}$ and \mathbf{D}_k can be computed in advance or *off-line*. When \mathbf{D} is block circulant, substantial computational savings result with the use of iteration (34.38) over the linear algorithms. Questions dealing with the best order p of algorithm (34.38) to be used in a given application, as well as comparisons of the trade-off between speed of computation and computational load, are addressed in [26]. One of the drawbacks of the higher order algorithms is that the application of constraints may lead to erroneous results. Combined adaptive or nonadaptive linear and higher order algorithms have been proposed in overcoming this difficulty [11, 26].

34.9 Other Forms of $\Phi(\mathbf{x})$

34.9.1 Ill-Posed Problems and Regularization Theory

The two most basic forms of the function $\Phi(\mathbf{x})$ have only been considered so far. These two forms are represented by Eqs. (34.22) and (34.26), and are meaningful when the noise in Eq. (34.1) is not taken into account. Without ignoring the noise, however, the solution of Eq. (34.1) represents an ill-posed problem. If the image formation process is modeled in a continuous infinite dimensional space, \mathbf{D} becomes an integral operator and Eq. (34.1) becomes a Fredholm integral equation of the first kind. Then the solution of Eq. (34.1) is almost always an ill-posed problem [42, 45, 59, 60]. This means that the unique least-squares solution of minimal norm of (34.1) does not depend continuously on the data, or that a bounded perturbation (noise) in the data results in an unbounded perturbation in the solution, or that the generalized inverse of \mathbf{D} is unbounded [42]. The integral operator \mathbf{D} has a countably infinite number of singular values that can be ordered with their limit approaching zero [42]. Since the finite dimensional discrete problem of image restoration results from the discretization of an ill-posed continuous problem, the matrix \mathbf{D} has (in addition to possibly a number of zero singular values) a cluster of very small singular values. Clearly, the finer the discretization (the larger the size of \mathbf{D}) the closer the limit of the singular values is approximated. Therefore, although the finite dimensional inverse problem is well posed in the least-squares sense [42], the ill-posedness of the continuous problem translates into an ill-conditioned matrix \mathbf{D} .

A regularization method replaces an ill-posed problem by a well-posed problem, whose solution is an acceptable approximation to the solution of the given ill-posed problem [39, 56]. In general, regularization methods aim at providing solutions which preserve the fidelity to the data but also satisfy our prior knowledge about certain properties of the solution. A class of regularization methods associates both the class of admissible solutions and the observation noise with random processes [12]. Another class of regularization methods regards the solution as a deterministic quantity. We give examples of this second class of regularization methods in the following.

34.9.2 Constrained Minimization Regularization Approaches

Most regularization approaches transform the original inverse problem into a constrained optimization problem. That is, a functional needs to be optimized with respect to the original image and possibly other parameters. By using the necessary condition for optimality, the gradient of the functional with respect to the original image is set equal to zero, therefore determining the mathematical form of $\Phi(\mathbf{x})$. The successive approximations iteration becomes in this case a gradient method with a fixed step (determined by β). We briefly mention next the general form of some of the commonly used functionals.

Set Theoretic Formulation

With this approach the problem of solving Eq. (34.1) is replaced by the problem of searching for vectors \mathbf{x} which belong to both sets [21, 25, 27]

$$\|\mathbf{D}\mathbf{x} - \mathbf{y}\| \leq \epsilon, \quad (34.40)$$

and

$$\|\mathbf{C}\mathbf{x}\| \leq E, \quad (34.41)$$

where ϵ is an estimate on the data accuracy (noise norm), E a prescribed constant, and \mathbf{C} a high-pass operator. Inequality (34.41) constrains the energy of the signal at high frequencies, therefore requiring that the restored signal is smooth. On the other hand, inequality (34.40) requires that the fidelity to the available data is preserved.

Inequalities (34.40) and (34.41) can be respectively rewritten as [25, 27]

$$(\mathbf{x} - \mathbf{x}^+)^T \frac{\mathbf{D}^T \mathbf{D}}{\epsilon^2} (\mathbf{x} - \mathbf{x}^+) \leq 1, \quad (34.42)$$

and

$$\mathbf{x}^T \frac{\mathbf{C}^T \mathbf{C}}{E^2} \mathbf{x} \leq 1, \quad (34.43)$$

where $\mathbf{x}^+ = \mathbf{D}^+ \mathbf{y}$. That is, each of them represents an N -dimensional ellipsoid, where N is the dimensionality of the vectors involved. The intersection of the two ellipsoids (assuming it is not empty) is also a convex set but not an ellipsoid. The center of one of the ellipsoids which bounds the intersection can be chosen as the solution to the problem [50]. Clearly, even if the intersection is not empty, the center of the bounding ellipsoid may not belong to the intersection, and, therefore, a posterior test is required. The equation the center of one of the bounding ellipsoids is satisfying is given by [25, 27]

$$\Phi(\mathbf{x}) = (\mathbf{D}^T \mathbf{D} + \alpha \mathbf{C}^T \mathbf{C}) \mathbf{x} - \mathbf{D}^T \mathbf{y} = 0, \quad (34.44)$$

where α , the *regularization parameter*, is equal to $(\epsilon/E)^2$.

Projection Onto Convex Sets (POCS) Approach

Iteration (34.37) can also be applied in finding a solution which belongs to both ellipsoids (34.42) and (34.43). The respective projections $P_1 \mathbf{x}$ and $P_2 \mathbf{x}$ are defined by [25]

$$\mathbf{P}_1 \mathbf{x} = \mathbf{x} + \lambda_1 (\mathbf{I} + \lambda_1 \mathbf{D}^T \mathbf{D})^{-1} \mathbf{D}^T (\mathbf{y} - \mathbf{D}\mathbf{x}) \quad (34.45)$$

$$\mathbf{P}_2 \mathbf{x} = [\mathbf{I} - \lambda_2 (\mathbf{I} + \lambda_2 \mathbf{C}^T \mathbf{C})^{-1} \mathbf{C}^T \mathbf{C}] \mathbf{x}, \quad (34.46)$$

where λ_1 and λ_2 need to be chosen so that conditions (34.42) and (34.43) are satisfied, respectively. Clearly, a number of other projection operators can be used in (34.37) which force the signal to exhibit certain known *a priori* properties expressed by convex sets.

A Functional Minimization Approach

The determination of the value of the regularization parameter is a critical issue in regularized restoration. A number of approaches for determining its value are presented in [13]. If only one of the parameters ϵ or E in (34.40) and (34.41) is known, a constrained least-squares formulation can be followed [9, 15]. With it, the size of one of the ellipsoids is minimized, subject to the constraint that the solution belongs to the surface of the other ellipsoid (the one defined by the known parameter). Following the Lagrangian approach, which transforms the constrained optimization problem into an unconstrained one, the following functional is minimized

$$M(\alpha, \mathbf{x}) = \|\mathbf{D}\mathbf{x} - \mathbf{y}\|^2 + \alpha \|\mathbf{C}\mathbf{x}\|^2. \quad (34.47)$$

The necessary condition for a minimum is that the gradient of $M(\alpha, \mathbf{x})$ is equal to zero. That is, in this case

$$\Phi(\mathbf{x}) = \nabla_{\mathbf{x}} M(\alpha, \mathbf{x}) = (\mathbf{D}^T \mathbf{D} + \alpha \mathbf{C}^T \mathbf{C}) \mathbf{x} - \mathbf{D}^T \mathbf{y}, \quad (34.48)$$

which is identical to (34.44), with the only difference that α now is not known, but needs to be determined.

Spatially Adaptive Iteration

Spatially adaptive image restoration is the next natural step in improving the quality of the restored images. There are various ways to argue the introduction of spatial adaptivity, the most commonly used ones being the nonhomogeneity or nonstationarity of the image field and the properties of the human visual system. In either case, the functional to be minimized takes the form [22, 23, 34]

$$M(\alpha, \mathbf{x}) = \|\mathbf{D}\mathbf{x} - \mathbf{y}\|_{\mathbf{W}_1}^2 + \alpha \|\mathbf{C}\mathbf{x}\|_{\mathbf{W}_2}^2, \quad (34.49)$$

in which case

$$\Phi(\mathbf{x}) = \nabla_{\mathbf{x}} M(\alpha, \mathbf{x}) = (\mathbf{D}^T \mathbf{W}_1^T \mathbf{W}_1 \mathbf{D} + \alpha \mathbf{C}^T \mathbf{W}_2^T \mathbf{W}_2 \mathbf{C}) \mathbf{x} - \mathbf{D}^T \mathbf{W}_1 \mathbf{y}. \quad (34.50)$$

The choice of the diagonal weighting matrices \mathbf{W}_1 and \mathbf{W}_2 can be justified in various ways. In [16, 22, 23, 25] both matrices are determined by the noise visibility matrix \mathbf{V} [2, 46]. That is, $\mathbf{W}_1 = \mathbf{V}^T \mathbf{V}$ and $\mathbf{W}_2 = \mathbf{I} - \mathbf{V}^T \mathbf{V}$. The entries of \mathbf{V} take values between 0 and 1. They are equal to 0 at the edges (noise is not visible), equal to 1 at the flat regions (noise is visible) and take values in between at the regions with moderate spatial activity. A study of the mapping between the level of spatial activity and the values of the visibility function appears in [11]. The weighting matrices can also be defined by considering the relationship of the restoration approach presented here to the MAP restoration approach [30]. Then, the weighting matrices \mathbf{W}_1 and \mathbf{W}_2 contain information about the nonstationarity and/or the nonwhiteness of the high-pass filtered image and noise, respectively.

Robust Functionals

Robust functionals can be employed for the representation of both the noise and the signal statistics. They allow for the efficient suppression of a wide variety of noise processes and permit the reconstruction of sharper edges than their quadratic counterparts. In a robust set-theoretic set-up a solution is sought by minimizing [65]

$$M(\alpha, \mathbf{x}) = R_n(\mathbf{y} - \mathbf{D}\mathbf{x}) + \alpha R_x(\mathbf{C}\mathbf{x}). \quad (34.51)$$

$R_n()$ and $R_x()$ are referred to as the residual and stabilizing functionals, respectively, and they are defined in terms of their *kernel functions*. The derivative of the kernel function is called the *influence function*.

$\Phi(\mathbf{x})$ in this case equals the gradient of $M(\alpha, \mathbf{x})$ in Eq. (34.51). A large number of robust functionals have been proposed in the literature. The properties of potential functions to be used in robust Bayesian estimation are listed in [35]. A robust maximum absolute entropy and a robust minimum absolute-information functionals are introduced in [65]. Clearly since the functionals $R_n()$ and $R_x()$ are typically nonlinear and may not be convex, the convergence analysis of iteration (34.21) or (34.36) is considerably more complicated.

34.9.3 Iteration Adaptive Image Restoration Algorithms

As it has become clear by now there are various pieces of information needed by any regularization algorithms in determining the unknown parameters. In the context of deterministic regularization, the most commonly needed parameter is the regularization parameter. Its determination depends on the noise statistics and the properties of the image. With the set theoretic regularization approach, it is required that the original image is smooth, in which case a bound on the energy of the high-pass filtered image is needed. This bound is proportional to the variance of the image in a stochastic context. In addition, knowledge of the noise variance is also required. In a MAP framework such parameters are called *hyperparameters* [8, 40]. Clearly, such parameters are not typically available and need to be estimated from the available noisy and blurred data. Various techniques for estimating the regularization parameter are discussed, for example, in [13].

In the following we briefly describe a new paradigm we have introduced in the context of iterative image restoration algorithms [18, 19, 20, 29, 30]. According to it, the required information by the deterministic regularization approach is updated at each restoration step, based on the partially restored image.

Spatially Adaptive Algorithm

For the spatially adaptive algorithm we mentioned above, the proposed general form of the weighted smoothing functional whose minimization will result in a restored image is written as

$$\begin{aligned} M_w(\lambda_w(\mathbf{x}), \mathbf{x}) &= \|\mathbf{y} - \mathbf{D}\mathbf{x}\|_{\mathbf{A}(\mathbf{x})}^2 + \lambda_w(\mathbf{x}) \|\mathbf{C}\mathbf{x}\|_{\mathbf{B}(\mathbf{x})}^2 \\ &= \|\mathbf{n}\|_{\mathbf{A}(\mathbf{x})}^2 + \lambda_w(\mathbf{x}) \|\mathbf{C}\mathbf{x}\|_{\mathbf{B}(\mathbf{x})}^2, \end{aligned} \quad (34.52)$$

where the weighting matrices $\mathbf{A}(\mathbf{x})$ and $\mathbf{B}(\mathbf{x})$, both functions of the original image, are used to incorporate noise and image characteristics into the restoration process, respectively. The regularization parameter, also a function of \mathbf{x} , is defined in such a way as to make the smoothing functional in (34.52) convex with a unique global minimizer.

One of the $\lambda_w(\mathbf{x})$ we have proposed is given by

$$\lambda_w(\mathbf{x}) = \frac{\|\mathbf{y} - \mathbf{D}\mathbf{x}\|_{\mathbf{A}(\mathbf{x})}^2}{(1/\gamma) - \|\mathbf{C}\mathbf{x}\|_{\mathbf{B}(\mathbf{x})}^2}, \quad (34.53)$$

where the parameter γ is determined from the convergence and convexity analyses.

The main objective with this approach is to employ an iterative algorithm to estimate the regularization parameter and the proper weighting matrices at the same time with the restored image. The available estimate of the restored image at each iteration step will be used for determining the value of the regularization parameter. That is, the regularization parameter is defined as a function of the original image (and eventually in practice of an estimate of it). Of great importance is the form of this functional, so that the smoothing functional to be minimized preserves its convexity and exhibits a global minimizer. $\lambda_w(\mathbf{x})$ maps a vector \mathbf{x} onto the positive real line. Its purpose is as before to control the relative contribution of the error term $\|\mathbf{y} - \mathbf{D}\mathbf{x}\|_{\mathbf{A}(\mathbf{x})}^2$, which enforces “faithfulness”

to the data, and the stabilizing functional $\|C\mathbf{x}\|_{\mathbf{B}(\mathbf{x})}^2$, which enforces smoothness on the solution. Its dependency, however, on the original image, as well as the available data, is explicitly utilized. This dependency on the other hand is implicitly utilized in the constrained least-squares approach, according to which the minimization of $M_w(\lambda_w(\mathbf{x}), \mathbf{x})$ and the determination of the regularization parameter $\lambda_w(\mathbf{x})$ are completely separate steps. The desired properties of $\lambda_w(\mathbf{x})$ and $M_w(\lambda_w(\mathbf{x}), \mathbf{x})$ are analyzed in [20]. The relationship of the resulting forms to the hierarchical Bayesian approach towards image restoration and estimation of the regularization parameters is explored in [40].

In this case, therefore, $\Phi(\mathbf{x}) = \nabla_{\mathbf{x}} M_w(\lambda_w(\mathbf{x}), \mathbf{x})$. The successive approximations iteration after some simplifications takes the form [20, 30]

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \left[D^T A(\mathbf{x}_k) \mathbf{y} - \left(D^T A(\mathbf{x}_k) D + \lambda_w(\mathbf{x}_k) C^T B(\mathbf{x}_k) C \right) \mathbf{x}_k \right]. \quad (34.54)$$

The information required in defining the regularization parameter and the weights for introducing the spatial adaptivity are defined based on the available information about the restored image at the k -th iteration step. Clearly for all this to make sense the convergence of iteration (34.54) has to be guaranteed. Furthermore, convergence to a unique fixed point, which removes the dependency of the final result on the initial conditions, is also desired. These issues are addressed in detail in [20, 30]. A major advantage of the proposed algorithm is that the convexity of the smoothing functional and the convergence of the resulting algorithm are guaranteed regardless of the choice of the weighting matrices. Another advantage of this algorithm is that the proposed adaptive algorithm simultaneously determines the regularization parameter and the desirable weighting matrices based on the restored image at each iteration step and restores the image, without any prior knowledge.

Frequency Adaptive Algorithm

Adaptivity is now introduced into the restoration process by using a constant smoothness constraint, but by assigning a different regularization parameter at each discrete frequency location. We can now “fine-tune” the regularization of each frequency component, thereby achieving improved results and at the same time speeding up the convergence of the iterative algorithm. The regularization parameters are evaluated simultaneously with the restored image based on the partially restored image.

In this algorithm, the following two ellipsoids $QE_{\mathbf{x}}$ and $QE_{\mathbf{x}/\mathbf{y}}$ are used

$$QE_{\mathbf{x}} = \{\mathbf{x} \mid \|C\mathbf{x}\|_{\mathbf{R}} \leq E_{\mathbf{R}}\} \quad (34.55)$$

and

$$QE_{\mathbf{x}/\mathbf{y}} = \{\mathbf{x} \mid \|\mathbf{y} - D\mathbf{x}\|_{\mathbf{P}} \leq \epsilon_{\mathbf{P}}\}, \quad (34.56)$$

where \mathbf{P} and \mathbf{R} are both block-circulant weighting matrices. Then a solution which belongs to the intersection of $QE_{\mathbf{x}}$ and $QE_{\mathbf{x}/\mathbf{y}}$ is given by

$$\left(D^T P^T P D + \lambda C^T R^T R C \right) \mathbf{x} = D^T P^T P \mathbf{y}, \quad (34.57)$$

where $\lambda = (\epsilon_{\mathbf{P}}/E_{\mathbf{R}})^2$. Let us define $P^T P = \mathbf{B}$, $\mathbf{R} = \mathbf{P}C$ and $\lambda C^T C = \mathbf{A}$. Then Eq. (34.57) can be written as

$$\mathbf{B} \left(D^T D + \mathbf{A} C^T C \right) \mathbf{x} = \mathbf{B} D^T \mathbf{y}, \quad (34.58)$$

since all matrices are block-circulant and they therefore commute. The regularization matrix \mathbf{A} is defined based on the set theoretic regularization as

$$\mathbf{A} = \|\mathbf{y} - D\mathbf{x}\|^2 [\|C\mathbf{x}\|^2 \mathbf{I} + \Delta]^{-1}, \quad (34.59)$$

where Δ is a block-circulant matrix used to ensure convergence. B plays the role of the “shaping” matrix [53] for maximizing the speed of convergence at every frequency component as well as for compensating for the near-singular frequency components [19].

With the above formulation, therefore,

$$\Phi(x) = B \left((D^T D + A C^T C) x - D^T y \right), \quad (34.60)$$

and the successive approximations iteration (34.21) becomes

$$x_{k+1} = x_k + B \left[D^T y - (D^T D + A_k C^T C) x_k \right], \quad (34.61)$$

where $A_k = \|y - D x_k\|^2 [\|C x_k\|^2 \mathbf{I} + \Delta_k]^{-1}$. It is mentioned here that iteration (34.61) can also be derived from the regularized equation

$$(D^T D + A C^T C) x = D^T y, \quad (34.62)$$

using the generalized Landweber’s iteration [53]. Since all matrices in iteration (34.61) are block-circulant, the iteration can be written in the discrete frequency domain as

$$X_{k+1}(\underline{p}) = X_k(\underline{p}) + \beta(\underline{p}) \left[D^*(\underline{p}) Y(\underline{p}) - (|D(\underline{p})|^2 + \lambda_k(\underline{p}) |C(\underline{p})|^2) X_k(\underline{p}) \right], \quad (34.63)$$

where $\underline{p} = (p_1, p_2)$, $0 \leq p_1 \leq N - 1$, $0 \leq p_2 \leq N - 1$, $X_{k+1}(\underline{p})$ and $Y(\underline{p})$ represent the 2D DFT of the unstacked image estimate x_{k+1} , and the noisy-blurred image y and $D(\underline{p})$, $C(\underline{p})$, $\beta(\underline{p})$, and $\lambda_k(\underline{p})$ represent 2D DFTs of the 2D sequences which form the block-circulant matrices D , C , B , and A_k , respectively. Since Δ_k is block-circulant $\lambda_k(\underline{p})$ is given by

$$\lambda_k(\underline{p}) = \frac{\sum_m |Y(\underline{m}) - D(\underline{m}) X_k(\underline{m})|^2}{\sum_n |C(\underline{n}) X_k(\underline{n})|^2 + \delta_k(\underline{p})}, \quad (34.64)$$

where $\delta_k(\underline{p})$ is the 2D DFT of the sequence which forms Δ_k .

The allowable range of each regularization and control parameter and the convergence analysis of the iterative algorithm are developed in detail in [19]. It is shown that the algorithm has more than two fixed points. The first fixed point is the inverse or generalized inverse solution of Eq. (34.58). The second type of fixed points are regularized approximations to the original image. Since there is more than one solution to iteration (34.63), the determination of the initial condition becomes important. It has been verified experimentally [19] that if a “smooth” image is used for $X_0(\underline{p})$ almost identical fixed points result independently of X_0 . The use of spectral filtering functions [53] is also incorporated into the iteration, as shown in [19].

34.10 Discussion

In this chapter we briefly described the application of the successive approximations-based class of iterative algorithms to the problem of restoring a noisy and blurred signal. We analyzed in some detail the simpler forms of the algorithm, while making reference to work which deals with more complicated forms of the algorithms. There are obviously a number of algorithms and issues pertaining to such algorithms which have not been addressed at all. For example, iterative algorithms with a varying relaxation parameter β , such as the steepest descent and conjugate gradient methods, can be applied to the image restoration problem [4, 37]. The number of iterations also represents a means for regularizing the restoration problem [55, 58]. Iterative algorithms which depend on more

than one previous restoration steps (multi-step algorithms) have also been considered, primarily for implementation reasons [24].

It is the hope and the expectation of the author that the material presented will form a good introduction to the topic for the engineer or the graduate student who would like to work in this area.

Introduction • Orthogonal Block Transforms • Useful Transforms • Remarks

AN IMPORTANT PROBLEM IN SIGNAL PROCESSING is the choice of how to represent a signal. It is for this reason that importance is attached to the choice of bases for the *linear* expansion of signals. That is, given a discrete-time signal $x(n)$ how to find $a_i(n)$ and $b_i(n)$ such that we can write

$$x(n) = \sum_i \langle x(n), a_i(n) \rangle b_i(n). \quad (\text{VIII.1})$$

If $b_i(n) = a_i(n)$, then (VIII.1) is the familiar orthonormal basis expansion formula [1]. Otherwise, the $b_i(n)$ are a set of biorthogonal functions with the property

$$\langle b_j(n), a_i(n) \rangle = \delta_{i-j}.$$

The function δ is defined such that $\delta_{i-j} = 0$, unless $i = j$, in which case $\delta_0 = 1$. We shall consider cases where the summation in (VIII.1) is infinite, but restrict our attention to the case where it is

finite for the moment; that is, where we have a finite number N of data samples, and so the space is finite dimensional.

We next set up the basic notation used throughout the chapter. Assume that we are operating in C^N , and that we have N basis vectors, the minimum number to span the space. Since the transform is linear, it can be written as a matrix. That is, if the \mathbf{a}_i^* are the rows of a matrix \mathbf{A} , then

$$\mathbf{A} \cdot \mathbf{x} = \begin{bmatrix} \langle x(n), a_0(n) \rangle \\ \langle x(n), a_1(n) \rangle \\ \vdots \\ \langle x(n), a_{N-2}(n) \rangle \\ \langle x(n), a_{N-1}(n) \rangle \end{bmatrix} \quad (\text{VIII.2})$$

and if \mathbf{b}_i are the columns of \mathbf{B} then

$$\mathbf{x} = \mathbf{B} \cdot \mathbf{A} \cdot \mathbf{x}. \quad (\text{VIII.3})$$

Clearly $\mathbf{B} = \mathbf{A}^{-1}$; if $\mathbf{B} = \mathbf{A}^*$ then \mathbf{A} is unitary, $b_i(n) = a_i(n)$ and we have that (VIII.1) is the orthonormal basis expansion.

Clearly the construction of bases is not difficult: any nonsingular $N \times N$ matrix will do for this space. Similarly, to get an orthonormal basis we need merely take the rows of any unitary $N \times N$ matrix, for example the identity \mathbf{I}_N . There are many reasons for desiring to carry out such an expansion. Much as Taylor or Fourier series are used in mathematics to simplify solutions to certain problems, the underlying goal is that a cleverly chosen expansion may make a given signal processing task simpler.

A major application is signal compression, where we wish to quantize the input signal in order to transmit it with as few bits as possible, while minimizing the distortion introduced. If the input vector comprises samples of a real signal, then the samples are probably highly correlated, and the identity basis (where the i th vector contains 1 in the i th position and is zero elsewhere) with scalar quantization will end up using many of its bits to transmit information which does not vary much from sample to sample. If we can choose a matrix \mathbf{A} such that the elements of $\mathbf{A} \cdot \mathbf{x}$ are much less correlated than those of \mathbf{x} , then the job of efficient quantization becomes a great deal simpler [2]. In fact, the Karhunen-Loève transform, which produces uncorrelated coefficients, is known to be optimal in a mean squared error sense [2].

Since in (VIII.1) the signal is written as a superposition of the basis sequences $b_i(n)$, we can say that if $b_i(n)$ has most of its energy concentrated around time $n = n_0$, then the coefficient $\langle x(n), a_i(n) \rangle$ measures to some degree the concentration of $x(n)$ at time $n = n_0$. Equally, taking the discrete Fourier transform of (VIII.1)

$$X(k) = \sum_i \langle x(n), a_i(n) \rangle B_i(k).$$

Thus, if $B_i(k)$ has most of its energy concentrated about frequency $k = k_0$, then $\langle x(n), a_i(n) \rangle$ measures to some degree the concentration of $X(k)$ at $k = k_0$. This basis function is mostly localized about the point (n_0, k_0) in the discrete-time discrete-frequency plane. Similarly, for each of the basis functions $b_i(n)$ we can find the area of the discrete-time discrete-frequency plane where most of their energy lies. All of the basis functions together will effectively cover the plane, because if any part were not covered there would be a “hole” in the basis, and we would not be able to completely represent all sequences in the space. Similarly the localization areas, or tiles, corresponding to distinct basis functions should not overlap by too much, since this would represent a redundancy in the system.

Choosing a basis can then be loosely thought of as choosing some tiling of the discrete-time discrete-frequency plane. For example, Fig. VIII.1 shows the tiling corresponding to various orthonormal bases in C^{64} . The horizontal axis represents discrete-time, and the vertical axis discrete-frequency. Naturally, each of the diagrams contains 64 tiles, since this is the number of vectors required for a

FIGURE VIII.1: Examples of tilings of the discrete-time discrete-frequency plane; time is the horizontal axis, frequency the vertical. (a) The identity transform. (b) Discrete Fourier transform. (c) Finite length discrete wavelet transform. (d) Arbitrary finite length transform.

basis, and each tile can be thought of as containing 64^2 points out of the total of 64^2 in this discrete-time discrete-frequency plane. The first is the identity basis, which has narrow vertical strips as tiles, since the basis sequences $\delta(n + k)$ are perfectly localized in time, but have energy spread equally at all discrete frequencies. That is, the tile is one discrete-time point wide and 64 discrete-frequency points long. The second, shown in Fig. VIII.1(b), corresponds to the discrete Fourier transform basis vectors $e^{j2\pi in/N}$; these of course are perfectly localized at the frequencies $i = 0, 1, \dots, N - 1$, but have equal energy at all times (i.e., 64 points wide, one point long). Figure VIII.1(c) shows the tiling corresponding to a discrete orthogonal wavelet transform (or logarithmic subband coder) operating over a finite length signal. Figure VIII.1(d) shows the tiling corresponding to a discrete orthogonal wavelet packet transform operating over a finite length signal, with arbitrary splits in time and frequency; construction of such schemes is discussed in Section 7.1. In Fig. VIII.1(c) and (d), the tiles have varying shapes but still contain 64 points each.

It should be emphasized that the localization of the energy of a basis function to the area covered by one of the tiles is only approximate. In practice, of course, we will always deal with real signals, and in general we will restrict the basis functions to be real also. When this is so, $\mathbf{B}^* = \mathbf{B}^T$ and the basis is orthonormal provided $\mathbf{A}^T \mathbf{A} = \mathbf{I} = \mathbf{A} \mathbf{A}^T$. Of the bases shown in Fig. VIII.1 only the discrete Fourier transform will be excluded with this restriction. One can, however, consider a real transform which has many properties in common with the DFT, for example the discrete Hartley transform [3].

While the above description was given in terms of finite-dimensional signal spaces, the interpre-

tation of the linear transform as a matrix operation, and the tiling approach remains essentially unchanged in the case of infinite length discrete-time signals. In fact, for bases with the structure we desire, construction in the infinite-dimensional case is easier than in the finite-dimensional case. The modifications necessary for the transition from R^N to $l^2(R)$ are that an infinite number of basis functions is required instead of N , the matrices \mathbf{A} and \mathbf{B} become doubly infinite, and the tilings are in the discrete-time continuous-frequency plane (the time axis ranges over Z , the frequency axis goes from 0 to π , assuming real signals).

Good decorrelation is one of the important factors in the construction of bases. If this were the only requirement, we would always use the Karhunen-Loève transform, which is an orthogonal data-dependent transform which produces uncorrelated samples. This is not used in practice, because estimating the coefficients of the matrix \mathbf{A} can be very difficult. Very significant also, however, is the complexity of calculating the coefficients of the transform using (VIII.2), and of putting the signal back together using (VIII.3). In general, for example, using the basis functions for R^N , evaluating each of the matrix multiplications in (VIII.2) and (VIII.3) will require $O(N^2)$ floating point operations, unless the matrices have some special structure. If, however, \mathbf{A} is sparse, or can be factored into matrices that are sparse, then the complexity required can be dramatically reduced. This is the case, for example, with the discrete Fourier transform, where there is an efficient $O(N \log N)$ algorithm to do the computations, which has been responsible for its popularity in practice. This will also be the case with the transforms that we consider, \mathbf{A} and \mathbf{B} will always have special structure to allow efficient implementation.

35.1 Filter Banks and Wavelets

The methods of designing bases that we will employ draw on ideas first used in the construction of multirate filter banks. The idea of such systems is to take an input system and split it into subsequences using banks of filters. This simplest case involves splitting into just two parts using a structure such as that shown in Fig. 35.1. This technique has a long history of use in the area of subband coding: first of speech [1, 2] and more recently of images [3, 4]. In fact, the most successful image coding schemes are based on filter bank expansions [5, 6, 7]. Recent texts on the subject are [8, 9, 10]. We will consider only the two-channel case in this section. If $\hat{X}(z) = X(z)$, then the filter bank has the perfect reconstruction property.

FIGURE 35.1: Maximally decimated two-channel multirate filter bank.

It is easily shown that the output $\hat{X}(z)$ of the overall analysis/synthesis system is given by:

$$\begin{aligned}\hat{X}(z) &= \frac{1}{2} [G_0(z) \ G_1(z)] \begin{bmatrix} H_0(z) \psi \ H_0(-z) \\ H_1(z) \psi \ H_1(-z) \end{bmatrix} \begin{bmatrix} X(z) \\ X(-z) \end{bmatrix} \\ &= \frac{1}{2} [H_0(z)G_0(z) + H_1(z)G_1(z)] \cdot X(z)\end{aligned}\tag{35.1}$$

$$+ \frac{1}{2} [H_0(-z)G_0(z) + H_1(-z)G_1(z)] \cdot X(-z).$$

Call the above 2×2 matrix $\mathbf{H}_m(z)$. This gives that the unique choice for the synthesis filters is

$$\begin{aligned} \begin{bmatrix} G_0(z) \\ G_1(z) \end{bmatrix} &= \begin{bmatrix} H_0(z) & H_0(-z) \\ H_1(z) & H_1(-z) \end{bmatrix}^{-1} \cdot \begin{bmatrix} 2 \\ 0 \end{bmatrix} \\ &= \frac{2}{\Delta_m(z)} \begin{bmatrix} H_1(-z) \\ -H_0(-z) \end{bmatrix}, \end{aligned} \quad (35.2)$$

where $\Delta_m(z) = \det \mathbf{H}_m(z)$.

If we observe that $\Delta_m(z) = -\Delta_m(-z)$ and define $P(z) = 2 \cdot H_0(z)H_1(-z)/\Delta_m(z) = H_0(z)G_0(z)$, it follows from (35.2) that $G_1(z)H_1(z) = 2 \cdot H_1(z)H_0(-z)/\Delta_m(-z) = P(-z)$. We can then write that the necessary and sufficient condition for perfect reconstruction (35.1) is:

$$P(z) + P(-z) = 2. \quad (35.3)$$

Since this condition plays an important role in what follows, we will refer to any function having this property as *valid*. The implication of this property is that all but one of the even-indexed coefficients of $P(z)$ are zero. That is

$$\begin{aligned} P(z) + P(-z) &= \sum_n (p(n)z^{-n} + p(n)(-z)^{-n}) \\ &= \sum_n 2 \cdot p(2n)z^{-(2n+1)}. \end{aligned}$$

For this to satisfy (35.3) requires $p(2n) = \delta_n$; thus, one of the polyphase components of $P(z)$ must be the unit sample. By polyphase components we mean the set of even-indexed samples, and the set of the odd-indexed samples. Such a function is illustrated in Fig. 35.2(a).

FIGURE 35.2: Zeros of the correlation functions. (a) Autocorrelation $H_0(-z)H_0(z^{-1})$. (b) Cross-correlation $H_0(-z)H_1(z^{-1})$.

Constructing such a function is not difficult. In general, however, we will wish to impose additional constraints on the filter banks. So, $P(z)$ will have to satisfy other constraints in addition to (35.3).

Observe that as a consequence of (35.2) $G_0(z)H_1(z)$, i.e., the cross-correlation of $g_1(n)$ and the time-reversed filter $h_0(-n)$, and $G_1(z)H_0(z)$, the cross-correlation of $g_1(n)$ and $h_0(-n)$, have only odd-indexed coefficients, just as for the function in Fig. 35.2(b), that is:

$$\langle g_0(n), h_1(2k - n) \rangle = 0, \quad (35.4)$$

$$\langle g_1(n), h_0(2k - n) \rangle = 0, \quad (35.5)$$

(note the time reversal in the inner product). Define now the matrix \mathbf{H}_0 as

$$\mathbf{H}_0 = \begin{bmatrix} \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \ddots & h_0(L-1) & h_0(L-2) & \cdots & \cdots & h_0(0) & 0 & 0 & \ddots \\ & 0 & 0 & h_0(L-1) & \cdots & h_0(2) & h_0(1) & h_0(0) & \\ & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \end{bmatrix}. \quad (35.6)$$

which has as its k th row the elements of the sequence $h_0(2k - n)$. Pre-multiplying by \mathbf{H}_0 corresponds to filtering by $H_0(z)$ followed by subsampling by a factor of 2. Also define

$$\mathbf{G}_0^T = \begin{bmatrix} \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \ddots & g_0(0) & g_0(1) & \cdots & \cdots & g_0(L-1) & 0 & 0 & \ddots \\ & 0 & 0 & g_0(0) & \cdots & g_0(L-3) & g_0(L-2) & g_0(L-1) & \\ & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \end{bmatrix}, \quad (35.7)$$

so \mathbf{G}_0 has as its k th column the elements of the sequence $g_0(n - 2k)$. Define \mathbf{H}_1 by replacing the coefficients of $h_0(n)$ with those of $h_1(n)$ in (35.6) and \mathbf{G}_1 by replacing the coefficients of $g_0(n)$ with those of $g_1(n)$ in (35.7).

We find that (35.4) gives that all rows of \mathbf{H}_1 are orthogonal to all columns of \mathbf{G}_0 . Similarly we find, from (35.5), that all of the columns of \mathbf{G}_1 are orthogonal to the rows of \mathbf{H}_0 . So, in matrix notation:

$$\mathbf{H}_0 \mathbf{G}_1 = \mathbf{0} = \mathbf{H}_1 \mathbf{G}_0. \quad (35.8)$$

Now $P(z) = G_0(z)H_0(z) = z^{-1}H_0(z)H_1(-z)$ and $P(-z) = G_1(z)H_1(z)$ are both valid and have the form given in Fig. 35.2 (a). Hence, the impulse responses of $g_i(n)$ and $h_i(n)$ are orthogonal with respect to even shifts

$$\langle g_i(n), h_i(2l - n) \rangle = \delta_l. \quad (35.9)$$

In operator notation:

$$\mathbf{H}_0 \mathbf{G}_0 = \mathbf{I} = \mathbf{H}_1 \mathbf{G}_1. \quad (35.10)$$

Since we have a perfect reconstruction system we get:

$$\mathbf{G}_0 \mathbf{H}_0 + \mathbf{G}_1 \mathbf{H}_1 = \mathbf{I}. \quad (35.11)$$

Of course (35.11) indicates that no nonzero vector can lie in the column nullspaces of both \mathbf{G}_0 and \mathbf{G}_1 . Note that (35.10) implies that $\mathbf{G}_0 \mathbf{H}_0$ and $\mathbf{G}_1 \mathbf{H}_1$ are each projections (since $\mathbf{G}_i \mathbf{H}_i \mathbf{G}_i \mathbf{H}_i = \mathbf{G}_i \mathbf{H}_i$). They project onto subspaces which are not, in general, orthogonal (since the operators are not self-adjoint). Because of (35.4), (35.5), and (35.9) the analysis/synthesis system is termed biorthogonal. If we interleave the rows of \mathbf{H}_0 and \mathbf{H}_1 , much as was done in the orthogonal case, and form again a block Toeplitz matrix

$$\mathbf{A} = \begin{bmatrix} \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ \ddots & h_0(L-1) & h_0(L-2) & \cdots & \cdots & h_0(0) & 0 & 0 & \ddots \\ & h_1(L-1) & h_1(L-2) & \cdots & \cdots & h_1(0) & 0 & 0 & \\ & 0 & 0 & h_0(L-1) & \cdots & h_0(2) & h_0(1) & h_0(0) & \\ & 0 & 0 & h_1(L-1) & \cdots & h_1(2) & h_1(1) & h_1(0) & \\ & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \end{bmatrix}, \quad (35.12)$$

we find that the rows of \mathbf{A} form a basis for $l^2(Z)$. If we form \mathbf{B} by interleaving the columns of \mathbf{G}_0 and \mathbf{G}_1 , we find

$$\mathbf{B} \cdot \mathbf{A} = \mathbf{I}.$$

In the special case where we have a unitary solution, one finds: $\mathbf{G}_0 = \mathbf{H}_0^T$ and $\mathbf{G}_1 = \mathbf{H}_1^T$, and (35.8) gives that we have projections onto subspaces which are mutually orthogonal. The system then simplifies to the orthogonal case, where $\mathbf{B} = \mathbf{A}^{-1} = \mathbf{A}^T$.

A point that we wish to emphasize is that in the conditions for perfect reconstruction, (35.2) and (35.3), the filters $H_0(z)$ and $G_0(z)$ are related via their product $P(z)$. It is the choice of the function $P(z)$ and the factorization taken that determines the properties of the filter bank. We conclude the introduction with a proposition that sums up the foregoing.

PROPOSITION 35.1 To design a two-channel perfect reconstruction filter bank, it is necessary and sufficient to find a $P(z)$ satisfying (35.3), factor it $P(z) = G_0(z)H_0(z)$ and assign the filters as given in (35.2).

35.1.1 Deriving Continuous-Time Bases From Discrete-Time Ones

We have seen that the construction of bases from discrete-time signals can be accomplished easily by using a perfect reconstruction filter bank as the basic building block. This gives us bases that have a certain structure, and for which the analysis and synthesis can be efficiently performed. The design of bases for continuous-time signals appears more difficult. However, it works out that we can mimic many of the ideas used in the discrete-time case, when we go about the construction of continuous-time bases.

In fact, there is a very close correspondence between the discrete-time bases generated by two-channel filter banks, and dyadic wavelet bases. These are continuous-time bases formed by the stretches and translates of a single function, where the stretches are integer powers of two:

$$\{\psi_{jk}(x) = 2^{-j/2}\psi(2^{-j}x - k), \quad j, k, \in \mathbb{Z}\} \quad (35.13)$$

This relation has been thoroughly explored in [11, 12].

To be precise, a basis of the form in (35.13) necessarily implies the existence of an underlying two-channel filter bank. Conversely, a two-channel filter bank can be used to generate a basis as in (35.13) provided that the lowpass filter $H_0(z)$ is *regular*. It is not our intention to go into the details of this connection, but the generation of wavelets from filter banks goes briefly as follows:

Considering the logarithmic tree of discrete-time filters in Fig. 35.3, one notices that the lower branch is a cascade of filters $H_0(z)$ followed by subsampling by 2. It is easily shown [12], that the cascade of i blocks of filtering operations, followed by subsampling by 2, is equivalent to a filter $H_0^{(i)}(z)$ with z -transform:

$$H_0^{(i)}(z) = \prod_{l=0}^{i-1} H_0(z^{2^l}), \quad i = 1, 2, \dots, \quad (35.14)$$

followed by subsampling by 2^i . We define $H_0^{(0)}(z) = 1$ to initialize the recursion. Now, in addition to the discrete-time filter, consider the function $f^{(i)}(x)$ which is piecewise constant on intervals of length $1/2^i$, and equal to:

$$f^{(i)}(x) = 2^{i/2} \cdot h_0^{(i)}(n), \quad n/2^i \leq x < (n+1)/2^i. \quad (35.15)$$

Note that the normalization by $2^{i/2}$ ensures that if $\sum (h_0^{(i)}(n))^2 = 1$ then $\int (f^{(i)}(x))^2 dx = 1$ as well. Also, it can be checked that $\|h_0^{(i)}\|_2 = 1$ when $\|h_0^{(i-1)}\|_2 = 1$. The relation between the sequence

$H_0^{(i)}(z)$ and the function $f^{(i)}(x)$ is clarified in Fig. 35.3, where the first three iterations of each is shown for the simple case of a filter of length 4.

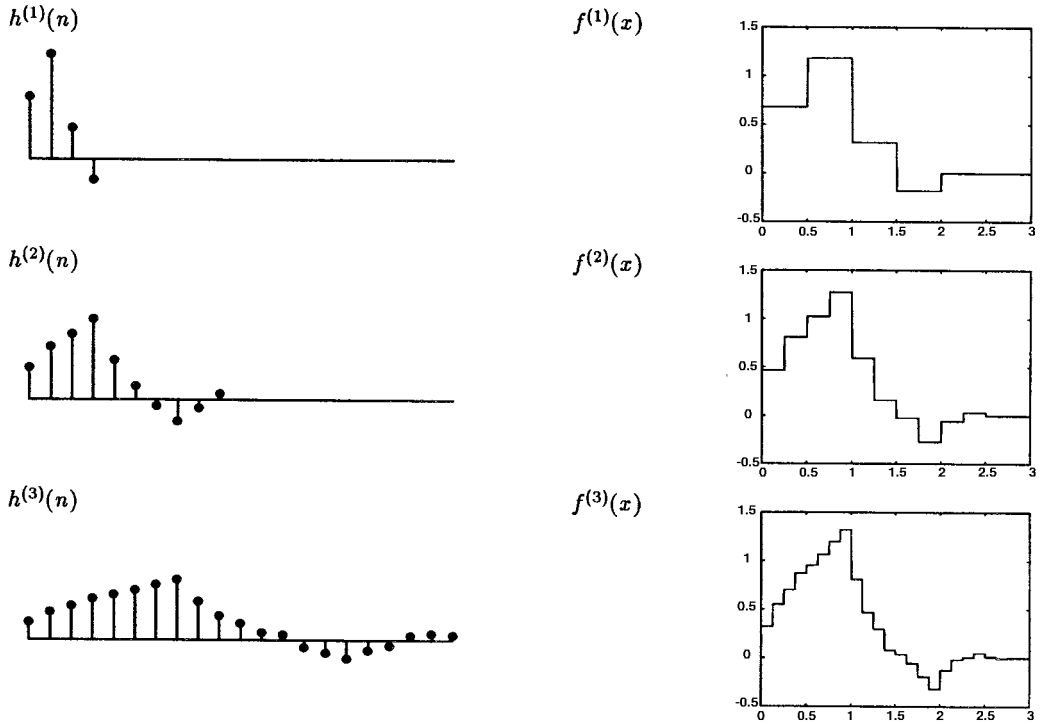

FIGURE 35.3: Iterations of the discrete-time filter (35.14) and the continuous-time function (35.15) for the case of a length-4 filter $H_0(z)$. The length of the filter $H_0^{(i)}(z)$ increases without bound, while the function $f^{(i)}(x)$ actually has bounded support.

We are going to use the sequence of functions $f^{(i)}(x)$ to converge to the scaling function $\phi(x)$ of a wavelet basis. Hence, a fundamental question is to find out whether and to what the function $f^{(i)}(x)$ converges as $i \rightarrow \infty$. First assume that the filter $H_0(z)$ has a zero at the half sampling frequency, or $H_0(e^{j\pi}) = 0$. This together with the fact that the filter impulse response is orthogonal to its even translates is equivalent to $\sum h_0(n) = H_0(1) = \sqrt{2}$. Define $M_0(z) = 1/\sqrt{2} \cdot H_0(z)$, that is $M_0(1) = 1$. Now factor $M_0(z)$ into its roots at π (there is at least one by assumption) and a remainder polynomial $K(z)$, in the following way:

$$M_0(z) = [(1 + z^{-1})/2]^N K(z).$$

Note that $K(1) = 1$ from the definitions. Now call B the supremum of $|K(z)|$ on the unit circle:

$$B = \sup_{\omega \in [0, 2\pi]} |K(e^{j\omega})|.$$

Then the following result from [11] holds:

PROPOSITION 35.2 [Daubechies 1988] If $B < 2^{N-1}$, and

$$\sum_{n=-\infty}^{\infty} |k(n)|^2 |n|^\epsilon < \infty, \text{ for some } \epsilon > 0, \quad (35.16)$$

then the piecewise constant function $f^{(i)}(x)$ defined in (35.15) converges pointwise to a continuous function $f^{(\infty)}(x)$.

This is a sufficient condition to ensure pointwise convergence to a continuous function, and can be used as a simple test. We shall refer to any filter for which the infinite product converges as *regular*.

If we indeed have convergence, then we define

$$f^{(\infty)}(x) = \phi(x)$$

as the analysis scaling function, and

$$\psi(x) = 2^{-1/2} \sum h_1(n) \phi(2x - n), \quad (35.17)$$

as the analysis wavelet. It can be shown that if the filters $h_0(n)$ and $h_1(n)$ are from a perfect reconstruction filter bank, then (35.13) indeed forms a continuous-time basis.

In a similar way we examine the cascade of i blocks of the synthesis filter $g_0(n)$

$$G_0^{(i)}(z) = \prod_{l=0}^{i-1} G_0(z^{2^l}), \quad i = 1, 2, \dots \quad (35.18)$$

Again, define $G_0^{(0)}(z) = 1$ to initialize the recursion, and normalize $G_0(1) = 1$. From this define a function which is piecewise constant on intervals of length $1/2^i$:

$$\check{f}^{(i)}(x) = 2^{i/2} \cdot g_0^{(i)}(-n), \quad n/2^i \leq x < (n+1)/2^i. \quad (35.19)$$

We call the limit $\check{f}^{(\infty)}(x)$, if it exists, $\check{\phi}(x)$ the synthesis scaling function, and we find

$$\check{\phi}(x) = 2^{1/2} \cdot \sum_{n=0}^{L-1} g_0(-n) \cdot \check{\phi}(2x - n) \quad (35.20)$$

$$\check{\psi}(x) = 2^{1/2} \cdot \sum_{n=0}^{L-1} g_1(-n) \cdot \check{\phi}(2x - n). \quad (35.21)$$

The biorthogonality properties of the analysis and synthesis continuous-time functions follow from the corresponding properties of the discrete-time ones. That is, (35.9) leads to

$$\langle \check{\phi}(x), \phi(x - k) \rangle = \delta_k. \quad (35.22)$$

and

$$\langle \check{\psi}(x), \psi(x - k) \rangle = \delta_k. \quad (35.23)$$

Similarly

$$\langle \check{\phi}(x), \psi(x - k) \rangle = 0 \quad (35.24)$$

$$\langle \check{\psi}(x), \phi(x - k) \rangle = 0, \quad (35.25)$$

come from (35.4) and (35.5), respectively.

We have shown that the conditions for perfect reconstruction on the filter coefficients lead to functions that have the biorthogonality properties as shown above. Orthogonality across scales is also easily verified:

$$\langle \check{\psi}(2^j x), \psi(2^i x - k) \rangle = \delta_{i-j} \delta_k.$$

Thus, the set $\{\psi(2^j x), \check{\psi}(2^i x - k), i, j, k \in \mathbb{Z}\}$ is biorthogonal. That it is complete can be verified as in the orthogonal case [13]. Hence, any function from $L^2(\mathbb{R})$ can be written:

$$f(x) = \sum_j \sum_l \langle f(x), 2^{-j/2} \psi(2^j x - l) \rangle 2^{-j/2} \check{\psi}(2^j x - l).$$

Note that $\psi(x)$ and $\check{\psi}(x)$ play interchangeable roles.

35.1.2 Two-Channel Filter Banks and Wavelets

We have seen that the design of discrete-time bases is not difficult: using two-channel filter banks as the basic building block they can be easily derived. We also know that, using (35.15) and (35.19), we can generate continuous-time bases quite easily as well. If we were just interested in the construction of bases, with no further requirements, we could stop here. However, for applications such as compression, we will often be interested in other properties of the basis functions, for example, whether or not they have any symmetry or finite support, and whether or not the basis is an orthonormal one. We examine these three structural properties for the remainder of this section. Chapter 36 deals with the design of the filters. Chapter 37 deals with time-varying filter banks, where the filters used, or the tree structure employing them, varies over time. Chapter 38 deals with the case of Lapped Transforms, a very important class of multirate filter banks that have achieved considerable success.

From the filter bank point of view, the properties we are most interested in are the following:

- **Orthogonality:**

$$\langle h_0(n), h_0(n + 2k) \rangle = \delta_k = \langle h_1(n), h_1(n + 2k) \rangle, \quad (35.26)$$

$$\langle h_0(n), h_1(n + 2k) \rangle = 0. \quad (35.27)$$

- **Linear phase:** $H_0(z)$, $H_1(z)$, $G_0(z)$, and $G_1(z)$ are all linear phase filters.
- **Finite support:** $H_0(z)$, $H_1(z)$, $G_0(z)$, and $G_1(z)$ are all FIR filters.

The reason for our interest is twofold. First, these properties are possibly of value in perfect reconstruction filter banks used in subband coding schemes. For example, orthogonality implies that the quantization noise in the two channels will be independent; linear phase is possibly of interest in very low bit-rate coding of images, and FIR filters have the advantage of having very simple low-complexity implementations. Second, these properties are carried over to the wavelets that are generated. So, if we design a filter bank with a certain set of properties, then the continuous-time basis that it generates will also have these properties.

PROPOSITION 35.3 If the filters belong to an orthogonal filter bank, we shall have

$$\langle \phi(x), \phi(x + k) \rangle = \delta_k = \langle \psi(x), \psi(x + k) \rangle,$$

$$\langle \phi(x), \psi(x + k) \rangle = 0.$$

PROOF 35.1 From the definition (35.15) $f^{(0)}(x)$ is just the indicator function on the interval $[0, 1]$; so we immediately get orthogonality at the 0th level, that is: $\langle f^{(0)}(x - l), f^{(0)}(x - k) \rangle = \delta_{kl}$. Now we assume orthogonality at the i th level:

$$\langle f^{(i)}(x - l), f^{(i)}(x - k) \rangle = \delta_{kl}, \quad (35.28)$$

and prove that this implies orthogonality at the $(i + 1)$ st level:

$$\begin{aligned} \langle f^{(i+1)}(x - l), f^{(i+1)}(x - k) \rangle &= 2 \sum_n \sum_m h_0(n) h_0(m) \\ &\quad \langle f^{(i)}(2x - 2l - n), f^{(i)}(2x - 2k - m) \rangle \frac{\delta_{n+2l-2k-m}}{2} \\ &= \sum_n h_0(n) h_0(n + 2l - 2k) \\ &= \delta_{kl}. \end{aligned}$$

Hence, by induction (35.28) holds for all i . So in the limit $i \rightarrow \infty$:

$$\langle \phi(x - l), \phi(x - k) \rangle = \delta_{kl}. \quad (35.29)$$

The orthogonal case gives considerable simplification, both in the discrete-time and continuous-time cases.

PROPOSITION 35.4 If the filters belong to an FIR filter bank, then $\phi(x)$, $\psi(x)$, $\check{\phi}(x)$, and $\check{\psi}(x)$ will have support on some finite interval.

PROOF 35.2 The filters $H_0^{(i)}(z)$ and $G_0^{(i)}(z)$ defined in (35.14) have respective lengths $(2^i - 1)(L_a - 1) + 1$ and $(2^i - 1)(L_s - 1) + 1$ where L_a and L_s are the lengths of $H_0(z)$ and $G_0(z)$. Hence, $f^{(i)}(x)$ in (35.15) is supported on the interval $[0, L_a - 1]$ and $\check{f}^{(i)}(x)$ on the interval $[0, L_s - 1]$. This holds $\forall i$; hence, in the limit $i \rightarrow \infty$ this gives the support of the scaling functions $\phi(x)$ and $\check{\phi}(x)$. That $\psi(x)$ and $\check{\psi}(x)$ have bounded support follow from (35.20) and (35.21).

PROPOSITION 35.5 If the filters belong to a linear phase filter bank, then $\phi(x)$, $\psi(x)$, $\check{\phi}(x)$, and $\check{\psi}(x)$ will be symmetric or antisymmetric.

PROOF 35.3 The filter $H_0^{(i)}(z)$ will have linear phase if $H_0(z)$ does. If $H_0^{(i)}(z)$ has length $(2^i - 1)(L_a - 1) + 1$, the point of symmetry is $(2^i - 1)(L_a - 1)/2$ which need not be an integer. The point of symmetry for $f^{(i)}(x)$ will then be $[(2^i - 1)(L_a - 1) + 1]/2^{i+1}$ or $[(2^i - 1)(L_a - 1) + 2]/2^{i+1}$. In either case, by taking the limit $i \rightarrow \infty$ we find that $\phi(x)$ is symmetric about the point $(L_a - 1)/2$ and similarly for the other cases.

Thus having established the relation between wavelets and filter banks we can examine the structure of filter banks in detail, and afterward use them to generate wavelets as described above. It should be emphasized that we are speaking of the two-channel, one-dimensional case. Multidimensional filter banks are a large subject in their own right [8, 10].

35.1.3 Structure of Two-Channel Filter Banks

We saw already that it is the choice of the function $P(z)$ and the factorization taken that determines the properties of the filter bank. In terms of $P(z)$, we give necessary and sufficient conditions for the three properties mentioned above:

- **Orthogonality:** $P(z)$ is an autocorrelation, and $H_0(z)$ and $G_0(z)$ are its spectral factors.
- **Linear phase:** $P(z)$ is linear phase, and $H_0(z)$ and $G_0(z)$ are its linear phase factors.
- **Finite support:** $P(z)$ is FIR, and $H_0(z)$ and $G_0(z)$ are its FIR factors.

Obviously the factorization is not unique in any of the cases above. The FIR case has been examined in detail in [11, 12, 14, 15, 16] and the linear phase case in [12, 15, 17]. In the rest of this paper we will present new results on the orthogonal case, but we shall also review the solutions that explicitly satisfy simultaneous constraints.

PROPOSITION 35.6 To have an orthogonal filter bank it is necessary and sufficient that $P(z)$ be an autocorrelation, and that $H_0(z)$ and $G_0(z)$ be its spectral factors.

PROPOSITION 35.7 To have a linear phase filter bank it is necessary and sufficient that $P(z)$ be a linear phase, and that $H_0(z)$ and $G_0(z)$ be its linear phase factors.

PROPOSITION 35.8 To have an FIR filter bank it is necessary and sufficient that $P(z)$ be FIR, and that $H_0(z)$ and $G_0(z)$ be its FIR factors.

Proofs can be found in [18]. Having seen that the design problem can be considered in terms of $P(z)$ and its factorizations, we consider the three conditions of interest from this point of view.

Orthogonality

In the case where the filter bank is to be orthogonal, we can obtain a complete constructive characterization of the solutions, as given by the following theorem, taken from [18].

THEOREM 35.1 All orthogonal rational two channel filter banks can be formed as follows:

1. Choosing an arbitrary polynomial $R(z)$, form:

$$P(z) = \frac{2 \cdot R(z)R(z^{-1})}{R(z)R(z^{-1}) + R(-z)R(-z^{-1})},$$

2. factor as $P(z) = H(z)H(z^{-1})$,
3. form the filter $H_0(z) = A_0(z)H(z)$, where $A_0(z)$ is an arbitrary allpass,
4. choose $H_1(z) = z^{2k-1}H_0(-z^{-1})A_1(z^2)$, where $A_1(z)$ is again an arbitrary allpass,
5. choose $G_0(z) = H_0(z^{-1})$, and $G_1(z) = -H_1(z^{-1})$.

For a proof, see [18, 19].

EXAMPLE 35.1:

Take $R(z) = (1 + z^{-1})^N$ as above and $N = 7$. It works out that in this case there is a closed form factorization for the filters.

$$\begin{aligned} P(z) &= \frac{(1, 14, 91, 364, 1001, 2002, 3003, 3432, 3003, 2002, 1001, 364, 91, 14, 1) \cdot z^7}{14z^6 + 364z^4 + 2002z^2 + 3432 + 2002z^{-2} + 364z^{-4} + 14z^{-6}} \\ &= \frac{E(z)E(z^{-1})}{K(z)K(z^{-1})}, \end{aligned}$$

where

$$\frac{E(z)}{K(z)} = \frac{(1 + 7z^{-1} + 21z^{-2} + 35z^{-3} + 35z^{-4} + 21z^{-5} + 7z^{-6} + z^{-7})}{\sqrt{2} \cdot (1 + 21z^{-2} + 35z^{-4} + 7z^{-6})}.$$

Note that we have used the following shorthand notation to list the coefficients of a causal FIR sequence:

$$\sum_{n=0}^{N-1} a_n z^{-n} = (a_0, a_1, a_2, \dots, a_{N-1}).$$

So, using the description of the filters in Theorem 35.1, with the simplest case $A_0(z) = A_1(z) = 1$ and $k = 0$ we find:

$$\begin{aligned} H_0(z) &= \frac{(1 + 7z^{-1} + 21z^{-2} + 35z^{-3} + 35z^{-4} + 21z^{-5} + 7z^{-6} + z^{-7})}{\sqrt{2} \cdot (1 + 21z^{-2} + 35z^{-4} + 7z^{-6})} \\ H_1(z) &= z^{-1} \frac{(1 - 7z^1 + 21z^2 - 35z^3 + 35z^4 - 21z^5 + 7z^6 - z^7)}{\sqrt{2} \cdot (1 + 21z^2 + 35z^4 + 7z^6)} \\ G_0(z) &= H_0(z^{-1}) \quad G_1(z) = H_1(z^{-1}). \end{aligned}$$

In the notation of Proposition 35.2, $B = 8 < 2^6$ so that for this choice of $H_0(z)$ the left-hand side of (35.15) converges to a continuous function. The wavelet, scaling function, and their spectra are shown in Fig. 35.4.

Finite Impulse Response and Symmetric Solutions

In the case where the filters are to be FIR, we merely require that $P(z)$ be FIR; it is trivially easy to design one. Similarly to have symmetric filters, we merely force $P(z)$ to be symmetric. Obviously any symmetric $P(z)$ which is FIR and satisfies (35.3) can be used to give symmetric FIR filters. We would like, in addition, that the lowpass filters are regular, so that we get symmetric bounded support continuous-time basis functions.

One strategy would be to design a $P(z)$ with the desired properties and then factor to find the filters. Alternatively, we can choose one of the factors, and then find the other necessary to make the product $P(z)$ satisfy (35.3). We will use this approach and, to ensure regularity, choose one factor to be $(1 + z^{-1})^{2N}$. This can be done by solving a linear system of equations [12].

EXAMPLE 35.2:

If we choose $N = 3$ we must find the complement to $(1 + z^{-1})^6$; so we solve the 3 by 3 system found by imposing the constraints on the coefficients of the odd powers of z^{-1} of

$$\begin{aligned} P(z) &= (k_0 + k_1 z^{-1} + k_2 z^{-2} + k_1 z^{-3} + k_0 z^{-4}) \\ &\cdot (1 + 6z^{-1} + 15z^{-2} + 20z^{-3} + 15z^{-4} + 6z^{-5} + z^{-6}) \cdot z^5. \end{aligned}$$

FIGURE 35.4: Example of Butterworth orthogonal wavelet; here $N = 7$, and the closed form factorization has been used. (a) The wavelet. (b) Spectrum of the wavelet. (c) Scaling function. (d) Spectrum of the scaling function.

So we solve:

$$\begin{pmatrix} 6 & 1 & 0 \\ 20 & 16 & 6 \\ 12 & 30 & 20 \end{pmatrix} \begin{pmatrix} k_0 \\ k_1 \\ k_2 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix},$$

giving $\mathbf{k}_6 = (3/2, -9, 19)/128$.

In general, therefore, we solve the system:

$$\mathbf{F}_{2N} \cdot \mathbf{k}_{2N} = \mathbf{e}_{2N}, \quad (35.30)$$

where \mathbf{F}_{2N} is the $N \times N$ matrix, $\mathbf{k}_{2N} = (k_0, \dots, k_{(k-1)})$, and \mathbf{e}_{2N} is the length k vector $(0, 0, \dots, 1)$.

Having found the coefficients of $K_{2N}(z)$, we factor it into linear phase components and then regroup these factors of $K_{2N}(z)$ and the $2N$ zeros at $z = -1$ to form two filters: $H_0(z)$ and $H_1(-z)$, both of which are to be regular.

FIGURE 35.5: Biorthogonal wavelets generated by filters of length 18 given in [12]. (a) Analysis wavelet function $\psi(x)$. (b) Spectrum of analysis wavelet. (c) Synthesis wavelet function $\psi(x)$. (d) Spectrum of synthesis wavelet.

35.1.4 Putting the Pieces Together

An important consideration that is often encountered in the design of wavelets, or of the filter banks that generate them, is the necessity of satisfying competing design constraints. This makes it necessary to clearly understand whether desired properties are mutually exclusive.

Perfect reconstruction solutions, with the constraint that $P(z)$ be rational with real coefficients, must satisfy (35.3). Such general solutions, which do not necessarily have additional properties, were given in [14].

The solutions of set A, where all of the filters involved are FIR, were studied in [14, 15]. Set B contains all orthogonal solutions, and has been the main focus of this paper. A complete characterization of this set was given in Theorem 35.1. A very different characterization, based on lattice structures, is given in [20]. Particular cases of orthogonal solutions were also given in [21]. Set C contains the solutions where all filters are linear phase, first examined in [15].

The earliest examples of perfect reconstruction solutions [22, 23] were orthogonal and FIR; i.e., they were in $A \cap B$. A constructive parametrization of $A \cap B$ was given in [24]. The construction

and characterization of examples which converge to wavelets was first done in [11]. Filter banks with FIR linear phase filters (i.e., $A \cap C$) were first given in [15], and also studied in terms of lattices in [17, 25]. The construction of wavelet examples is given in [13] and [12]. Filter banks, which are linear phase and orthogonal, were constructed in Chapter 36 and were presented in [18].

That there exist only trivial solutions which are linear phase, orthogonal and FIR is indicated by the intersection $A \cap B \cap C$; the only solutions are two tap filters [11, 12, 26].

It warrants emphasis that Fig. 35.6 illustrates the filter bank solutions; if the filters are regular, then they will lead to wavelets. Of the dyadic wavelet bases known to the authors, the only ones based on filters where $P(z)$ is not rational are those of Meyer [27], and the only ones where the filter coefficients are complex are those of Lawton [28]. For the case of the Battle-Lemarié wavelets, while the filters themselves are not rational, the $P(z)$ function is; hence, the filters would belong to $B \cap C$ in the figure.

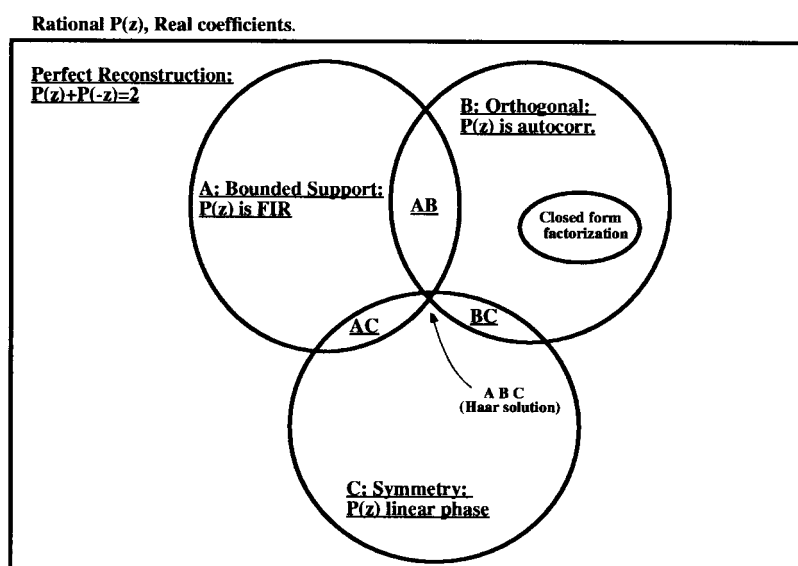

FIGURE 35.6: Two channel perfect reconstruction filter banks. The Venn diagram illustrates which competing constraints can be simultaneously satisfied. The sets A , B , C contain FIR, orthogonal, and linear phase solutions, respectively. Solutions in the intersection $A \cap B$ are examined in [11, 14, 23, 24]; those in the intersection $A \cap C$ are detailed in [12, 13, 15, 17, 25]; solutions in $B \cap C$ are constructed in [18]. The intersection $A \cap B \cap C$ contains only trivial solutions.

[References](#)

The interest in digital filter banks has grown dramatically over the last few years. Owing to the trend toward lower cost, higher speed microprocessors, digital solutions are becoming attractive for a wide variety of applications. Filter banks allow signals to be decomposed into subbands, often facilitating more efficient and effective processing. They are particularly visible in the areas of image compression, speech coding, and image analysis.

The desired characteristics of a subband decomposition will naturally vary from application to application. Moreover, within any given application, there are a myriad of issues to consider. First, one might consider whether to use FIR or IIR filters. IIR designs can offer computational advantages, while FIR designs can offer greater flexibility in filter characteristics. In this chapter we focus exclusively on FIR design. Second, one might identify the time-frequency or space-frequency representation that is most appropriate. Uniform decompositions and octave-band decompositions are particularly popular at present. At the next level, characteristics of the analysis filters should be defined. This involves imposing specifications on the analysis filter passband deviations, transition bands, and stopband deviations. Alternately or in addition, time domain characteristics may be imposed, such as limits on the step response ripples, and degree of regularity.

One can consider similar constraints for the synthesis filters. For coding applications, the characteristics of the synthesis filters often have a dominant effect on the subjective quality of the output. Finally, one should consider analysis-synthesis characteristics. That is, one has flexibility to specify the overall behavior of the system. In most cases, one views having exact reconstruction as being ideal. Occasionally, however, it may be possible to trade some small loss in reconstruction quality for significant gains in computation, speed, or cost. In addition to specifying the quality of reconstruction, it is generally possible to control the overall delay of the system from end to end. In some applications, such as two-way speech and video coding, latency represents a source of quality degradation. Thus, having explicit control over the analysis-synthesis delay can lead to improvement in quality.

The intelligent design of applications-specific filter banks involves first identifying the relevant parameters and optimizing the system with respect to them. As is typical, the filter bank analysis and reconstruction equations lead to complex tradeoffs among complexity, system delay, filter quality, filter length, and quality of performance. This chapter is devoted to presenting an introduction to filter bank design. Filter bank design has reached a state of maturity in many regards. To cover all of

FIGURE 36.1: Block diagram of an M -band analysis-synthesis filter bank.

FIGURE 36.2: Two-band analysis-synthesis filter bank.

the important contributions in any level of detail would be impossible in a single chapter. However, it is possible to gain some insight and appreciation for general design strategies germane to this topic. In addition to discussing design methodologies for linear analysis-synthesis systems, we also consider the design of a couple of new nonlinear classes of filter banks that are currently receiving attention in the literature. This discussion along with the referenced articles should provide a convenient introduction to the design of many useful filter banks.

36.1 Filter Bank Equations

A broad class of linear filter banks can be represented by the block diagram shown in Fig. 36.1. This is a linear time-varying system that decomposes the input into M -subbands, each one of which is decimated by a factor of R . When $R = M$, the system is said to be *critically sampled* or *maximally decimated*. Maximally decimated systems are generally the ones of choice because they can be information preserving, and are not data expansive.

The simplest filter bank of this class is the two-band system, an example of which is shown in Fig. 36.2. Here, there are only two analysis filters: $H_0(z)$, a lowpass filter; and $H_1(z)$, a highpass filter. Similarly, there are two synthesis filters: a lowpass $G_0(z)$, and a highpass $G_1(z)$. Let us consider this two-band filter bank first. In the process, we will develop a design methodology that can be extended to the more complex problem of M -band systems.

Examining the two-band filter bank in Fig. 36.2, we see that the input $x[n]$ is lowpass and highpass filtered, resulting in $v_0[n]$ and $v_1[n]$. These signals are then downsampled by a factor of two, leading to the analysis section outputs, $y_0[n]$ and $y_1[n]$. The downsampling operation is time varying, which implies a non-trivial relationship between $v_k[n]$ and $y_k[n]$ (where $k = 0, 1$). In general, downsampling a signal $v_k[n]$ by an integer factor R is described in the time domain by the equation

$$y_k[n] = v_k[Rn].$$

In the frequency domain, this relationship is given by

$$Y_k(e^{j\omega}) = \frac{1}{R} \sum_{r=0}^{R-1} V_k \left(e^{j\left(\frac{\omega}{R} + \frac{2\pi r}{R}\right)} \right).$$

The equivalent equation in the z domain is

$$Y_k(z) = \frac{1}{R} \sum_{r=0}^{R-1} V_k \left(W_R^r z^{\frac{1}{R}} \right)$$

where $W_R^r = e^{-j\frac{2\pi r}{R}}$.

In the synthesis section, the subband signals $y_0[n]$ and $y_1[n]$ are upsampled to give $s_0[n]$ and $s_1[n]$. They are then filtered by the lowpass and highpass filters, $G_0(z)$ and $G_1(z)$, respectively, before being summed together. The upsampling operation (for an arbitrary positive integer R) can be defined by

$$s_k[n] = \begin{cases} y_k[n/R] & \text{for } n = 0, \pm R, \pm 2R, \pm 3R, \dots \\ 0 & \text{otherwise} \end{cases}$$

in the time domain, and

$$S_k(e^{j\omega}) = Y_k(e^{jR\omega}) \quad \text{and} \quad S_k(z) = Y_k(z^R)$$

in the frequency and z domains, respectively.

Using the expressions for the downsampling and upsampling operations, we can describe the two-band filter bank in terms of z -domain equations. The outputs after analysis filtering are

$$V_k(z) = H_k(z)X(z), \quad k = 0, 1.$$

After decimation and recognizing that $W_2^1 = -1$, we obtain

$$Y_k(z) = \frac{1}{2} \left[H_k \left(z^{\frac{1}{2}} \right) X \left(z^{\frac{1}{2}} \right) + H_k \left(-z^{\frac{1}{2}} \right) X \left(-z^{\frac{1}{2}} \right) \right], \quad k = 0, 1. \quad (36.1)$$

Thus, Eq. (36.1) defines completely the input-output relationship for the analysis section in the z domain.

In the synthesis section, the subbands are upsampled giving

$$S_k(z) = Y_k(z^2), \quad k = 0, 1.$$

This implies that

$$S_k(z) = \frac{1}{2} (H_k(z)X(z) + H_k(-z)X(-z)), \quad k = 0, 1.$$

Passing $S_k(z)$ through the synthesis filters and then summing yields the reconstructed output

$$\begin{aligned} \hat{X}(z) &= \frac{1}{2} G_0(z) [H_0(z)X(z) + H_0(-z)X(-z)] \\ &\quad + \frac{1}{2} G_1(z) [H_1(z)X(z) + H_1(-z)X(-z)]. \end{aligned} \quad (36.2)$$

For virtually any application for which one can conceive, the synthesis filters should allow the input to be reconstructed exactly or with a minimal amount of distortion. In other words, ideally we want

$$\hat{X}(z) = z^{-n_0} X(z),$$

where n_0 is the integer system delay. An intuitive approach to handling this problem is to use the AC-matrix formulation, which we introduce next.

36.1.1 The AC Matrix

The aliasing component matrix (or AC matrix) represents a simple and intuitive idea originally introduced in [6] for handling analysis and reconstruction. The analysis-synthesis equation (36.2) for the two-band case can be expressed as

$$\begin{aligned}\hat{X}(z) &= \frac{1}{2} [H_0(z)G_0(z) + H_1(z)G_1(z)] X(z) \\ &\quad + \frac{1}{2} [H_0(-z)G_0(z) + H_1(-z)G_1(z)] X(-z) .\end{aligned}$$

The idea of the AC matrix is to represent the equations in matrix form. For the two-band system, this results in

$$\hat{X}(z) = \frac{1}{2} [X(z), X(-z)] \underbrace{\begin{bmatrix} H_0(z) & H_1(z) \\ H_0(-z) & H_1(-z) \end{bmatrix}}_{\text{AC matrix}} \begin{bmatrix} G_0(z) \\ G_1(z) \end{bmatrix} ,$$

where the AC matrix is as shown above. The AC matrix is so designated because it contains the analysis filters and all the associated aliasing components. Exact reconstruction is then obtained when

$$\begin{bmatrix} H_0(z) & H_1(z) \\ H_0(-z) & H_1(-z) \end{bmatrix} \begin{bmatrix} G_0(z) \\ G_1(z) \end{bmatrix} = \begin{bmatrix} T(z) \\ 0 \end{bmatrix}$$

where $T(z)$ is required to be the scaled integer delay $2z^{-n_0}$. The term $T(z)$ is the transfer function of the overall system. The zero term below $T(z)$ determines the amount of aliasing present in the reconstructed signal. Because this term is zero, all aliasing is explicitly removed.

With the equations expressed in matrix form, we can solve for the synthesis filters, which yields

$$\begin{bmatrix} G_0(z) \\ G_1(z) \end{bmatrix} = \frac{1}{H_0(z)H_1(-z) - H_0(-z)H_1(z)} \begin{bmatrix} H_1(-z) & -H_1(z) \\ -H_0(-z) & H_0(z) \end{bmatrix} \begin{bmatrix} T(z) \\ 0 \end{bmatrix} . \quad (36.3)$$

Often for a variety of reasons, we would like both the analysis and synthesis filters to be FIR. This means the determinant of the AC matrix should be a constant delay. The earliest solution to the FIR filter bank problem was presented by Croisier et al. in 1976 [18]. Their solution was to let

$$H_1(z) = H_0(-z)$$

and

$$\begin{aligned}G_0(z) &= H_0(z) \\ G_1(z) &= -H_0(-z) .\end{aligned}$$

This is the quadrature mirror filter (QMF) solution. From the equations in (36.3), it can be seen that this solution cancels all the aliasing and results in a system transfer function

$$T(z) = H_0(z)H_1(-z) - H_0(-z)H_1(z) .$$

As it turns out, with careful design $T(z)$ can be made to be close to a constant delay. However, some amount of distortion will always be present. In 1980 Johnston designed a set of optimized QMFs which are now widely used. The coefficient values may be found in several sources [16, 17, 19].

Interestingly, the equations in (36.3) imply that exact reconstruction is possible by forcing the AC-matrix determinant to be a constant delay. The design of such exact reconstruction filters is discussed in the next section.

FIGURE 36.3: Example of a zero-phase half-band lowpass filter.

36.1.2 Spectral Factorization

The question at hand is how do we determine $H_0(z)$ and $H_1(z)$ such that $T(z)$ is an integer delay z^{-n_0} . A solution to this problem was introduced in 1984 [7], based on the observation that $H_0(z)H_1(-z)$ is a lowpass filter [which we denote $F_0(z)$] and $H_0(-z)H_1(z)$ is its corresponding frequency shifted highpass filter. A unity transfer function can be constructed by forcing $F_0(z)$ and $F_0(-z)$ to be complementary half-band lowpass and highpass filters. Many fine techniques are available for the design of half-band lowpass filters, such as the Parks-McClellan algorithm, Kaiser window design, Hamming window design, the eigenfilter method, and others. Zero-phase half-band filters have the property that zeros occur in the impulse response at $n = \pm 2, \pm 4, \pm 6, \dots$, etc. An illustration is shown in Fig. 36.3. Once designed, $F_0(z)$ can be factored into two lowpass filters, $H_0(z)$ and $H_1(-z)$. The design procedure can be summarized as follows.

1. First design a $(2N - 1)$ -tap half-band lowpass filter, using the Parks-McClellan algorithm, for example. This can be done by constraining the passband and stopband cutoff frequencies to be $\omega_p = \pi - \omega_s$, and using equal passband and stopband error weightings. The resulting filter will have equal passband and stopband ripples, i.e., $\delta_p = \delta_s = \delta$.
2. Add the value δ to the $f[0]$ (center) tap value. This forces $F(e^{j\omega}) \geq 0$ for all ω .
3. Spectrally factor $F(z)$ into two lowpass filters, $H_0(z)$ and $H_1(-z)$. Generally the best way to factor $F(z)$ is such that $H_1(-z) = H_0(z^{-1})$. Note that the factorization will not be unique and the roots should be split so that if a particular root is assigned to $H_0(z)$, its reciprocal should be given to $H_0(z^{-1})$.

The result of the above procedure is that $H_0(z)$ will be a power complementary, even length, FIR filter that will form the basis for a perfect reconstruction filter bank. Note that since $H_1(z)$ is just a time-reversed, spectrally shifted version of $H_0(z)$,

$$|H_0(e^{j\omega})| = |H_1(-e^{j\omega})|.$$

Smith and Barnwell designed and published a set of optimal exact reconstruction filters [1]. The filter coefficients for $H_0(z)$ are given in Table 36.1. The analysis and synthesis filters are obtained from $H_0(z)$ by

$$\begin{aligned} G_0(z) &= H_0(z^{-1}) \\ G_1(z) &= H_0(-z) \\ H_1(z) &= H_0(-z^{-1}). \end{aligned}$$

A complete discussion of this approach can be found in many references [1, 6, 7, 25, 27, 28].

8-Tap filter

For the M -channel case shown in Fig. 36.1, where the bands are assumed to be maximally decimated, the same AC-matrix approach can be employed, leading to the equations

$$\hat{X}(z) = \frac{1}{M} \underbrace{\begin{bmatrix} X(z), \dots, X(zW_M^{M-1}) \end{bmatrix}}_{\mathbf{x}^T} \underbrace{\begin{bmatrix} H_0(z) & \dots & H_{M-1}(z) \\ H_0(zW_M^1) & \dots & H_{M-1}(zW_M^1) \\ \vdots & & \vdots \\ H_0(zW_M^{M-1}) & \dots & H_{M-1}(zW_M^{M-1}) \end{bmatrix}}_{\mathbf{H}} \underbrace{\begin{bmatrix} G_0(z) \\ G_1(z) \\ \vdots \\ G_{M-1}(z) \end{bmatrix}}_{\mathbf{g}},$$

where $W_M = e^{-j\frac{2\pi}{M}}$. This can be rewritten compactly as

$$\hat{X}(z) \frac{1}{M} \mathbf{x}^T(z) \mathbf{H}(z) \mathbf{g}(z),$$

where \mathbf{x} is the input vector, \mathbf{g} is the synthesis filter vector, and \mathbf{H} is the AC matrix. However, the AC-matrix determinant for systems with $M > 2$ is typically too intricate for the spectral factorization approach outlined above. An effective approach for handling the design of M -band systems was introduced by Vaidyanathan in [30]. It is based on a lattice implementation structure and is discussed next.

FIGURE 36.4: Flow graph of a two-band lattice structure with three stages.

36.1.3 Lattice Implementations

In addition to the direct form structures shown in Figs. 36.1 and 36.2, filter banks can be implemented using lattice structures. For simplicity, consider the two-band case first. An example of a lattice structure for a two-band analysis system is shown in Fig. 36.4. It is composed of a cascade of criss-cross elements, each of which has a set of coefficients associated with it. Conveniently, each section, which we denote \mathbf{R}_m , can be described by a matrix. For the two-band lattice, these matrices have the form

$$\mathbf{R}_m = \begin{bmatrix} 1 & r_m \\ -r_m & 1 \end{bmatrix}.$$

Interspersed between the coefficient matrices are delay matrices, $\Lambda(z)$, having the form

$$\Lambda(z) = \begin{bmatrix} 1 & 0 \\ 0 & z^{-1} \end{bmatrix}.$$

It can be shown [27] that lattice filters can represent a wide class of exact reconstruction filter banks. Two points regarding lattice filter banks are particularly noteworthy. First, the lattice structure provides an efficient form of implementation. Moreover, the synthesis filter bank is directly related to the analysis bank, since each matrix in the analysis cascade is invertible. Consequently, the synthesis bank consists of the cascade of inverse section matrices. Second, the structure also provides a convenient way to design the filter bank. Each lattice coefficient can be optimized using standard minimization routines to minimize a passband-stopband error cost function for the filters. This approach to design can be used for two-band as well as M -band filter banks [5, 27, 28].

36.1.4 Time-Domain Design

One of the most flexible design approaches is the time domain formulation proposed by Nayebi et al. [3, 8]. This formulation has enabled the discovery of previously unknown classes of filter banks, such as low and variable delay systems [12], time-varying filter banks [4], and block decimation systems [9]. It is attractive because it enables the design of virtually all linear filter banks. The idea underlying this approach is that the conditions for exact reconstruction can be expressed in the time domain in a convenient matrix form. Let us explore this approach in the context of an M -band filter bank. Because of the decimation operations, the overall M -band analysis-synthesis system is periodically time-varying. Thus, we can view an arbitrary maximally decimated M -band system as having M linear time invariant transfer functions associated with it. One can think of the problem as trying to devise M subsampled systems, each one of which exactly reconstructs. This is equivalent to saying that for each impulse input, $\delta[n - i]$, to the analysis-synthesis system, that impulse should appear at the system output at time $n = i + n_0$, where $i = 0, 1, 2, \dots, M - 1$ and n_0 is the system delay.

This amounts to setting up an overconstrained linear system $\mathbf{AS} = \mathbf{B}$, where the matrix \mathbf{A} is created using the analysis filter coefficients, the matrix \mathbf{B} is the desired response of zeros except at the appropriate delay points (i.e., $\delta[n - n_0]$) and \mathbf{S} is a matrix containing synthesis filter coefficients.

Particular linear combinations of analysis and synthesis filter coefficients occur at different points in time for different input impulses. The idea is to make **A**, **S**, and **B** such that they describe completely all M transfer functions that comprise the periodically time-varying system.

The matrix **A** is a matrix of filter coefficients and zeros that effectively describe the decimated convolution operations inherent in the filter bank. For convenience, we express the analysis coefficients as a matrix **h**, where

$$\mathbf{h} = \begin{bmatrix} h_0[0] & h_1[0] & \cdots & h_{M-1}[0] \\ h_0[1] & h_1[1] & \cdots & h_{M-1}[1] \\ \vdots & \vdots & & \vdots \\ h_0[N-1] & h_1[N-1] & \cdots & h_{M-1}[N-1] \end{bmatrix}.$$

The zeros are represented by an $M \times M$ matrix of zeros, denoted **O_M**. With these terms, we can write the $(2N - M) \times N$ matrix **A**,

$$\mathbf{A} = \begin{bmatrix} \begin{bmatrix} \mathbf{h}[n] \\ \mathbf{O}_M \end{bmatrix} & \begin{bmatrix} \mathbf{O}_M \\ \mathbf{h}[n] \end{bmatrix} & \cdots & \begin{bmatrix} \mathbf{O}_M \\ \vdots \\ \mathbf{O}_M \end{bmatrix} \\ \vdots & \vdots & \cdots & \vdots \\ \mathbf{O}_M & \mathbf{O}_M & \cdots & \begin{bmatrix} \mathbf{h}[n] \end{bmatrix} \end{bmatrix}.$$

The synthesis filters **S** can be expressed most conveniently in terms of the $M \times M$ matrix

$$\mathbf{Q}_i = \begin{bmatrix} g_0[i] & g_0[i+1] & \cdots & g_0[i+M-1] \\ g_1[i] & g_1[i+1] & \cdots & g_1[i+M-1] \\ \vdots & \vdots & & \vdots \\ g_{M-1}[i] & g_{M-1}[i+1] & \cdots & g_{M-1}[i+M-1] \end{bmatrix},$$

where $i = 0, 1, \dots, L-1$ and N is assumed to be equal to LM . The synthesis matrix **S** is then given by

$$\mathbf{S} = \begin{bmatrix} \mathbf{Q}_0 \\ \mathbf{Q}_M \\ \vdots \\ \mathbf{Q}_{iM} \\ \vdots \\ \mathbf{Q}_{(L-1)M} \end{bmatrix}.$$

Finally, to achieve exact reconstruction we want the impulse responses associated with each of the M constituent transfer functions in the periodically time-varying system to be an impulse. Therefore, **B** is a matrix of zero-element column vectors, each with a single “one” at the location of the particular transfer function group delay. More specifically, the matrix has the form

$$\mathbf{B} = \begin{bmatrix} \mathbf{O}_M \\ \mathbf{O}_M \\ \vdots \\ \mathbf{J}_M \\ \vdots \\ \mathbf{O}_M \\ \mathbf{O}_M \end{bmatrix}$$

where \mathbf{J}_M is the $M \times M$ antidiagonal identity matrix

$$\mathbf{J}_M = \begin{bmatrix} 0 & \cdots & 0 & 1 \\ 0 & \cdots & 1 & 0 \\ \vdots & & \vdots & \vdots \\ 1 & \cdots & 0 & 0 \end{bmatrix}.$$

It is important to mention here that the location of \mathbf{J}_M within the matrix \mathbf{B} is a system design issue. The case shown here, where it is centered within \mathbf{B} , corresponds to an overall system delay of $N - 1$. This is the natural case for systems with N -tap filters. There are many fine points associated with these time domain conditions. For a complete discussion, the reader is referred to [3].

With the reconstruction equations in place, we now turn our attention to the design of the filters. The problem here is that this is an over-constrained system. The matrix \mathbf{A} is of size $(2N - M) \times N$. If we think of the synthesis filter coefficients as the parameters to be solved for, we find $M(2N - M)$ equations and MN unknowns. Clearly, the best we can hope for is to determine \mathbf{B} in an approximate sense. Using least-squares approximation, we let

$$\mathbf{S} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{B}.$$

Here, it is assumed that $(\mathbf{A}^T \mathbf{A})^{-1}$ exists. This is not automatically the case. However, if reasonable lowpass and highpass filters are used as an initial starting point, there is rarely a problem.

This solution gives the best synthesis filter set for a particular analysis set and system delay $N - 1$. The resulting matrix $\mathbf{AS} = \hat{\mathbf{B}}$ will be close to \mathbf{B} but not equal to it in general. The next step in the design is to allow the analysis filter coefficients to vary in an optimization routine to reduce the Frobenius matrix norm, $\|\hat{\mathbf{B}} - \mathbf{B}\|_F^2$. The locally optimal solution will be,

$$\mathbf{S} = (\mathbf{A}^T \mathbf{A})^{-1} \mathbf{B}, \text{ such that } \|\hat{\mathbf{B}} - \mathbf{B}\|_F^2 \text{ is minimized.}$$

Any number of routines may be used to find this minimum. A simple gradient search that updates the analysis filter coefficients will suffice in most cases. Note that, as written, there are no constraints on the analysis filters other than that they provide an invertible $\mathbf{A}^T \mathbf{A}$ matrix. One can easily start imposing constraints relevant to system quality. Most often we find it appropriate to include constraints on the frequency domain characteristics of the individual analysis filters. This can be done conveniently by creating a cost function comprised of the passband and stopband filter errors. For example, in the two-band case, inclusion of such filter frequency constraints gives rise to the overall error function

$$\epsilon = \|\hat{\mathbf{B}} - \mathbf{B}\|_F^2 + \int_0^{\pi_p} |1 - H_1(e^{j\omega})|^2 d\omega + \int_{\pi_s}^{\pi} |H_0(e^{j\omega})|^2 d\omega.$$

This reduces the overall system error of the filter bank while at the same time reducing the stopband errors in analysis filters. Other options in constructing the error function can address control over the step response of the filters, the width of the transition bands, and whether an l_2 norm or an l_∞ norm is used as an optimality criterion.

By properly weighting the reconstruction and frequency response terms in the error function, exact reconstruction can be obtained, if such a solution exists. If an exact reconstruction solution does not exist, the design algorithm will find the locally optimal solution subject to the specified constraints.

Functionality of the Design Formulation

One of the distinct advantages of the time-domain design method is its flexibility. The discussion above assumed that the system delay was $N - 1$ where N is the filter length. For the time-domain formulation, the amount of overall system delay can be thought of as an input to the design algorithm. In other words, one can pre-specify the desired system delay and then find the locally optimal set of analysis and synthesis filters that reduce the cost function while maintaining the specified delay. Control over the system delay is given by the position of \mathbf{J}_M in the matrix \mathbf{B} . Placing \mathbf{J}_M at or near the top of \mathbf{B} lowers the system delay while positioning it at or near the bottom increases the system delay. One consideration here is the effect on filter bank quality. Experiments have shown that as the delay moves toward the extremes, the impact of the overconstrained equations is more severe. One is forced to either tolerate poorer frequency response characteristics or perhaps allow a little distortion in the reconstruction.

The cost function allows for an infinite variety of systems to be designed. The algorithm will converge to a filter set that optimizes the cost function as it is given. This provides the freedom to tradeoff among reconstruction error, frequency domain characteristics, and time domain characteristics. To aid in finding a particular locally optimal solution, the cost function can be allowed to be “adaptive”. If exact reconstruction is desired, a heavy weighting may be placed on the reconstruction term in the cost function initially, until that term goes to zero. Then the cost function can be adjusted with new weightings that address reducing the error associated with the remaining distortion components.

This time domain formulation has been used to design an unprecedented variety of filter banks, including the first block decimation systems, the first time-varying systems, the first low delay systems, cosine modulated filter banks, nonuniform band filter banks, and many others [3, 4, 9, 10, 11]. One of the most important in this list is cosine modulated filter banks because they can be implemented very efficiently by using FFT-class algorithms. Cosine modulated filter banks may be designed in a variety of ways. Excellent discussions on this topic are given by Malvar [20, 24], Vaidyanathan [21, 27], Vetterli [23], and many others.

Linear filter banks have proven to be effective in many applications. Perhaps their most widespread use is in the area of coding. Subband coders for speech audio, image, and video signals tend to work very well. However, at low bit rates, distortions can be detected. Thus, there is interest in designing filter banks that are less prone to producing annoying distortions in these cases. Other nonlinear classes of filter banks can be considered that display different forms of distortion at low bit rates. In the remainder of this chapter, we discuss the design of two nonlinear filter banks that are presently being studied.

36.2 Finite Field Filter Banks

A new and interesting variant of the classical analysis-synthesis system can be achieved by imposing the explicit constraint that the discrete amplitude range of the subbands is confined. For conventional filter banks, we assume the input signal has a finite number of amplitude values. For instance, in the case of subband image coding, the input will typically contain 8 bits or 256 amplitude levels. However, the subband outputs may contain millions of possible amplitude values. For a coding application, we can think of the input as having a small alphabet (e.g., 256 unique values), and the analysis filter output as having a large alphabet (millions). Conceivably, one might be able to improve coding performance in some situations by designing a filter bank that constrains the output alphabet to be small. With this as motivation, we consider the problem of designing exact reconstruction filter banks with this constraint, an idea originally introduced by Vaidyanathan [37].

To begin our discussion, consider an input image with an alphabet size N (e.g., 256 gray levels). The output is expanded to an alphabet size of $M \times N$ after subband filtering. The value of M is governed by the length and coefficient values of the filter. M can be very large. The design task of

interest here is to construct a filter bank where M is very small, ideally unity. In other words, we are constraining the system to operate in a finite field of our choosing, e.g., $\text{GF}(N)$. In order to meet this finite field condition, an operational change is needed. Specifically, the finite field filter bank should operate in an integer field. Consequently, the filters used should be perfect reconstruction filters with integer coefficients. This modification makes it possible to perform wrap-around arithmetic. Wrap-around arithmetic restricts outputs to a finite field by performing all operation modulo N .

The design of a finite field filter bank is relatively simple. The image is passed through analysis filters using wrap-around arithmetic. This means that every operation is either modulo- N addition or modulo- N multiplication. Hence, the subband outputs will have an integer alphabet of size N . To reconstruct, the image is passed through the synthesis filters using the same wrap-around arithmetic within the same finite integer field. The bands are then combined using modulo- N addition. As it turns out, the resulting signal will not match the original. However, the signal can be corrected by applying a mapping based on the gain of the filter banks, M , and the dynamic range, N . Let us assume that the input is an image with N' discrete levels, and that all operations have been performed modulo N . Each value of the output image is found in set \mathbf{B} and can be mapped into set \mathbf{A} , where

$$\mathbf{A} = \{0, 1, 2, \dots, N' - 1\} \quad \mathbf{B} = ((M \times \mathbf{A}))_N.$$

The resulting output image \hat{x} will be, under certain conditions, an exact reconstruction of the input image x .

There are two conditions that must be satisfied in order to obtain exact reconstruction. First, the subband output alphabet size N must be equal to or greater than the input alphabet size N' . This is a necessary condition in order to unambiguously resolve all values of the input. Second, the system gain M is constrained in relation to the subband output size N . The system gain is governed by the analysis and synthesis filters in the following way:

$$M = \left(\sum_n |h_0[n]| \times \sum_n |g_0[n]| \right) + \left(\sum_n |h_1[n]| \times \sum_n |g_1[n]| \right)$$

where $h_0[n]$ and $h_1[n]$ are the analysis filters and $g_0[n]$ and $g_1[n]$ are the synthesis filters. The relation between M and N is crucial in obtaining perfect reconstruction. These two numbers must be relatively prime. That is, M and N can have no common factors. For example, if M is two, any odd value of N would be valid. Ideally, we might want $N = N'$. However, to satisfy the last condition M is determined by the system and N is adjusted slightly up from N' . It is typically easier to adjust N .

To illustrate the differences in outputs obtained from conventional and finite field filter banks, consider the following comparison. For a conventional two-band system with two-tap Haar analysis filters, an input of

$$x = 0, 0, 0, 4, 2, 3, 0, 1, 2, 0, 0, \dots$$

will yield the outputs

$$\begin{aligned} y_0 &= 0, 4, 5, 1, 2, \dots \\ y_1 &= 0, 4, 1, 1, -2, \dots \end{aligned}$$

However, for the equivalent finite field system (like the one shown in Fig. 36.5), the outputs are noticeably different. For the finite field case, all operations are performed modulo N . Thus, for the same input the outputs produced are

$$\begin{aligned} y_0 &= 0, 4, 0, 1, 2, \dots \\ y_1 &= 0, 4, 1, 1, 3, \dots \end{aligned}$$

FIGURE 36.5: Block diagram of a two-band finite field filter bank.

Notice that the alphabet here is confined to the integers 0, 1, 2, 3, 4 because we have set $N = 5$. For the reconstruction, the outputs shown in the figure will be

$$\begin{aligned}\hat{x}_0 &= 0, 4, 4, 0, 0, 1, 1, 2, 2, \dots \\ \hat{x}_1 &= 0, 1, 4, 4, 1, 4, 1, 2, 3, \dots\end{aligned}$$

Adding these together, modulo N gives

$$\hat{x}_p = 0, 0, 3, 4, 1, 0, 2, 4, 0, \dots$$

Now unscrambling them in the post-mapping step shown in the figure gives

$$\hat{x} = 0, 0, 4, 2, 3, 0, 1, 2, 0, \dots = x.$$

It is interesting to compare the analysis section outputs of finite field and conventional filter banks for the two-band case. The lower band output of a conventional filter bank has a dynamic range that is usually much greater than the dynamic range of the input. The values in the lower band tend to have a Gaussian distribution over the range. By constraining the alphabet size, the first-order entropy can be reduced. The amount of the reduction depends on the size of M . The higher band in the conventional filter bank has a dynamic range that might be larger than N ; however, the values are clustered around zero. When modulo operations are performed, the negative values go to a high value so not much overlap is obtained. Therefore, the alphabet constraint has little or no effect on the higher bands. The finite field filter bank reduces the overall first-order entropy because the entropy is reduced in the lower band. The degree by which the entropy is reduced is greatly dependent on the image and the filter gains.

How do finite field filter banks affect input images with different dynamic ranges? This effect is dependent on the same two components that have previously been discussed, the system gain M , and the subband output size N . Let us assume the subband output range N is set equal to the input image range N' . Now we can examine the effects of different system gains given N . For example, if the image is binary ($N = 2$), the system gain must be odd. Examining the decomposition of such an image, we can see that it appears very noisy. This is because the dynamic range of the system is small and the gain is large. The image is essentially wrapping around on itself so many times it is difficult to observe the original image in the bands. In a case where $N > 2$, a filter with a smaller gain is more realizable. For example, if $N = 255$, we can choose a system gain of 2. In this decomposition (Fig. 36.6), the lower band image is not what we are accustomed to observing in a conventional decomposition. This case does have a lower first-order entropy than its conventional counterpart.

FIGURE 36.6: A four-level octave band decomposition using finite field filter banks.

Finite field filter banks are still in their early phases of study. As a result of the constraints, filter quality is limited. Thus, the net gains achievable in an application could be favorable or unfavorable. One must pay careful attention to the subband output size, filter length, and coefficient values during the design of the filter bank. Nonetheless, it seems that finite field filter banks are potentially attractive in some applications.

36.3 Nonlinear Filter Banks

One of the driving forces for research in filter banks is image coding for low bit rate applications. Presently, subband image coders represent the best approach known for image compression. As with any coder, at low rates distortions occur. Subband coders based on conventional linear filter banks suffer from ringing effects due to the Gibbs phenomenon. These ringing effects occur around edges or high contrast regions. One way to eliminate ringing is to use nonlinear filter banks. There are pros and cons regarding the utility of nonlinear filter banks. However, the design of the systems is rather new and interesting.

Nonlinear filter banks can be constructed within a general two-band framework. A nonlinear filter may be placed in the highpass analysis and in the lowpass synthesis block of the systems. The condition for exact reconstruction will be discussed later. What type of nonlinear filter is an open question. While there are many candidates, the constraints of the overall system restrict the design of filters in terms of type and degrees of freedom in optimization. The most widely used nonlinear filter is the rank-order filter. In this discussion, we consider rank-order filters, more specifically, median filters. The performance of such filters is determined by the rank used and the region of support. The popular N -point median filter has a rank of $(N + 1)/2$, where N is assumed to be odd. Egger et al. [31] suggested a simple two-band nonlinear filter bank that upholds the exact reconstruction property. The lowpass channel consists of direct downsampling, while the highpass channel involves

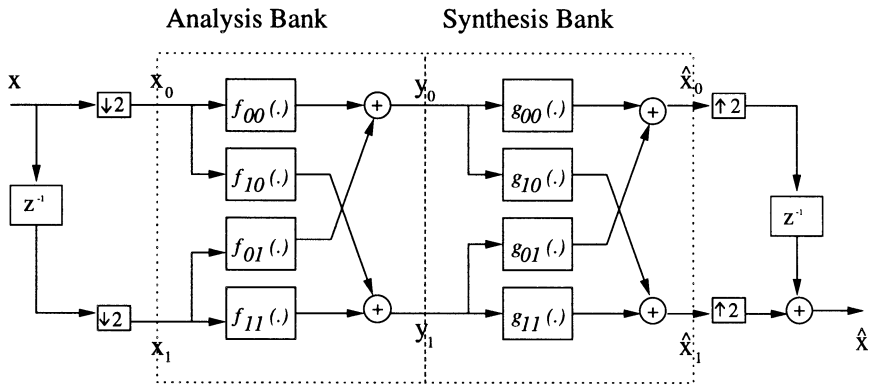

FIGURE 36.7: A two-band polyphase nonlinear filter bank.

a median filter (differencing) operation to achieve a highpass representation for the other channel. Because straight downsampling and median filtering are involve, there is an inherent finite field constraining property built in to the system. Although these features seem attractive, the system is severely limited by its lack of filtering power. Most notably, the lowpass channel has massive aliasing since no filtering is performed. For many applications, aliasing of this type is not desirable. This problem can be addressed somewhat by using the modified filter bank introduced by Florencio and Schafer [32]. In the two-band system of Florencio and Schafer shown in Fig. 36.7, each channel can be expressed as a filtered combination of the input. This structure can be recognized as a classical polyphase implementation for a two-band filter bank. Here, however, we allow the polyphase filters f_{ij} and g_{ij} to be nonlinear filters. Thus,

$$\begin{aligned} y_0[n] &= f_{00}(x_0[n]) + f_{01}(x_1[n]) \\ y_1[n] &= f_{10}(x_0[n]) + f_{11}(x_1[n]) \end{aligned}$$

where $f_{ij}(\cdot)$ are the linear or nonlinear polyphase analysis filters. To reconstruct the signal, the output can be expressed as a filtered combination of the channels,

$$\hat{x}_0 = g_{00}(y_0) + g_{01}(y_1) \quad \hat{x}_1 = g_{10}(y_0) + g_{11}(y_1)$$

where $g_{ij}(\cdot)$ are the linear or nonlinear polyphase synthesis filters. The perfect reconstruction conditions are based on these different classes or structures. The Type I structure consists of $f_{00}(\cdot) = f_{11}(\cdot) = I$ (identity), and either $f_{10}(\cdot) = 0$ or $f_{01}(\cdot) = 0$. The other is any causal transformation. To obtain perfect reconstruction, $g_{00}(\cdot) = g_{11}(\cdot) = I$, $g_{10}(\cdot) = f_{10}(\cdot)$, and $g_{01}(\cdot) = -f_{01}(\cdot)$. The Type II structure consists of $f_{10}(\cdot) = f_{01}(\cdot) = 0$ and both $f_{00}(\cdot)$ and $f_{11}(\cdot)$ being invertible functions. To obtain perfect reconstruction $g_{01}(\cdot) = g_{10}(\cdot) = 0$, $g_{00}(\cdot) = f_{00}^{-1}(\cdot)$, and $g_{11}(\cdot) = f_{11}^{-1}(\cdot)$. The Type III structure consists of $f_{10}(\cdot) = f_{01}(\cdot) = I$ and $f_{00}(\cdot) = f_{11}(\cdot) = 0$. To obtain perfect reconstruction, $g_{01}(\cdot) = g_{10}(\cdot) = I$ and $g_{00}(\cdot) = g_{11}(\cdot) = 0$.

Similar to linear filter banks, this nonlinear filter bank achieves an overall reduction in first-order entropy. Since perfect reconstruction is achieved in the two-band decomposition, perfect reconstruction can be maintained when used in tree structured systems for compression applications. After quantization, coding, and reconstruction, different features will be affected in different ways. The main advantage of nonlinear filtering is that the edges associated with high contrast features are preserved well, and no “ringing” occurs. However, because of the nature of the sampling in the lower band, texture regions are distorted. Using cascaded sections is a way to help preserve the texture. As it turns out, sections can be cascaded in a way that preserves exact reconstruction. For

FIGURE 36.8: Comparison of outputs from one linear and three nonlinear filter banks. (a) A four-band linear decomposition using four-tap QMFs. (b) A four-band nonlinear decomposition using the method of Egger and Li. (c) A four-band nonlinear decomposition using the two-stage method of Florencio and Schafer. (d) The residual image obtained from subtracting the nonlinear decomposition result in (b) from the result in (c).

example, let the first stage of the filter contain $f_{01}(\cdot) = 0$, with $f_{10}(\cdot)$ being a four-point median filter. Let the second stage be defined by $f_{10}(\cdot) = 0$ with $f_{01}(\cdot)$ being a four-point median filter with a 0.5 gain (to maintain the dynamic range of the input). The resulting two bands are similar to the bands of the comparable linear case but have the advantages of a nonlinear system. Most notably, the lower band of the nonlinear case has a reduction in higher frequencies, very similar to the linear case. These differences are illustrated in Fig. 36.8 for a four-band decomposition of an image. A conventional QMF decomposition is shown in (a). Next to it in (b) and (c) are the nonlinear decompositions obtained using the Egger and Li approach, and the two-stage approach of Florencio and Schafer, respectively. All show similarities. However, more energy is contained in the high frequency subbands of the nonlinear results. In comparing carefully the two nonlinear results, we can observe that the two-stage approach of Florencio and Schafer has less aliasing in the lowest band and more closely follows the linear result. The difference image between the two nonlinear results is given in (d).

It is clear that there are many possibilities for constructing nonlinear filter banks. What is less obvious at this point is the impact of these systems in practical situations. Given that development related to these filter banks is only in the formative stages, only time will tell. Regardless of whether conventional or nonlinear filter banks are ultimately employed, the variety of design options and design techniques offer many useful solutions to engineering problems. More in-depth discussions on applications can be found in the references.

37.1 Introduction

Time-frequency representations (TFR) combine the time-domain and frequency-domain representations into a single framework to obtain the notion of time-frequency. TFR offer the time localization vs. frequency localization tradeoff between two extreme cases of time-domain and frequency-domain representations. The short-time Fourier transform (STFT) [1, 2, 3, 4, 5] and the Gabor transform [6] are the classical examples of linear time-frequency transforms which use time-shifted and frequency-shifted basis functions.

In conventional time-frequency transforms, the underlying basis functions are fixed in time and define a specific tiling of the time-frequency plane. The term *time-frequency tile* of a particular basis function is meant to designate the region in the plane that contains most of that function's energy. The short-time Fourier transform and the wavelet transform are just two of many possible tilings of the time-frequency plane. These two are illustrated in Fig. 37.1(a) and (b), respectively. In these figures, the rectangular representation for a tile is purely symbolic, since no function can have compact support in both time and frequency. Other arbitrary tilings of the time-frequency plane are possible such as the example shown in Fig. 37.1(c). In the discrete domain, linear time-frequency transforms can be implemented in the form of filter bank structures.

It is well known that the time-frequency energy distribution of signals often changes with time. Thus, in this sense, the conventional linear time-frequency transform paradigm is fundamentally mismatched to many signals of interest. A more flexible and accurate approach is obtained if the basis functions of the transform are allowed to adapt to the signal properties. An example of such a time-varying tiling is shown in Figure 37.1(d). In this scenario, the time-frequency tiling of the transform can be changed from good frequency localization to good time localization and vice versa. Time-varying filter banks provide such flexible and adaptive time-frequency tilings.

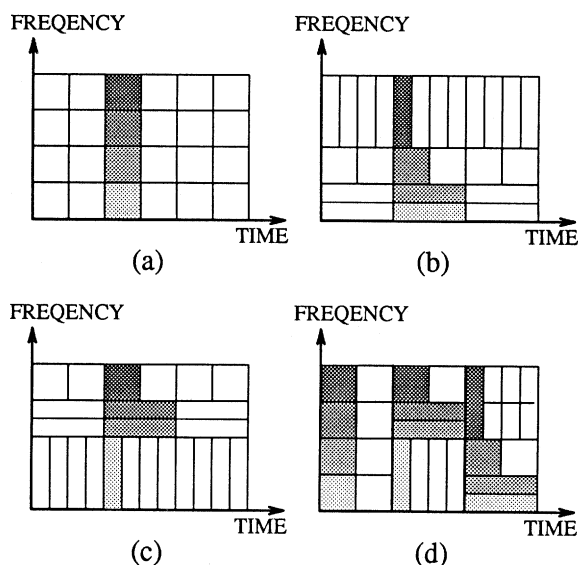

FIGURE 37.1: The time-frequency tiling for different time-frequency transforms: (a) The STFT, (b) the wavelet transform, (c) an example of general tiling, and (d) an example of the time-varying tiling.

The concept of time varying (or adaptive) filter banks was originally introduced in [7] by Nayebi et al. The ideas underlying their method were later developed and extended to a more general case in which it was also shown that the number of frequency bands could also be made adaptive [8, 9, 10, 11]. De Queiroz and Rao [12] reported time-varying extended lapped transforms and Herley et al. [13, 14, 15] introduced another time-domain approach for designing time-varying lossless filter banks. Arrowood and Smith [16] demonstrated a method for switching between filter banks using lattice structures. In [17], the authors presented yet another formulation for designing time-varying filter banks using a different factorization of the paraunitary transform. Chen and Vaidyanathan [18] reported a noncausal approach to time-varying filter banks by using time-reversed filters. Phoong and Vaidyanathan [19] studied time-varying paraunitary filter banks using polyphase approach. In [11, 20, 21, 22], the post filtering technique for designing time-varying filter bank was reported. The design of multidimensional time-varying filter bank was addressed in [23, 24]. In this article, we introduce the notion of the time-varying filter banks and briefly discuss some design methods.

37.2 Analysis of Time-Varying Filter Banks

Time-varying filter banks are analysis-synthesis systems in which the analysis filters, the synthesis filters, the number of bands, the decimation rates, and the frequency coverage of the bands are changed (in part or in total) in time, as is shown in Fig. 37.2. By carefully adapting the analysis section to the temporal properties of the input signal, better performance can be achieved in processing the signal. In the absence of processing errors, the reconstructed output $\hat{x}(n)$ should closely approximate a delayed version of the original signal $x(n)$. When $\hat{x}(n - \Delta) = x(n)$ for some integer constant, Δ , then we say that the filter bank is perfectly reconstructing (PR). The intent of the design is to choose the time-varying analysis and synthesis filters along with the time-varying down/up samplers so that the system requirements are met subject to the constraint that the analysis-synthesis filter bank be PR at all times.

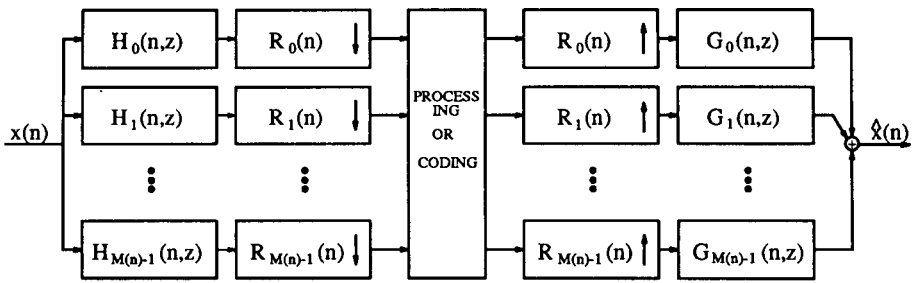

FIGURE 37.2: The time-varying filter bank structure with time-varying filters and time-dependent down/up samplers.

One general method for analysis of time-varying filter banks is the time-domain formulation reported in [10, 22]. In this method, the time-varying impulse response of the entire filter bank is derived in terms of the analysis and synthesis filter coefficients.

Figure (37.3) shows the diagram of a time-varying filter bank. In this figure, the filter bank is divided into three stages: the analysis filters, the down/up samplers, and the synthesis filters. The signals $x(n)$ and $\hat{x}(n)$ are the filter bank input and output at time n , respectively. The outputs of the analysis filters are shown by $\mathbf{v}(n) = [v_0(n), v_1(n), \dots, v_{M(n)-1}(n)]^T$, where $v_i(n)$ is the output of the i th analysis filter at time n . The outputs of the down/up samplers at time n is called $\mathbf{w}(n) = [w_0(n), w_1(n), \dots, w_{M(n)-1}(n)]^T$.

FIGURE 37.3: Time-varying filter bank as a cascade of analysis filters, down/up samplers, and synthesis filters.

The input/output relation of the analysis filters can be expressed by

$$\mathbf{v}(n) = \mathbf{P}(n)\mathbf{x}_N(n) . \quad (37.1)$$

$\mathbf{P}(n)$ is an $M(n) \times N(n)$ matrix whose m th row is comprised of the coefficients of the m th analysis filter at time n and $\mathbf{x}_N(n)$ is the input vector of length $N(n)$ at time n :

$$\mathbf{x}_N(n) = [x(n), x(n-1), x(n-2), \dots, x(n-N(n)+1)]^T . \quad (37.2)$$

The input/output function of down/up samplers can be expressed in the form

$$\mathbf{w}(n) = \Lambda(n)\mathbf{v}(n) \quad (37.3)$$

where $\Lambda(n)$ is a diagonal matrix of size $M(n) \times M(n)$. The m th diagonal element of $\Lambda(n)$, at time n , is 1 if the input and output of the m th down/up sampler are identical, otherwise it is zero.

To write the input/output relationship of the synthesis filters, $\mathbf{Q}(n)$ is defined as

$$\begin{aligned}\mathbf{Q}(n) &= \begin{bmatrix} g_0(n, 0) & g_0(n, 1) & g_0(n, 2) & \dots & g_0(n, N(n) - 1) \\ g_1(n, 0) & g_1(n, 1) & g_1(n, 2) & \dots & g_1(n, N(n) - 1) \\ g_2(n, 0) & g_2(n, 1) & g_2(n, 2) & \dots & g_2(n, N(n) - 1) \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ g_{M(n)-1}(n, 0) & g_{M(n)-1}(n, 1) & g_{M(n)-1}(n, 2) & \dots & g_{M(n)-1}(n, N(n) - 1) \end{bmatrix} \\ &= [\mathbf{q}_0(n) \quad \mathbf{q}_1(n) \quad \mathbf{q}_2(n) \quad \dots \quad \mathbf{q}_{N(n)-1}(n)]\end{aligned}\quad (37.4)$$

where $\mathbf{q}_i(n) = [g_0(n, i), g_1(n, i), g_2(n, i), \dots, g_{M(n)-1}(n, i)]^T$, is a vector of length $M(n)$ and $g_i(n, j)$ denotes the j th coefficient of the i th synthesis filter. At time n , the m th synthesis filter is convolved with vector $[w_m(n), w_m(n-1), \dots, w_m(n-N(n)+1)]^T$ and all outputs are added together. Using Eq. (37.4), the output of the filter bank at time n can be written as:

$$\hat{x}(n) = \sum_{i=0}^{N(n)-1} \mathbf{q}_i^T(n) \mathbf{w}(n-i). \quad (37.5)$$

If $\mathbf{s}(n)$ and $\hat{\mathbf{w}}(n)$ are defined as

$$\mathbf{s}(n) = [\mathbf{q}_0^T(n), \mathbf{q}_1^T(n), \mathbf{q}_2^T, \dots, \mathbf{q}_{N(n)-1}^T(n)]^T \quad (37.6)$$

$$\hat{\mathbf{w}}(n) = [\mathbf{w}^T(n), \mathbf{w}^T(n-1), \mathbf{w}^T(n-2), \dots, \mathbf{w}^T(n-N(n)+1)]^T, \quad (37.7)$$

then Eq. (37.5) can be written in the form of one inner product,

$$\hat{x}(n) = \mathbf{s}^T(n) \hat{\mathbf{w}}(n) \quad (37.8)$$

where $\mathbf{s}(n)$ and $\hat{\mathbf{w}}(n)$ are vectors of length $N(n)M(n)$. Using Eqs. (37.1), (37.3), (37.7), and (37.8), the input/output function of the filter bank can be written as:

$$\hat{x}(n) = \mathbf{s}^T(n) \begin{bmatrix} \Lambda(n) \mathbf{P}(n) \mathbf{x}_N(n) \\ \Lambda(n-1) \mathbf{P}(n-1) \mathbf{x}_N(n-1) \\ \Lambda(n-2) \mathbf{P}(n-2) \mathbf{x}_N(n-2) \\ \vdots \\ \Lambda(n-N(n)+1) \mathbf{P}(n-N(n)+1) \mathbf{x}_N(n-N(n)+1) \end{bmatrix}. \quad (37.9)$$

As the last $N(n)-1$ elements of vector $\mathbf{x}_N(n-i)$ are identical to the first $N(n)-1$ elements of vector $\mathbf{x}_N(n-i-1)$, the latter equation can be expressed by

$$\begin{aligned}\hat{x}(n) &= \mathbf{s}^T(n) \begin{bmatrix} \begin{bmatrix} \Lambda(n) \mathbf{P}(n) & \mathbf{0} \dots \dots \mathbf{0} \\ \mathbf{0} \begin{bmatrix} \Lambda(n-1) \mathbf{P}(n-1) & \mathbf{0} \dots \dots \mathbf{0} \\ \Lambda(n-2) \mathbf{P}(n-2) & \mathbf{0} \dots \dots \mathbf{0} \end{bmatrix} \\ \vdots \\ \mathbf{0} \dots \dots \mathbf{0} \begin{bmatrix} \Lambda(n-N(n)+1) \mathbf{P}(n-N(n)+1) \end{bmatrix} \end{bmatrix} \\ \begin{bmatrix} x(n) \\ x(n-1) \\ x(n-2) \\ \vdots \\ x(n-2N(n)+1) \end{bmatrix} \end{bmatrix}\end{aligned}\quad (37.10)$$

where \mathbf{O} is the zero column vector with length $M(n)$. Thus, the input/output function of a time-varying filter bank can be expressed in the form of

$$\hat{x}(n) = \mathbf{z}^T(n) \mathbf{x}_I(n) \quad (37.11)$$

where $\mathbf{x}_I(n) = [x(n), x(n-1), \dots, x(n-I+1)]^T$ and $I(n) = 2N(n) - 1$ and $\mathbf{z}(n)$ is the time-varying impulse response vector of the filter bank at time n :

$$\mathbf{z}(n) = \mathbf{A}(n) \mathbf{s}(n). \quad (37.12)$$

The matrix $\mathbf{A}(n)$ is the $[2N(n) - 1] \times [N(n) M(n)]$ matrix

$$\mathbf{A}(n) = \begin{bmatrix} \begin{bmatrix} \mathbf{P}(n)^T \Lambda(n) \\ \mathbf{O}^T \\ \mathbf{O}^T \\ \vdots \\ \mathbf{O}^T \end{bmatrix} & \begin{bmatrix} \mathbf{O}^T \\ \mathbf{P}(n-1)^T \Lambda(n-1) \\ \mathbf{O}^T \\ \vdots \\ \mathbf{O}^T \end{bmatrix} & \ddots & \begin{bmatrix} \mathbf{O}^T \\ \vdots \\ \mathbf{O}^T \\ \mathbf{P}(n-N(n)+1)^T \Lambda(n-N(n)+1) \end{bmatrix} \end{bmatrix}. \quad (37.13)$$

For a perfect reconstruction filter bank with a delay of Δ , it is necessary and sufficient that all elements but the $(\Delta + 1)$ th in $\mathbf{z}(n)$ be equal to zero at all times. The $(\Delta + 1)$ th entry of $\mathbf{z}(n)$ must be equal to one. If the ideal impulse response is $\mathbf{b}(n)$, the filter bank is PR if and only if

$$\mathbf{A}(n) \mathbf{s}(n) = \mathbf{b}(n) \quad \text{for all } n. \quad (37.14)$$

37.3 Direct Switching of Filter Banks

Changing from one arbitrary filter bank to another independently designed filter bank without using any intermediate filters is called *direct switching*. Direct switching is the simplest switching scheme and does not require additional steps in switching between two filter banks. But such switching will result in a substantial amount of reconstruction distortion during the transition period. This is because during the transition, none of the synthesis filters satisfies the exact reconstruction conditions. Figure (37.4) shows an example of a direct switching filter bank. Figure (37.5) shows the time-varying impulse response of the above system around the transition periods. In this figure, $z(n, m)$ is the response of the system at time n to the unit input at time m . For a PR system, $z(n, m)$ has a height of 1 along the diagonal and 0 everywhere else in the (m, n) -plane. As is shown, the time-varying filter bank is PR before and after but not during the transition periods. In this case, each switching operation generates a distortion with an 8-sample duration. One way to reduce the distortion is to switch the synthesis filters with an appropriate delay with respect to the analysis switching time. This delay may reduce the output distortion, but it can not eliminate it.

37.4 Time-Varying Filter Bank Design Techniques

The basic time-varying filter bank design methods are summarized in Table 37.1. These techniques can be divided into two major approaches which are briefly described in the following sections.

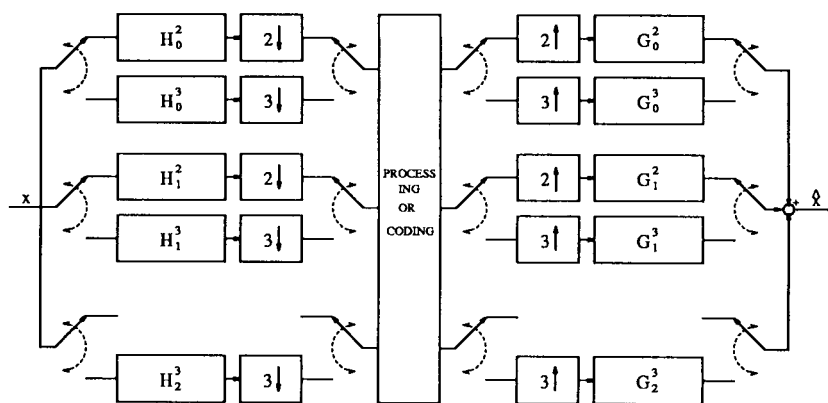

FIGURE 37.4: Block diagram of a time-varying analysis/synthesis filter bank that switches between a two- and three-band decomposition.

TABLE 37.1 Comparison of Time-Varying Filter Bank Different Designing Methods

		Intermediate analysis	Changing freq. resolution	Filter bank requirement	Computational complexity
Intermediate analysis synthesis (IAS)	Arrowood Smith	Yes	Indirect	Lattice structures	Low
	de Queiroz Rao	Yes	Indirect	ELT	Low
	Gopinath Burrus	Yes	Indirect	Paraunitary	Low
	Herley et. al	Yes	Direct	Paraunitary	Low
	Chen Vaidyanathan	Yes	Direct	Noncausal synthesis	Low
Instantaneous transform switching (ITS)	Least square synthesis	No	Direct	General (not PR)	Low
	Redesigning analysis	No	Direct	General	High
	Post filtering	No	Direct	General	Low

37.4.1 Approach I: Intermediate Analysis-Synthesis (IAS)

In the first approach, both analysis and synthesis filters are allowed to change during the transition period to maintain perfect reconstruction. We refer to this approach as the intermediate analysis-synthesis (IAS) approach.

In [16], the authors have chosen to start with the lattice implementation of time-invariant two-band filter banks, originally proposed by Vaidyanathan [25] for time-invariant case. Consider the lattice structure shown in Fig. 37.6. Figure 37.6(a) represents a lossless two-band analysis filter bank, consisting of $J + 1$ lattice stages. The corresponding synthesis filter bank is shown in Fig. 37.6(b). As is shown, for each stage in the analysis filter bank, there exists a corresponding stage in the synthesis filter bank with similar, but inverse functionality. As long as each two corresponding lattice stages in the analysis and synthesis sections are PR, the overall system is PR. To switch one filter bank to another, the lattice stages of the analysis section are changed from one set to another. If the corresponding lattice stages of the synthesis section are also changed according to the changes of the analysis section, the PR property will hold during transition. Due to the existence of delay elements, any change in the analysis section must be followed with the corresponding change in the synthesis section, but with an appropriate delay. For example, the parameter α_j of the analysis and synthesis filter banks can

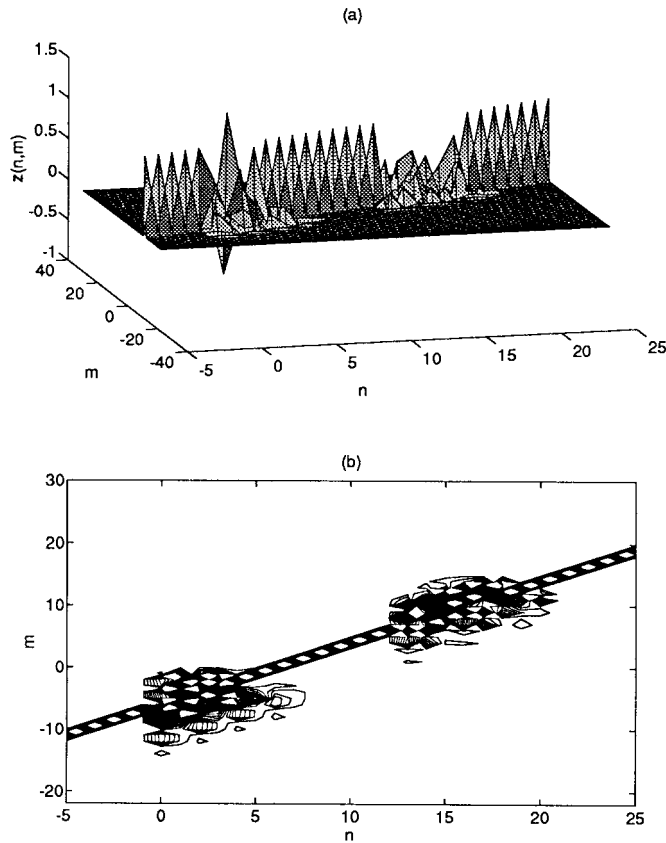

FIGURE 37.5: The time-varying impulse response for direct switching between the two- and the three-band system. The filter bank is switched from the two-band to the three-band at time $n = 0$ and switched back at time $n = 13$. (a) Surface plot, (b) contour plot.

be changed instantaneously. But any change in parameter α_{j-1} in the analysis filter bank must be followed with the similar change in the synthesis filter bank after one sample delay. Because of such delays, switching between two PR filter banks can occur only by going through a transition period in which both analysis and synthesis filter banks are changing in time.

In [12, 26], the design of time-varying extended lapped transform (ELT) [27, 28] was reported. The extended lapped transform is a cosine-modulated filter bank with an additional constraint on the filter lengths. Here, the design procedure is based on factorization of the time-domain transform matrix into permutation and rotation matrices. As the ELT is paraunitary, the inverse transform can be obtained by reversing the order of the matrix multiplication. Since any orthogonal transform is a succession of plane rotations, any changes in these rotation angles result in changing the filter bank without losing the orthogonality property. The authors derived a general frame work for M -band ELT transforms compared to the two-band case approach in [16]. This method parallels the lattice technique [16] except with the mild modification of imposing the additional ELT constraints. In [17], the authors presented yet another formulation for designing time-varying filter banks. In this paper, a different factorization of the paraunitary transform has been shown which is not based on plane rotations unlike the ones in [12, 26]. Using this factorization, a paraunitary filter bank can be implemented in the form of some cascade structures. Again, to switch one filter bank to

FIGURE 37.6: The block diagram of a two-band paraunitary filter bank in lattice form: (a) analysis lattice, (b) synthesis lattice.

another, the corresponding structures in the analysis and synthesis filter bank are changed similarly but with an appropriate delay. If the orthogonality property in each cascade structure is maintained, the time-varying filter bank remains PR. This formulation is very similar to the ones in [12, 16, 26], but represent a more general form of factorization. In fact, all above procedures consider similar frameworks of structures that inherently guarantee the exact reconstruction.

Herley et al. [13, 14, 15, 29] introduced a time-domain method for designing time-varying paraunitary filter banks. In this approach, the time-invariant analysis transforms do not overlap. As a simple example, consider the case of switching between two paraunitary time-invariant filter banks. The analysis transform around the transition period can be written as

$$\mathbf{T} = \begin{bmatrix} \begin{bmatrix} \mathbf{P}_1 \end{bmatrix} \\ \begin{bmatrix} \mathbf{P}_T \end{bmatrix} \\ \begin{bmatrix} \mathbf{P}_2 \end{bmatrix} \end{bmatrix}. \quad (37.15)$$

The matrices \mathbf{P}_1 and \mathbf{P}_2 represent paraunitary transforms and therefore are unitary matrices. Their nonzero columns also do not overlap with each other. The matrix \mathbf{P}_T represents the analysis filter bank during the transition period. In order to find this filter bank, the matrix \mathbf{P}_T is initially replaced with a zero matrix. Then, the null space of the transform \mathbf{T} is found. Any matrix that spans this subspace can be a candidate vector for \mathbf{P}_T . By choosing enough independent vectors of this null space and applying the Gram-Schmidt procedure to them, an orthogonal transform can be selected for \mathbf{P}_T . This method has also been applied to time-varying modulated lapped transforms [24] and two-dimensional time-varying paraunitary filter banks [30].

The basic property of all above procedures is the use of intermediate analysis transforms in the transition period. The characteristics of these analysis transforms are not easy to control and typically the intermediate filters are not well-behaved.

37.4.2 Approach II: Instantaneous Transform Switching (ITS)

In the second approach, the analysis filters are switched instantaneously and time-varying synthesis filters are used in the transition period. We refer to this approach as the instantaneous transform switching (ITS) approach. In the ITS approach, the analysis filter bank may be switched to another set of analysis filters arbitrarily. This means that the basis vectors and the tiling of the time-frequency plane can be changed instantaneously. To achieve PR at each time in the transition period, a new synthesis section is designed to ensure proper reconstruction.

In the least squares (LS) method [10], for any given set of analysis filters, a LS solution of Eq. (37.14) can be used to obtain the “best” synthesis filters of the corresponding system (in $L2$ norm):

$$\mathbf{s}(n)^{LS} = \left(\mathbf{A}(n)^T \mathbf{A}(n) \right)^{-1} \mathbf{A}(n)^T \mathbf{b}(n) \quad (37.16)$$

The advantage of the LS approach is that there is no limitation on the number of analysis filter banks that can be used in the system. The disadvantage of the LS method is that it does not achieve PR. However, experiments have shown that the reconstruction is significantly improved in this method compared to direct switching [10].

In the LS solution, $\mathbf{b}(n)$ is projected onto the column space of $\mathbf{A}(n)$. For PR, the projection error should be zero. Thus, to obtain time-varying PR filter banks, the reconstruction error, $\|\mathbf{A}(n)\mathbf{s}(n) - \mathbf{b}(n)\|^2$, can be brought to zero with an optimization procedure. The optimization operates on the analysis filter coefficients and modifies the range space of $\mathbf{A}(n)$ until $\mathbf{b}(n) \in \text{range}(\mathbf{A}(n))$. Although the $\mathbf{s}(n)$'s at different states are independent of each other, since the $\mathbf{A}(n)$'s have some common elements, optimization procedures should be applied to all analysis sections at the same time. This method is referred to as “redesigning analysis” [10].

The last ITS method, post filtering, uses conventional filter banks with time-varying coefficients followed by a time-varying post filter. The post filter provides exact reconstruction during transition periods, while it operates as a constant delay elsewhere. Assume at time n_0 the time-varying filter bank is switched from the first filter bank to the second. If the length of the transition period is L samples, the output of the filter bank in the interval $[n_0, n_0 + L - 1]$ is distorted because of switching. The post filter removes this distortion. The block diagram of such a system is shown in Fig. (37.7). In this figure, $\mathbf{z}(n)$ and $\mathbf{y}(n)$ are the analysis/synthesis filter bank and post filter impulse responses,

FIGURE 37.7: The block diagram of time-varying filter bank and post filter.

respectively. If the delays of the filter bank and the post filter are denoted Δ and Θ , respectively, we can write

$$\hat{x}(n) = \begin{cases} \text{Distorted} & \text{if } n_0 \leq n < n_0 + L \\ x(n - \Delta) & \text{otherwise} \end{cases} \quad (37.17)$$

The desired output of the post filter is

$$\tilde{x}(n) = x(n - \Theta - \Delta) \quad (37.18)$$

The input/output relation of the time-varying filter bank during the transition period can be written as

$$\hat{x}(n) = \mathbf{z}^T(n) \mathbf{x}_I(n) \quad (37.19)$$

where $\mathbf{x}_I(n)$ is the input vector at time n :

$$\mathbf{x}_I(n) = [x(n), x(n-1), x(n-2), \dots, x(n-I+1)]^T.$$

$\mathbf{z}(n)$ is a vector of length I and represents the time-varying impulse response of the filter bank at time n . If the transition impulse response matrix is defined to be

$$\mathbf{Z} = \begin{bmatrix} [\mathbf{z}(n_0 + L - 1)] & O & O \\ O & [\mathbf{z}(n_0 + L - 2)] & O \\ O & O & \ddots \\ \vdots & \vdots & \vdots \\ O & O & [\mathbf{z}(n_0)] \end{bmatrix}, \quad (37.20)$$

then the input/output relation of the filter bank in the transition period can be described as

$$\hat{\mathbf{x}}_L(n_0 + L - 1) = \mathbf{Z}^T \mathbf{x}_K(n_0 + L - 1) \quad (37.21)$$

where \mathbf{Z} is a $K \times L$ matrix and $K = I + L - 1$. In Eq. (37.21), the $I - \Delta - 1$ samples before and Δ samples after the transition period are used to evaluate the output. The above intervals are called the tail and head of the transition period, respectively. Since the first and second filter banks are PR, the tail and head samples are exactly reconstructed. We write $\mathbf{x}_K(n_0 + L - 1)$ as the concatenation of three vectors:

$$\mathbf{x}_K(n_0 + L - 1) = \begin{bmatrix} \mathbf{x}_a \\ \mathbf{x}_t \\ \mathbf{x}_b \end{bmatrix}, \quad (37.22)$$

where \mathbf{x}_a and \mathbf{x}_b are the input signals in the head and tail regions while \mathbf{x}_t represents the input samples which are distorted during the transition period. Using this notation, Eq. (37.21) can be written as

$$\hat{\mathbf{x}}_L(n_0 + L - 1) = \mathbf{Z}_a^T \mathbf{x}_a + \mathbf{Z}_t^T \mathbf{x}_t + \mathbf{Z}_b^T \mathbf{x}_b \quad (37.23)$$

where

$$\mathbf{Z} = \begin{bmatrix} \mathbf{Z}_a \\ \mathbf{Z}_t \\ \mathbf{Z}_b \end{bmatrix}. \quad (37.24)$$

By replacing vectors \mathbf{x}_b and \mathbf{x}_a with their corresponding output vectors $\hat{\mathbf{x}}_a$ and $\hat{\mathbf{x}}_b$, \mathbf{x}_t of Eq. (37.23) can be written as

$$\begin{aligned} \mathbf{x}_t &= (\mathbf{Z}_t^T)^{-1} (\hat{\mathbf{x}}_t - \mathbf{Z}_a^T \hat{\mathbf{x}}_a - \mathbf{Z}_b^T \hat{\mathbf{x}}_b) \\ &= \mathbf{Y}^T \hat{\mathbf{x}}_K. \end{aligned} \quad (37.25)$$

Equation (37.25) describes the post filter input-output relationship during the transition region. In this equation, \mathbf{Y} is the time-varying post filter impulse response which is defined as

$$\mathbf{Y} = \begin{bmatrix} -\mathbf{Z}_a \mathbf{Z}_t^{-1} \\ \mathbf{Z}_t^{-1} \\ -\mathbf{Z}_b \mathbf{Z}_t^{-1} \end{bmatrix}. \quad (37.26)$$

From Eq. (37.25), it is obvious that the condition for causal post filtering is

$$\Theta \geq L + \Delta - 1. \quad (37.27)$$

The post filter exists if \mathbf{Z}_t has an inverse. It can be shown that the transition response matrix \mathbf{Z}_t , can be described by a matrix, product of the form

$$\mathbf{Z}_t = \Psi_L \mathbf{S} \quad (37.28)$$

where Ψ_L is the analysis transform applied to those input samples that are distorted during the transition period and \mathbf{S} contains the synthesis filters during the transition period. In order for \mathbf{Z}_t to be invertible, it is necessary (but not sufficient) that Ψ_L and \mathbf{S} be full rank matrices. The analysis sections are defined by the required properties of the first and second filter banks and Ψ_L is fixed. Therefore, a filter bank is switchable to another filter bank if the corresponding Ψ_L is a full rank matrix. In this case, by proper design of the synthesis section, both \mathbf{S} and \mathbf{Z}_t will be full rank. Two methods to obtain proper synthesis filters are shown in [20, 22].

37.5 Conclusion

In this article, we briefly review some analysis and design methods of time-varying filter banks.

Time-varying filter banks can provide a more flexible and accurate approach in which the basis functions of the time-frequency transform are allowed to adapt to the signal properties.

A simple form of time-varying filter bank is achieved by changing the filters of an analysis-synthesis system among a number of choices. Even if all the analysis and synthesis filters are PR sets, exact reconstruction will not normally be achieved during the transition periods. To eliminate all distortion during a transition period, new time-varying analysis and/or synthesis sections are required for the transition periods.

Two different approaches for the design were discussed here. In the first approach, both analysis and synthesis filters are allowed to change during the transition period to maintain PR and so it is called the intermediate analysis-synthesis (IAS) approach. In the second approach, the analysis filters are switched instantaneously and time-varying synthesis filters are used in the transition period. This approach is known as the instantaneous transform switching (ITS) approach.

In the IAS approach, both analysis and synthesis filters can change during the transitions rather than only the synthesis filters in ITS approach. That implies that maintaining PR conditions is easier in the IAS approach. Note that the analysis filters in the transition periods are designed only to satisfy PR conditions and they do not usually meet the desired time and frequency characteristics.

In the ITS approach, only synthesis filters are allowed to be time-varying in the transition periods. These methods have the advantage of providing instantaneous switching between the analysis transforms compared to IAS methods. But they have different drawbacks: the LS method does not satisfy PR conditions at all times, the redesigning analysis method requires jointly optimization of the time-invariant analysis section, and finally the post filtering method has the drawback of additional computational complexity required for post filtering.

The analysis and design methods of the time-varying filter bank have been developed to design adaptive time-frequency transforms. These adaptive transforms have many potential applications in areas such as time-frequency representation, subband image and video coding, and speech and audio coding. But since the developments of the time-varying filter bank theory is very new, its applications have not been investigated yet.

38.1 Introduction

The idea of a lapped transform (LT) maintaining orthogonality and non-expansion of the samples was developed in the early 1980s at MIT by a group of researchers unhappy with the blocking artifacts so common in traditional block transform coding of images. The idea was to extend the basis function beyond the block boundaries, creating an overlap, in order to eliminate the blocking effect. This idea was not new, but the new ingredient to overlapping blocks would be the fact that the number of transform coefficients would be the same as if there was no overlap, and that the transform would maintain orthogonality. Cassereau [1] introduced the lapped orthogonal transform (LOT), and Malvar [5, 6, 7] gave the LOT its design strategy and a fast algorithm. The equivalence between an LOT and a multirate filter bank was later pointed out by Malvar [9]. Based on cosine modulated filter banks [15], modulated lapped transforms were designed [8, 25]. Modulated transforms were generalized for an arbitrary overlap later creating the class of extended lapped transforms (ELT) [10]–[13]. Recently a new class of LTs with symmetric bases was developed yielding the class of generalized LOTs (GenLOT) [17, 19, 20]. As we mentioned, filter banks and LTs are the same, although studied independently in the past. We, however, refer to LTs for paraunitary uniform FIR filter banks with fast implementation algorithms based on special factorizations of the basis functions.

We assume a one-dimensional input sequence $x(n)$ which is transformed into several coefficients $y_i(n)$, where $y_i(n)$ would belong to the i th subband. We also will use the discrete cosine transform [23] and another cosine transform variation, which we abbreviate as DCT and DCT-IV (DCT type 4), respectively [23].

38.2 Orthogonal Block Transforms

In traditional block-transform processing, such as in image and audio coding, the signal is divided into blocks of M samples, and each block is processed independently [2, 3, 12, 14, 22, 23, 24]. Let

the samples in the m th block be denoted as

$$\mathbf{x}_m^T = [x_0(m), x_1(m), \dots, x_{M-1}(m)] , \quad (38.1)$$

for $x_k(m) = x(mM + k)$ and let the corresponding transform vector be

$$\mathbf{y}_m^T = [y_0(m), y_1(m), \dots, y_{M-1}(m)] . \quad (38.2)$$

For a real unitary transform \mathbf{A} , $\mathbf{A}^T = \mathbf{A}^{-1}$. The forward and inverse transforms for the m th block are

$$\mathbf{y}_m = \mathbf{A}\mathbf{x}_m , \quad (38.3)$$

and

$$\mathbf{x}_m = \mathbf{A}^T \mathbf{y}_m . \quad (38.4)$$

The rows of \mathbf{A} , denoted \mathbf{a}_n^T ($0 \leq n \leq M - 1$), are called the basis vectors because they form an orthogonal basis for the M -tuples over the real field [24]. The transform vector coefficients $[y_0(m), y_1(m), \dots, y_{M-1}(m)]$ represent the corresponding weights of vector \mathbf{x}_m with respect to this basis.

If the input signal is represented by vector \mathbf{x} while the subbands are grouped into blocks in vector \mathbf{y} , we can represent the transform \mathbf{T} which operates over the entire signal as a block diagonal matrix:

$$\mathbf{T} = \text{diag} \{ \dots , \mathbf{A}, \mathbf{A}, \mathbf{A}, \dots \} , \quad (38.5)$$

where, of course, \mathbf{T} is an orthogonal matrix.

38.2.1 Orthogonal Lapped Transforms

For lapped transforms [12], the basis vectors can have length L , such that $L > M$, extending across traditional block boundaries. Thus, the transform matrix is no longer square and most of the equations valid for block transforms do not apply to an LT. We will concentrate our efforts on *orthogonal* LTs [12] and consider $L = NM$, where N is the overlap factor. Note that N , M , and hence L are all integers. As in the case of block transforms, we define the transform matrix as containing the orthonormal basis vectors as its rows. A lapped transform matrix \mathbf{P} of dimensions $M \times L$ can be divided into square $M \times M$ submatrices \mathbf{P}_i ($i = 0, 1, \dots, N - 1$) as

$$\mathbf{P} = [\mathbf{P}_0 \ \mathbf{P}_1 \ \dots \ \mathbf{P}_{N-1}] . \quad (38.6)$$

The orthogonality property does not hold because \mathbf{P} is no longer a square matrix and it is replaced by other properties which we will discuss later.

If we divide the signal into blocks, each of size M , we would have vectors \mathbf{x}_m and \mathbf{y}_m such as in 38.1 and 38.2. These blocks are not used by LTs in a straightforward manner. The actual vector which is transformed by the matrix \mathbf{P} has to have L samples and, at block number m , it is composed of the samples of \mathbf{x}_m plus $L - M$ samples. These samples are chosen by picking $(L - M)/2$ samples at each side of the block \mathbf{x}_m , as shown in Fig. 38.1, for $N = 2$. However, the number of transform coefficients at each step is M , and, in this respect, there is no change in the way we represent the transform-domain blocks \mathbf{y}_m .

The input vector of length L is denoted as \mathbf{v}_m , which is centered around the block \mathbf{x}_m , and is defined as

$$\mathbf{v}_m^T = \left[x \left(mM - (N - 1) \frac{M}{2} \right) \cdots x \left(mM + (N + 1) \frac{M}{2} - 1 \right) \right] . \quad (38.7)$$

FIGURE 38.1: The signal samples are divided into blocks of M samples. The lapped transform uses neighboring block samples, as in this example for $N = 2$, i.e., $L = 2M$, yielding an overlap of $(L - M)/2 = M/2$ samples on either side of a block.

Then, we have

$$\mathbf{y}_m = \mathbf{P} \mathbf{v}_m . \quad (38.8)$$

The inverse transform is not direct as in the case of block transforms, i.e., with the knowledge of \mathbf{y}_m we do not know the samples in the support region of \mathbf{v}_m , and neither in the support region of \mathbf{x}_m . We can reconstruct a vector $\hat{\mathbf{v}}_m$ from \mathbf{y}_m , as

$$\hat{\mathbf{v}}_m = \mathbf{P}^T \mathbf{y}_m . \quad (38.9)$$

where $\hat{\mathbf{v}}_m \neq \mathbf{v}_m$. To reconstruct the original sequence, it is necessary to accumulate the results of the vectors $\hat{\mathbf{v}}_m$, in a sense that a particular sample $x(n)$ will be reconstructed from the sum of the contributions it receives from all $\hat{\mathbf{v}}_m$, such that $x(n)$ was included in the region of support of the corresponding \mathbf{v}_m . This additional complication comes from the fact that \mathbf{P} is not a square matrix [12]. However, the whole analysis-synthesis system (applied to the entire input vector) is orthogonal, assuring the PR property using 38.9.

We can also describe the process using a sliding rectangular window applied over the samples of $x(n)$. As an M -sample, block \mathbf{y}_m is computed using \mathbf{v}_m , \mathbf{y}_{m+1} is computed from \mathbf{v}_{m+1} which is obtained by shifting the window to the right by M samples, as shown in Fig. 38.2.

FIGURE 38.2: Illustration of a lapped transform with $N = 2$ applied to signal $x(n)$, yielding transform domain signal $y(n)$. The input L -tuple as vector \mathbf{v}_m is obtained by a sliding window advancing M samples, generating \mathbf{y}_m . This sliding is also valid for the synthesis side.

As the reader may have noticed, the region of support of all vectors \mathbf{v}_m is greater than the region of support of the input vector. Hence, a special treatment has to be given to the transform at the borders. We will discuss this fact later and assume infinite-length signals until then, or assume the length is very large and the borders of the signal are far enough from the region to which we are focusing our attention.

If we denote by \mathbf{x} the input vector and by \mathbf{y} the transform-domain vector, we can be consistent with our notation of transform matrices by defining a matrix \mathbf{T} such that $\mathbf{y} = \mathbf{T}\mathbf{x}$ and $\hat{\mathbf{x}} = \mathbf{T}^T\mathbf{y}$. In this case, we have

$$\mathbf{T} = \begin{bmatrix} & & & & & \\ & & & & & \\ & & \mathbf{P} & & & \\ & & & \mathbf{P} & & \\ & & & & \mathbf{P} & \\ & & & & & \ddots \end{bmatrix}. \quad (38.10)$$

where the displacement of the matrices \mathbf{P} obeys the following

$$\mathbf{T} = \begin{bmatrix} & & & & & \\ & & & & & \\ & & \mathbf{P}_0 & \mathbf{P}_1 & \ddots & \mathbf{P}_{N-1} \\ & & & \mathbf{P}_0 & \mathbf{P}_1 & \ddots & \mathbf{P}_{N-1} \\ & & & & \ddots & \ddots & \\ & & & & & \ddots & \end{bmatrix}. \quad (38.11)$$

\mathbf{T} has as many block-rows as transform operations over each vector \mathbf{v}_m .

Let the rows of \mathbf{P} be denoted by $1 \times L$ vectors \mathbf{p}_i^T ($0 \leq i \leq M-1$), so that $\mathbf{P}^T = [\mathbf{p}_0, \dots, \mathbf{p}_{M-1}]$. In an analogy to the block transform case, we have

$$y_i(m) = \mathbf{p}_i^T \mathbf{v}_m. \quad (38.12)$$

The vectors \mathbf{p}_i are the basis vectors of the lapped transform. They form an orthogonal basis for an M -dimensional subspace (there are only M vectors) of the L -tuples over the real field.

Assuming that the entire input and output signals are represented by the vectors \mathbf{x} and \mathbf{y} , respectively, and that the signals have infinite length, then, from 38.10, we have

$$\mathbf{y} = \mathbf{T}\mathbf{x} \quad (38.13)$$

and, if \mathbf{T} is orthogonal,

$$\mathbf{x} = \mathbf{T}^T\mathbf{y}. \quad (38.14)$$

The conditions for orthogonality of the LT are expressed as the orthogonality of \mathbf{T} . Therefore, the following equations are equivalent in a sense that they state the PR property along with the orthogonality of the LT.

$$\sum_{i=0}^{N-1-l} \mathbf{p}_i \mathbf{p}_{i+l}^T = \sum_{i=0}^{N-1-l} \mathbf{p}_i^T \mathbf{p}_{i+l} = \delta(l) \mathbf{I}_M. \quad (38.15)$$

$$\mathbf{T}\mathbf{T}^T = \mathbf{T}^T\mathbf{T} = \mathbf{I}_\infty \quad (38.16)$$

It is worthwhile to reaffirm that orthogonal LTs are a uniform maximally decimated FIR filter bank. Assume the filters in such a filter bank have L -tap impulse responses $f_i(n)$ and $g_i(n)$ ($0 \leq i \leq M-1, 0 \leq n \leq L-1$), for the analysis and synthesis filters, respectively. If the filters originally have a length smaller than L , one can pad the impulse response with 0s until $L = NM$. In other words, we force the basis vectors to have a common length which is an integer multiple of the block size. Assume the entries of \mathbf{P} are denoted by $\{p_{ij}\}$. One can translate the notation from LTs to filter banks by using

$$p_{kn} = f_k(L-1-n) = g_k(n) \quad (38.17)$$

38.3 Useful Transforms

38.3.1 Extended Lapped Transform (ELT)

Cosine modulated filter banks are filter banks based on a low-pass prototype filter modulating a cosine sequence. By a proper choice of the phase of the cosine sequence, Malvar developed the modulated lapped transform (MLT) [8], which led to the so-called extended lapped transforms (ELT) [10, 11, 12, 13]. The ELT allows several overlapping factors N , generating a family of LTs with good filter frequency response and fast implementation algorithm.

In the ELTs, the filter length L is basically an even multiple of the block size M , as $L = NM = 2kM$. The MLT-ELT class is defined by

$$p_{k,n} = h(n) \cos \left[\left(k + \frac{1}{2} \right) \left(\left(n - \frac{L-1}{2} \right) \frac{\pi}{M} + (N+1) \frac{\pi}{2} \right) \right] \quad (38.18)$$

for $k = 0, 1, \dots, M-1$ and $n = 0, 1, \dots, L-1$. $h(n)$ is a symmetric window modulating the cosine sequence and the impulse response of a low-pass prototype (with cutoff frequency at $\pi/2M$) which is translated in frequency to M different frequency slots in order to construct the uniform filter bank. The ELTs have as their major plus a fast implementation algorithm, which is depicted in Fig. 38.3 in an example for $M = 8$. The free parameters in the design of an ELT are the coefficients of the prototype filter. Such degrees of freedom are translated in the fast algorithm as rotation angles.

For the case $N = 4$ there is a useful parameterized design [11, 12, 13]. In this design, we have:

$$\theta_{k0} = -\frac{\pi}{2} + \mu_{M/2+k} \quad (38.19)$$

$$\theta_{k1} = -\frac{\pi}{2} + \mu_{M/2-1-k} \quad (38.20)$$

where

$$\mu_i = \left[\left(\frac{1-\gamma}{2M} \right) (2k+1) + \gamma \right] \quad (38.21)$$

and γ is a control parameter, for $0 \leq k \leq (M/2)-1$. γ controls the trade-off between the attenuation and transition region of the prototype filter. For $N = 4$, the relation between angles and $h(n)$ is:

$$h(k) = \cos(\theta_{k0}) \cos(\theta_{k1}) \quad (38.22)$$

$$h(M-1-k) = \cos(\theta_{k0}) \sin(\theta_{k1}) \quad (38.23)$$

$$h(M+k) = \sin(\theta_{k0}) \cos(\theta_{k1}) \quad (38.24)$$

$$h(2M-1-k) = -\sin(\theta_{k0}) \sin(\theta_{k1}) \quad (38.25)$$

for $k = 0, 1, \dots, M/2-1$. See [12] for optimized angles for ELTs. Further details on ELTs can be found in [10, 11, 12, 13, 17].

38.3.2 Generalized Linear-Phase Lapped Orthogonal Transform (GenLOT)

The generalized linear-phase lapped orthogonal transform (GenLOT) is also a useful family of LTs possessing symmetric bases (linear-phase filters). The use of linear-phase filters is a popular requirement in image processing applications. Let

$$\mathbf{W} = \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{I}_{M/2} & \mathbf{I}_{M/2} \\ \mathbf{I}_{M/2} & -\mathbf{I}_{M/2} \end{bmatrix} \quad \text{and} \quad \Psi_i = \begin{bmatrix} \mathbf{U}_i & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & \mathbf{V}_i \end{bmatrix}, \quad (38.26)$$

FIGURE 38.3: Implementation flow-graph for the ELT with $M = 8$.

where \mathbf{U}_i and \mathbf{V}_i can be any $M/2 \times M/2$ orthogonal matrices. Let the transform matrix \mathbf{P} for the GenLOT be constructed interactively. Let $\mathbf{P}^{(i)}$ be the partial reconstruction of \mathbf{P} after including up to the i th stage. We start by setting $\mathbf{P}^{(0)} = \mathbf{E}_0$ where \mathbf{E}_0 is an orthogonal matrix with symmetric rows. The recursion is given by:

$$\mathbf{P}^{(i)} = \Psi_i \mathbf{WZ} \begin{bmatrix} \mathbf{WP}^{(i-1)} & \mathbf{0}_M \\ \mathbf{0}_M & \mathbf{WP}^{(i-1)} \end{bmatrix} \quad (38.27)$$

where

$$\mathbf{Z} = \begin{bmatrix} \mathbf{0}_{M/2} & \mathbf{0}_{M/2} & \mathbf{I}_{M/2} & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & \mathbf{I}_{M/2} & \mathbf{0}_{M/2} & \mathbf{0}_{M/2} \end{bmatrix}. \quad (38.28)$$

At the final stage we set $\mathbf{P} = \mathbf{P}^{(N-1)}$. \mathbf{E}_0 is usually the DCT while the other factors (\mathbf{U}_i and \mathbf{V}_i) are found through optimization routines. More details on GenLOTs and their design can be found in [17, 19, 20]. The implementation flow-graph of a GenLOT with $M = 8$ is shown in Fig. 38.4.

38.4 Remarks

We hope this introductory work is helpful in understanding the basic concepts of lapped transforms. Filter banks are covered in other parts of this book. An excellent book by Vaidyanathan [28] has a thorough coverage of such subject. The interrelations of filter banks and LTs are well covered by Malvar [12] and Queiroz [17]. For image processing and coding, it is necessary to process finite-length signals. As we discussed, such an issue is not so straightforward in a general case. Algorithms to implement LTs over finite-length signals are discussed in [7, 12, 16, 17, 18, 21]. These algorithms

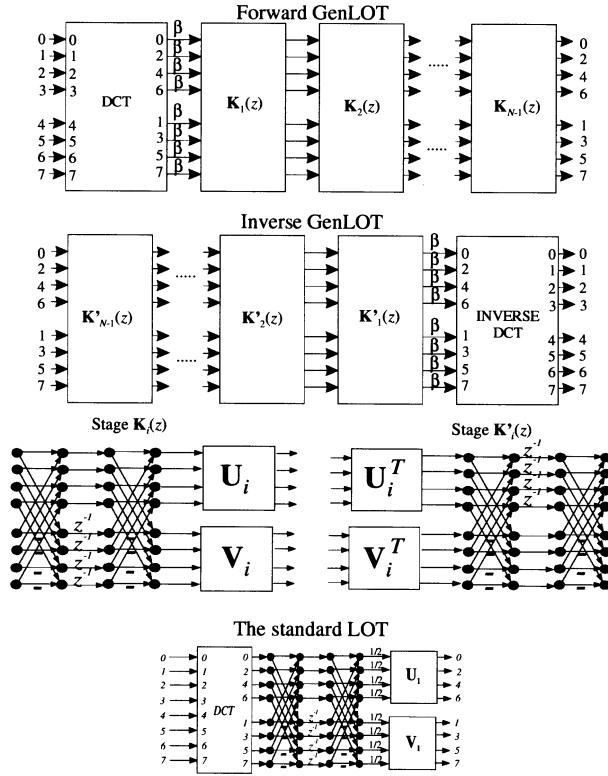

FIGURE 38.4: Implementation flow-graph for the GenLOT with $M = 8$, where $\beta = 2^{N-1}$.

can be general or specific. The specific algorithms are generally targeted to a particular LT invariantly seeking a very fast implementation. In general, Malvar's book [12] is an excellent reference for lapped transforms and their related topics.

AS WE ENTER THE 21ST CENTURY, digital audio communications will have become nearly as prevalent as digital speech communications. In particular, new technologies for audio storage and transmission will make available music and wideband signals in a flexible variety of standard formats.

The fundamental underpinning for these technologies is audio compression based on perceptually-tuned shaping of the quantization noise. The next chapter in this section describes psychoacoustics knowledge that suggests the general principles of *perceptual audio coding*. Succeeding chapters in this section are devoted to descriptions of established examples of *perceptual audio coders*. These include MPEG standards, and coders developed by Dolby, Sony, and Bell Laboratories.

The dimensions of coder performance are quality, bit rate, delay, and complexity. The quality vs. bit rate tradeoffs are particularly important.

Audio Quality

The three parameters of digital audio quality are *signal bandwidth*, *fidelity* and *spatial realism*.

Compact-disk (CD) signals have a bandwidth of 20–20,000 Hz, while traditional telephone speech has a bandwidth of 200–3400 Hz. Intermediate bandwidths characterize various grades of wideband speech and audio, including roughly defined ranges of quality referred to as AM radio and FM radio quality (bandwidths on the order of 7–10 and 12–15 kHz, respectively).

In the context of digital coding, fidelity refers to the level of perceptibility of quantization or reconstruction noise. The highest level of fidelity is one where the noise is imperceptible in formal listening tests. Lower levels of fidelity are acceptable in some applications if they are not annoying, although in general it is good practice to sacrifice some bandwidth in the interest of greater fidelity, for a given bit rate in coding. Five-point scales of signal fidelity are common in both speech and audio coding.

Spatial realism is generally provided by increasing the number of coded (and reproduced) spatial channels. Common formats are 1-channel (*mono*), 2-channel (*stereo*), 5-channel (3 front, 2 rear), 5.1-channel (5-channel plus subwoofer) and 8-channel (6 front, 2 rear). For given constraints on bandwidth and fidelity, the required bit rate in coding increases as a function of the number of channels; but the increase is slower than linear, because of the presence of interchannel redundancy. The notion of perceptual coding originally developed for exploiting the perceptual irrelevancies of a single-channel audio signal extends also to the methods used in exploiting interchannel redundancy.

Bit Rate

The CD-stereo signal has a digital representation rate of 1406 kilobits per second (kb/s). Current technology for perceptual audio coding reproduces CD-stereo with perfect fidelity at bit rates as low as 128 kb/s, depending on the input signal. CD-like reproduction is possible at bit rates as low as 64 kb/s for stereo. Single-channel reproduction of FM-radio-like music is possible at 32 kb/s. Single-channel reproduction of AM-radio-like music and wideband speech is possible at rates approaching 16 kb/s for all but the most demanding signals. Techniques for so-called “pseudo-stereo” can provide additional enhancement of digital single-channel audio.

Applications of Digital Audio

The capabilities of audio compression have combined with increasingly affordable implementations on platforms for digital signal processing (DSP), native signal processing (NSP) in a computer’s (native) processor, and application-specific integrated circuits (ASICs) to create revolutionary applications of digital audio. International and national standards have contributed immensely to this revolution. Some of these standards only specify the bit-stream syntax and decoder, leaving room for future, sometimes proprietary, enhancements of the encoding algorithm.

The domains of applications include *transmission* (for example, digital audio broadcasting), *storage* (for example, the minidisk and the digital versatile disk, DVD), and *networking* (music preview, distribution, and publishing). The networking applications will make digital audio communications as commonplace as digital telephony.

The Future of Digital Audio

Remarkable as the capabilities and applications mentioned above are, there are even greater challenges and opportunities for the practitioners of digital audio technology. It is unlikely that we have reached or even approached the fundamental limits of performance in terms of audio quality at a given bit rate. Newer capabilities in this technology (in terms of audio fidelity, bandwidth, and

spatial realism) will continue to lead to newer classes of applications in audio communications. New technologies for embedded coding and universal coding will create interesting new options for digital networking and seamless communication of speech and music signals. Finally, co-designs of audio processing with image and video processing will lead to currently unavailable capabilities for multimedia networking games, computer agents, and personal communication services. These scenarios will call upon our best capabilities in signal compression as well as advances in the sister disciplines of signal synthesis and recognition by machine.

In this chapter we review properties of auditory perception that are relevant to the design of coders for acoustic signals. The chapter begins with a general definition of a perceptual coder, then considers what the “ideal” psychophysical model would consist of and what use a coder could be expected to make of this model. We then present some basic definitions and concepts. The chapter continues with a review of relevant psychophysical data, including results on threshold, just-noticeable differences, masking, and loudness. Finally, we attempt to summarize the present state of the art, the capabilities and limitations of present-day perceptual coders for audio and speech, and what areas most need work.

39.1 Introduction

A coded signal differs in some respect from the original signal. One task in designing a coder is to minimize some measure of this difference under the constraints imposed by bit rate, complexity, or cost. What is the appropriate measure of difference? The most straightforward approach is to minimize some physical measure of the difference between original and coded signal. The designer might attempt to minimize RMS difference between the original and coded waveform, or perhaps the difference between original and coded power spectra on a frame-by-frame basis. However, if the purpose of the coder is to encode acoustic signals that are eventually to be listened to¹ by people,

¹Perceptual coding is not limited to speech and audio. It can be applied also to image and video [16]. In this paper we consider only coders for acoustic signals.

these physical measures do not directly address the appropriate issue. For signals that are to be listened to by people, the “best” coder is the one that sounds the best. There is a very clear distinction between *physical* and *perceptual* measures of a signal (frequency vs. pitch, intensity vs. loudness, for example). A perceptual coder can be defined as a coder that minimizes some measure of the difference between original and coded signal so as to minimize the perceptual impact of the coding noise. We can define the best coder given a particular set of constraints as the one in which the coding noise is least objectionable.

It follows that the designer of a perceptual coder needs some way to determine the perceptual quality of a coded signal. “Perceptual quality” is a poorly defined concept, and it will be seen that in some sense it cannot be uniquely defined. We can, however, attempt to provide a partial answer to the question of how it can be determined. We can present something of what is known about human auditory perception from psychophysical listening experiments and show how these phenomena relate to the design of a coder.

One requirement for successful design of a perceptual coder is a satisfactory model for the signal-dependent sensitivity of the auditory system. Present-day models are incomplete, but we can attempt to specify what the properties of a complete model would be. One possible specification is that, for any given waveform (the signal), it accurately predicts the loudness, as a function of pitch and of time, of any added waveform (the noise). If we had such a complete model, then we would in principle be able to build a transparent coder, defined as one in which the coded signal is indistinguishable from the original signal, or at least we would be able to determine whether or not a given coder was transparent. It is relatively simple to design a psychophysical listening experiment to determine whether the coding noise is audible, or equivalently, whether the subject can distinguish between original and coded signal. Any subject with normal hearing could be expected to give similar results to this experiment. While present-day models are far from complete, we can at least describe the properties of a complete model.

There is a second requirement that is more difficult to satisfy. This is the need to be able to determine which of two coded samples, each of which has audible coding noise, is preferable. While a satisfactory model for the signal-dependent sensitivity of the auditory system is in principle sufficient for the design of a transparent coder, the question of how to build the best nontransparent coder does not have a unique answer. Often, design constraints preclude building a transparent coder. Even the best coder built under these constraints will result in audible coding noise, and it is under some conditions impossible to specify uniquely how best to distribute this noise. One listener may prefer the more intelligible version, while another may prefer the more natural sounding version. The preferences of even a single listener might very well depend on the application. In the absence of any better criterion, we can attempt to minimize the loudness of the coding noise, but it must be understood that this is an incomplete solution.

Our purpose in this paper is to present something of what is known about human auditory perception in a form that may be useful to the designer of a perceptual coder. We do not attempt to answer the question of how this knowledge is to be utilized, how to build a coder. Present-day perceptual coders for the most part utilize a *feedforward* paradigm: analysis of the signal to be coded produces specifications for allowable coding noise. Perhaps a more general method is a *feedback* paradigm, in which the perceptual model somehow makes possible a decision as to which of two coded signals is “better”. This decision process can then be iterated to arrive at some optimum solution. It will be seen that for proper exploitation of some aspects of auditory perception the feedforward paradigm may be inadequate and the potentially more time-consuming feedback paradigm may be required. How this is to be done is part of the challenge facing the designer.

39.2 Definitions

In this section we define some fundamental terms and concepts and clarify the distinction between physical and perceptual measures.

39.2.1 Loudness

When we increase the intensity of a stimulus its loudness increases, but that does not mean that intensity and loudness are the same thing. *Intensity* is a physical measure. We can measure the intensity of a signal with an appropriate measuring instrument, and if the measuring instrument is standardized and calibrated correctly anyone else anywhere in the world can measure the same signal and get the same result. *Loudness* is *perceptual magnitude*. It can be defined as “that attribute of auditory sensation in terms of which sounds can be ordered on a scale extending from quiet to loud” ([23], p.47). We cannot measure it directly. All we can do is ask questions of a subject and from the responses attempt to infer something about loudness. Furthermore, we have no guarantee that a particular stimulus will be as loud for one subject as for another. The best we can do is assume that, for a particular stimulus, loudness judgments for one group of normal-hearing people will be similar to loudness judgments for another group.

There are two commonly used measures of loudness. One is *loudness level* (unit *phon*) and the other is *loudness* (unit *sones*). These two measures differ in what they describe and how they are obtained. The phon is defined as the intensity, in dB SPL, of an equally loud 1-kHz tone. The sone is defined in terms of subjectively measured loudness ratios. A stimulus half as loud as a one-sones stimulus has a loudness of 0.5 sones, a stimulus ten times as loud has a loudness of 10 sones, etc. A 1-kHz tone at 40 dB SPL is arbitrarily defined to have a loudness of one sone.

The argument can be made that loudness matching, the procedure used to obtain the phon scale, is a less subjective procedure than loudness scaling, the procedure used to obtain the sone scale. This argument would lead to the conclusion that the phon is the more objective of the two measures and that the sone is more subject to individual variability. This argument breaks down on two counts: first, for dissimilar stimuli even the supposedly straightforward loudness-matching task is subject to large and poorly understood order and bias effects that can only be described as subjective. While loudness matching of two equal-frequency tone bursts generally gives stable and repeatable results, the task becomes more difficult when the frequencies of the two tone bursts differ. Loudness matching between two dissimilar stimuli, as for example between a pure tone and a multicomponent complex signal, is even more difficult and yields less stable results. Loudness-matching experiments have to be designed carefully, and results from these experiments have to be interpreted with caution. Second, it is possible to measure loudness in sones, at least approximately, by means of a loudness-matching procedure. Fletcher [6] states that under some conditions loudness adds. Binaural presentation of a stimulus results in loudness doubling; and two equally-loud stimuli, far enough apart in frequency that they do not mask each other, are twice as loud as one. If loudness additivity holds, then it follows that the sone scale can be generated by matching loudness of a test stimulus to binaural stimuli or to pairs of tones. This approach must be treated with caution. As Fletcher states, “However, this method [scaling] is related more directly to the scale we are seeking (the sone scale) than the two preceding ones (binaural or monaural loudness additivity)” ([6], p. 278). The loudness additivity approach relies on the assumption that loudness summation is perfect, and there is some more recent evidence [28, 33] that loudness summation, at least for binaural vs. monaural presentation, is not perfect.

39.2.2 Pitch

The American Standards Association defines pitch as “that attribute of auditory sensation in which sounds may be ordered on a musical scale”. Pitch bears much the same relationship to frequency as loudness does to intensity: frequency is an objective physical measure, while pitch is a subjective perceptual measure. Just as there is not a one-to-one relationship between intensity and loudness, so also there is not a one-to-one relationship between frequency and pitch. Under some conditions, for example, loudness can be shown to decrease with decreasing frequency with intensity held constant, and pitch can be shown to decrease with increasing intensity with frequency held constant ([40], p. 409).

39.2.3 Threshold of Hearing

Since the concept of threshold is basic to much of what follows, it is worthwhile at this point to discuss it in some detail. It will be seen that thresholds are determined not only by the stimulus and the observer but also by the method of measurement. While this discussion is phrased in terms of threshold of hearing, much of what follows applies as well to differential thresholds (just-noticeable differences) discussed in the next subsection.

By the simplest definition, the threshold of hearing (equivalently, auditory threshold) is the lowest intensity that the listener can hear. This definition is inadequate because we cannot directly measure the listener’s perception. A first-order correction, therefore, is that the threshold of hearing is the lowest intensity that elicits from the listener the response that the sound is audible. Given this definition, we can present a stimulus to the listener and ask whether he or she can hear it. If we do this, we soon find that identical stimuli do not always elicit identical responses. In general, the probability of a positive response increases with increasing stimulus intensity and can be described by a *psychometric function* such as that shown for a hypothetical experiment in Fig. 39.1. Here the stimulus intensity (in dB) appears on the abscissa and the probability $P(C)$ of a positive response appears on the ordinate. The yes-no experiment could be described by a psychometric function that ranges from zero to one, and threshold could be defined as the stimulus intensity that elicits a positive response in 50% of the trials.

FIGURE 39.1: Idealized psychometric functions for hypothetical yes-no experiment (zero to one) and for hypothetical two-interval forced-choice experiment (0.5 to one).

A difficulty with the simple yes-no experiment is that we have no control over the subject's *criterion level*. The subject may be using a strict criterion ("yes" only if the signal is definitely present) or a lax criterion ("yes" if the signal might be present). The subject can respond correctly either by a positive response in the presence of a stimulus (*hit*) or by a negative response in the absence of a stimulus (*correct rejection*). Similarly the subject can respond incorrectly either by a negative response in the presence of a stimulus (*miss*) or by a positive response in the absence of a stimulus (*false alarm*). Unless the experimenter is willing to use an elaborate and time-consuming procedure that involves assigning rewards to correct responses and penalties to incorrect responses, the criterion level is uncontrolled.

The field of psychophysics that deals with this complication is called *detection theory*. The field of psychophysical detection theory is highly developed [12] and a complete description is far beyond the scope of this paper. Very briefly, the subject's response is considered to be based on an internal *decision variable*, a random variable drawn from a distribution with mean and standard deviation that depend on the stimulus. If we assume that the decision variable is normally distributed with a fixed standard deviation σ and a mean that depends only on stimulus intensity, then we can define an *index of sensitivity* d' for a given stimulus intensity as the difference between m_0 (the mean in the absence of the stimulus) and m_s (the mean in the presence of the stimulus), divided by σ . An *ideal observer* (a hypothetical subject who does the best possible job for the task at hand) gives a positive response if and only if the decision variable exceeds an internal criterion level. An increase in criterion level decreases the probability of a false alarm and increases the probability of a miss.

A simple and satisfactory way to deal with the problem of uncontrolled criterion level is to use a *criterion-free* experimental paradigm. The simplest is perhaps the two-interval forced choice (2IFC) paradigm, in which the stimulus is presented at random in one of two observation intervals. The subject's task is to determine which of the two intervals contained the stimulus. The ideal observer selects the interval that elicits the larger decision variable, and criterion level is no longer a factor. Now the subject has a 50% chance of choosing the correct interval even in the absence of any stimulus, so the psychometric function goes from 0.5 to 1.0 as shown in Fig. 39.1. A reasonable definition of threshold is $P(C) = 0.75$, halfway between the chance level of 0.5 and one. If the decision variable is normally distributed with a fixed standard deviation, it can be shown that this definition of threshold corresponds to a d' of 0.95.

The number of intervals can be increased beyond two. In this case, the ideal observer responds correctly if the decision variable for the interval containing the stimulus is larger than the largest of the $N-1$ decision variables for the intervals not containing the stimulus. A common practice is, for an N -interval forced choice paradigm (NIFC), to define threshold as the point halfway between the chance level of $1/N$ and one. This is a perfectly acceptable practice so long as it is recognized that the measured threshold is influenced by the number of alternatives. For a 3IFC paradigm this definition of threshold corresponds to a d' of 1.12 and for a 4IFC paradigm it corresponds to a d' of 1.24.

39.2.4 Differential Threshold

The differential threshold is conceptually similar to the auditory threshold discussed above, and many of the same comments apply. The differential threshold, or just-noticeable difference (JND), is the amount by which some attribute of a signal has to change in order for the observer to be able to detect the change. A tone burst, for example, can be specified in terms of frequency, intensity, and duration, and a differential threshold for any of these three attributes can be defined and measured.

The first attempt to provide a quantitative description of differential thresholds was provided by the German physiologist E. H. Weber in the first half of the 19th century. According to *Weber's law*, the just-noticeable difference ΔI is proportional to the stimulus intensity I , or $\Delta I / I = K$, where the constant of proportionality $\Delta I / I$ is known as the *Weber fraction*. This was supposed to be a general description of sensitivity to changes of intensity for a variety of sensory modalities, not limited just

to hearing, and it has since been applied to perception of nonintensive variables such as frequency. It was recognized at an early stage that this law breaks down at near-threshold intensities, and in the latter half of the 19th century the German physicist G. T. Fechner suggested the modification that is now known as the *modified Weber law*, $\Delta I / (I + I_0) = K$, where I_0 is a constant. While Weber's law provides a reasonable first-order description of intensity and frequency discrimination in hearing, in general it does not hold exactly, as will be seen below.

As with the threshold of hearing, the differential threshold can be measured in different ways, and the result depends to some extent on how it is measured. The simplest method is a same-different paradigm, in which two stimuli are presented and the subject's task is to judge whether or not they are the same. This method suffers from the same drawback as the yes-no paradigm for auditory threshold: we do not have control over the subject's criterion level.

If the physical attribute being measured is simply related to some perceptual attribute, then the differential threshold can be measured by requiring the subject to judge which of two stimuli has more of that perceptual attribute. A just-noticeable difference for frequency, for example, could be measured by requiring the subject to judge which of two stimuli is of higher pitch; or a just noticeable difference for intensity could be measured by requiring the subject to judge which of two stimuli is louder. As with the 2IFC paradigm discussed above for auditory threshold, this method removes the problem of uncontrolled criterion level.

There are more general methods that do not assume a knowledge of the relationship between the physical attribute being measured and a perceptual attribute. The most useful, perhaps, is the N-interval forced choice method: N stimuli are presented, one of which differs from the other N-1 along the dimension being measured. The subject's task is to specify which one of the N stimuli is different from the other N-1.

Note that there is a close parallel between the differential threshold and the auditory threshold described in the previous subsection. The auditory threshold can be regarded as a special case of the just-noticeable difference for intensity, where the question is by how much the intensity has to differ from zero in order to be detectable.

39.2.5 Masked Threshold

The *masked threshold* of a signal is defined as the threshold of that signal (the *probe*) in the presence of another signal (the *masker*). A related term is *masking*, which is the elevation of threshold of the probe by the masker: it is the difference between masked and absolute threshold. More generally, the reduction of loudness of a supra-threshold signal is also referred to as masking. It will be seen that masking can appear in many forms, depending on spectral and temporal relationships between probe and masker.

Many of the comments that applied to measurement of absolute and differential thresholds also apply to measurement of masked threshold. The simplest method is to present masker plus probe and ask the subject whether or not the probe is present. Once again there is a problem with criterion level. Another method is to present stimuli in two intervals and ask the subject which one contains the probe. This method can give useful results but can, under some conditions, give misleading results. Suppose, for example, that the probe and masker are both pure tones at 1 kHz, but that the two signals are 180° out of phase. As the intensity of the probe is increased from zero, the intensity of the composite signal will first decrease, then increase. The two signals, masker alone and masker plus probe, may be easily distinguishable, but in the absence of additional information the subject has no way of telling which is which.

A more robust method for measuring masked threshold is the N-interval forced choice method described above, in which the subject specifies which of the N stimuli differs from the other N-1. Subjective percepts in masking experiments can be quite complex and can differ from one observer to another. In the N-interval forced choice method the observer has the freedom to base judgments

on whatever attribute is most easily detected, and it is not necessary to instruct the observer what to listen for.

Note that the differential threshold for intensity can be regarded as a special case of the masked threshold in which the probe is an intensity-scaled version of the masker.

A note on terminology: suppose two signals, $x_1(t)$ and $[x_1(t) + x_2(t)]$ are just distinguishable. If $x_2(t)$ is a scaled version of $x_1(t)$, then we are dealing with intensity discrimination. If $x_1(t)$ and $x_2(t)$ are two different signals, then we are dealing with masking, with $x_1(t)$ the masker and $x_2(t)$ the probe. In either case, the difference can be described in several ways. These ways include (1) the intensity increment between $x_1(t)$ and $[x_1(t) + x_2(t)]$, ΔI ; (2) the intensity increment relative to $x_1(t)$, $\Delta I/I$; (3) the intensity ratio between $x_1(t)$ and $[x_1(t) + x_2(t)]$, $(I + \Delta I)/I$; (4) the intensity increment in dB, $10 \times \log_{10}(\Delta I/I)$; and (5) the intensity ratio in dB, $10 \times \log_{10}[(I + \Delta I)/I]$. These ways are equivalent in that they show the same information, although for a particular application one way may be preferable to another for presentation purposes. Another measure that is often used, particularly in the design of perceptual coders, is the intensity of the probe $x_2(t)$. This measure is subject to misinterpretation and must be used with caution. Depending on the coherence between $x_1(t)$ and $x_2(t)$, a given probe intensity can result in a wide range of intensity increments ΔI . The resulting ambiguity has been responsible for some confusion.

39.2.6 Critical Bands and Peripheral Auditory Filters

The concepts of *critical bands* and *peripheral auditory filters* are central to much of the auditory modeling work that is used in present-day perceptual coders. Scharf, in a classic review article [33], defines the empirical critical bandwidth as “that bandwidth at which subjective responses rather abruptly change”. Simply put, for some psychophysical tasks the auditory system behaves as if it consisted of a bank of bandpass filters (the critical bands) followed by energy detectors. Examples of critical-band behavior that are particularly relevant for the designer of a coder include the relationship between bandwidth and loudness (Fig. 39.5) and the relationship between bandwidth and masking (Fig. 39.10). Another example of critical-band behavior is phase sensitivity: in experiments measuring the detectability of amplitude and of frequency modulation, the auditory system appears to be sensitive to the relative phase of the components of a complex sound only so long as the components are within a critical band [9, 45].

The concept of the critical band was introduced more than a half-century ago by Fletcher [6], and since that time it has been studied extensively. Fletcher’s pioneering contribution is ably documented by Allen [1], and Scharf’s 1970 review article [33] gives references to some later work. More recently, Moore and his co-workers have made extensive measurements of peripheral auditory filters [24].

The value of critical bandwidths has been the subject of some discussion, because of questions of definition and method of measurement. Figure 39.2 ([31], Fig. 1) shows critical bandwidth as a function of frequency for Scharf’s empirical definition (the bandwidth at which subjective responses undergo some sort of change). Results from several experiments are superimposed here, and they are in substantial agreement with each other. Moore and Glasberg [26] argue that the bandwidths shown in Fig. 39.2 are determined not only by the bandwidth of peripheral auditory filters but also by changes in processing efficiency. By their argument, the bandwidth of peripheral auditory filters is somewhat smaller than the values shown in Fig. 39.2 at frequencies above 1 kHz and substantially smaller, by as much as an octave, at lower frequencies.

39.3 Summary of Relevant Psychophysical Data

In Section 39.2, we introduced some basic concepts and definitions. In this section, we review some relevant psychophysical results. There are several excellent books and book chapters that have been

FIGURE 39.2: Empirical critical bandwidth. (Source: Scharf, B., Critical bands, ch. 5 in *Foundations of Modern Auditory Theory*, Vol. 1, Tobias, J.V., ed., Academic Press, NY, 1970. With permission).

written on this subject, and we have neither the space nor the inclination to duplicate material found in these other sources. Our attempt here is to make the reader aware of some relevant results and to refer him or her to sources where more extensive treatments may be found.

39.3.1 Loudness

Loudness Level and Frequency

For pure tones, loudness depends on both intensity and frequency. Figure 39.3 (modified from [37], p. 124) shows loudness level contours. The curves are labeled in phons and, in parentheses, sones. These curves have been remeasured many times since, with some variation in the results, but the basic conclusions remain unchanged. The most sensitive region is around 2-3 kHz. The low-frequency slope of the loudness level contours is flatter at high loudness levels than at low. It follows that loudness level grows more rapidly with intensity at low frequencies than at high. The 38- and 48-phon contours are (by definition) separated by 10 dB at 1 kHz, but they are only about 5 dB apart at 100 Hz.

This figure also shows contours that specify the dynamic range of hearing. Tones below the 8-phon contour are inaudible, and tones above the dotted line are uncomfortable. The dynamic range of hearing, the distance between these two contours, is greatest around 2 to 3 kHz and decreases at lower and higher frequencies. In practice, the useful dynamic range is substantially less. We know today that extended exposure to sounds at much lower levels than the dotted line in Fig. 39.3 can result in temporary or permanent damage to the ear. It has been suggested that extended exposure to sounds as low as 70 to 75 dB(A) may produce permanent high-frequency threshold shifts in some

individuals [39].

FIGURE 39.3: Loudness level contours. Parameters: phons (sones). The bottom curve (8 phons) is at the threshold of hearing. The dotted line shows Wegel's 1932 results for "threshold of feeling". This line is many dB above levels that are known today to produce permanent damage to the auditory system. (Modified from Stevens, S.S. and Davis, H.W., *Hearing*, John Wiley & Sons, New York, 1938).

Loudness and Intensity

Figure 39.4 (modified from [32], Fig. 5) shows *loudness growth functions*, the relationship between stimulus intensity in dB SPL and loudness in sones, for tones of different frequencies. As can be seen in Fig. 39.4, the loudness growth function depends on frequency. Above about 40 dB SPL for a 1-kHz tone the relationship is approximately described by the power law $L(I) = (I/I_0)^{1/3}$, so that if the intensity I is increased by 9 dB the loudness L is approximately doubled.² The relationship between loudness and intensity has been modeled extensively [1, 6, 46].

Loudness and Bandwidth

The loudness of a complex sound of fixed intensity, whether a tone complex or a band of noise, depends on its bandwidth, as is shown in Fig. 39.5 ([48], Fig. 3). For sounds well above threshold, the loudness remains more or less constant so long as the bandwidth is less than a critical band. If the bandwidth is greater than a critical band, the loudness increases with increasing bandwidth. Near threshold the trend is reversed, and the loudness decreases with increasing bandwidth.³

²This power-law relationship between physical and perceptual measures of a stimulus was studied in great detail by S. S. Stevens. This relationship is now commonly referred to as *Stevens' Law*. Stevens measured exponents for many sensory modalities, ranging from a low of 0.33 for loudness and brightness to a high of 3.5 for electric shock produced by a 60-Hz electric current delivered to the skin.

³These data were obtained by comparing the loudness of a single 1-kHz tone and the loudness of a four-tone complex of the specified bandwidth centered at 1 kHz. The systematic difference between results when the tone was adjusted ("T"

FIGURE 39.4: Loudness growth functions. (Modified from Scharf, B., Loudness, ch. 6 in *Handbook of Perception*, Vol. IV, *Hearing*, Carterette, E.C. and Friedman M.P., eds., Academic Press, New York, 1978. With permission).

These phenomena have been modeled successfully by utilizing the loudness growth functions shown in Fig. 39.4 in a model that calculates total loudness by summing the specific loudness per critical band [49]. The loudness growth function is very steep near threshold, so that dividing the total energy of the signal into two or more critical bands results in a reduction of total loudness. The loudness growth function well above threshold is less steep, so that dividing the total energy of the signal into two or more critical bands results in an increase of total loudness.

Loudness and Duration

Everything we have talked about so far applies to steady-state, long-duration stimuli. These results are reasonably well understood and can be modeled reasonably well by present-day models. However, there is a host of psychophysical data having to do with aspects of temporal structure of the signal that are less well understood and less well modeled. The subject of temporal dynamics of auditory perception is an area where there is a great deal of room for improvement in models for perceptual auditory coders. One example of this subject is the relationship between loudness and duration discussed here. Other examples appear in a later section on temporal aspects of masking.

There is general agreement that, for fixed intensity, loudness increases with duration up to stimulus durations of a few hundred milliseconds. (Other factors, usually discussed under the terms adaptation

symbol) and when the complex was adjusted ("C" symbol) is an example of the bias effects mentioned in section 39.2.1 (**Loudness**).

FIGURE 39.5: Loudness vs. bandwidth of tone complex. (Source: Zwicker, E. et al., Critical bandwidth in loudness summation, *J. Acoust. Soc. Am.*, 29: 548-557, 1957. With permission).

FIGURE 39.6: Frequency JND as a function of frequency and intensity (Modified from Wier, C.C. et al., Frequency discrimination as a function of frequency and sensation level, *J. Acoust. Soc. Am.*, 61: 178-184, 1977. With permission).

or fatigue, come into play for longer durations of many seconds or minutes. We will not discuss these factors here.) The duration below which loudness increases with increasing duration is sometimes referred to as the *critical duration*. Scharf [32] provides an excellent summary of studies of the relationship between loudness and duration. In his survey, he cites values of critical duration ranging from 10 msec to over 500 msec. About half the studies in Scharf's survey show that the total energy (intensity \times duration) stays constant below the critical duration for constant loudness, while the remaining studies are about evenly split between total energy increasing and total energy decreasing with increasing duration.

One possible explanation for this confused state of affairs is the inherent difficulty of making loudness matches between dissimilar stimuli, discussed above in Section 39.2.1 (**Loudness**). Two stimuli of different durations differ by more than "loudness", and depending on a variety of poorly-understood experimental or individual factors what appears to be the same experiment may yield different results in different laboratories or with different subjects.

Some support for this explanation comes from the fact that studies of threshold intensity as a function of duration are generally in better agreement with each other than studies of loudness as a function of duration. As discussed above in Section 39.2.3 (**Threshold of Hearing**) measurements of auditory threshold depend to some extent on the method of measurement, but it is still possible to establish an internally-consistent criterion-free measure. The exact results depend to some extent on signal frequency, but there is reasonable agreement among various studies that total energy at threshold remains approximately constant between about 10 msec and 100 msec. (See [41] for a survey of studies of threshold intensity as a function of duration.)

39.3.2 Differential Thresholds

Frequency

Figure 39.6 shows frequency JND as a function of frequency and intensity as measured in the most recent comprehensive study [43]. The frequency JND generally increases with increasing frequency and decreases with increasing intensity, ranging from about 1 Hz at low frequency and moderate intensity to more than 100 Hz at high frequency and low intensity.

The results shown in Fig. 39.6 are in basic agreement with results from most other studies of frequency JND's with the exception of the earliest comprehensive study, by Shower and Biddulph ([43], p. 180). Shower and Biddulph [35] found a more gradual increase of frequency JND with frequency. As we have noted above, the results obtained in experiments of this nature are strongly influenced by details of the method of measurement. Shower and Biddulph measured detectability of frequency modulation of a pure tone; most other experimenters measured the ability of subjects to correctly identify whether one tone burst was of higher or lower frequency than another. Why this difference in procedure should produce this difference in results, or even whether this difference in procedure is solely responsible for the difference in results, is unclear.

The Weber fraction $\Delta f/f$, where Δf is the frequency JND, is smallest at mid frequencies, in the region from 500 Hz to 2 kHz. It increases somewhat at lower frequencies, and it increases very sharply at high frequencies above about 4 kHz. Wier et al. [43] in their Fig. 1, reproduced here as our Fig. 39.6, plotted $\log \Delta f$ against \sqrt{f} . They found that this choice of axes resulted in the closest fit to a straight line. It is not clear that this choice of axes has any theoretical basis; it appears simply to be a choice that happens to work well. There have been extensive attempts to model frequency selectivity. These studies suggest that the auditory system uses the timing of individual nerve impulses at low frequencies, but that at high frequencies above a few kHz this timing information is no longer available and the auditory system relies exclusively on place information from the mechanically tuned inner ear.

Rosenblith and Stevens [30] provide an interesting example of the interaction between method of

measurement and observed result. They compared frequency JNDs using two methods. One was an “AX” method, in which the subject judged whether the second of a pair of tone bursts was of higher or lower frequency than the first of the pair. The other was an “ABX” method, in which the subject judged whether the third of three tone bursts, at the same frequency as one of the first two tone bursts, was more similar to the first or to the second burst. They found that frequency JNDs measured using the AX method were approximately half the size of frequency JNDs measured using the ABX method, and they concluded that “... it would be rather imprudent to postulate a “true” DL (difference limen), or to infer the behavior of the peripheral organ from the size of a DL measured under a given set of conditions”. They discussed their results in terms of information theory, an active topic at the time, and were unable to reach any definite conclusion. An analysis of their results in terms of detection theory, which at that time was in its infancy, predicts their results almost exactly.⁴

Intensity

The Weber fraction $\Delta I/I$ for pure tones is not constant but decreases slightly as stimulus intensity increases. This change has been termed the *near miss to Weber’s law*. In most studies, the Weber fraction has been found to be independent of frequency. An exception is Riesz’s study [29], in which the Weber fraction was at a minimum at approximately 2 kHz and increased at higher and lower frequencies.

Typical results are summarized in Fig. 39.7 ([18], Fig. 4). The solid straight line is a good fit to Jesteadt’s intensity JND data at frequencies from 200 Hz to 8 kHz. The Weber fraction decreases from about 0.44 at 5 dB SL (decibels above threshold) to about 0.12 at 80 dB SL. These results are in substantial agreement with most other studies with the exception of Riesz’s study. Riesz’s data are shown in Fig. 39.7 as the curves identified by symbols. There is a larger change of intensity JND with intensity, and the intensity JND depends on frequency.

There is an interesting parallel between the results for intensity JND and the results for frequency JND. In both cases, results from most studies are in agreement with the exception of one study: Shower and Biddulph for frequency JND, and Riesz for intensity JND. In both cases, most studies measured the ability of subjects to correctly identify the difference between two tone bursts. Both of the outlying studies measured, instead, the ability of subjects to identify modulation of a tone: Shower and Biddulph used frequency modulation and Riesz used amplitude modulation. It appears that a modulated continuous tone may give different results than a pair of tone bursts. Whether this is a real effect, and, if it is, whether it is due to stimulus artifact or to properties of the auditory system, is unclear. The subject merits further investigation.

The Weber fraction for wideband noise appears to be independent of intensity. Miller [21] measured detectability of intensity increments in wide-band noise and found that the Weber fraction $\Delta I/I$ was approximately constant at 0.099 above 30 dB SL. It increased below 30 dB SL, which led Miller to revive Fechner’s modification of Weber’s law as discussed above in Section 39.2.4 (**Differential Threshold**).

39.3.3 Masking

No aspect of auditory psychophysics is more relevant to the design of perceptual auditory coders than masking, since the basic objective is to use the masking properties of speech to hide the coding noise.

⁴Assume RV’s A, B, and X are drawn independently from normal distributions with means m_A , m_B and m_X , respectively, and equal standard deviations σ . It can be shown that the relevant decision variable in the AX experiment has mean $m_A - m_X$ and standard deviation $\sqrt{2} \times \sigma$, while the relevant decision variable in the ABX experiment has mean $m_A - m_B$ and standard deviation $\sqrt{6} \times \sigma$, a value almost twice as large.

FIGURE 39.7: Summary of intensity JNDs for pure tones. Jesteadt et al. [18] found that the Weber fraction $\Delta I/I$ was independent of frequency (straight line). Riesz [29], using a different procedure, found a dependence (connected points). (Source: Jesteadt, W. et al., Intensity Discrimination as a function of frequency and sensation level, *J. Acoust. Soc. Am.*, 61: 169-177, 1977. With permission).

It will be seen that while we can use present-day knowledge of masking to great advantage, there is still much to be learned about properties of masking if we are to fully exploit it. Since some of the major unresolved problems in modeling masking are related to the relative bandwidth of masker and probe, our approach here is to present masking in terms of this relative bandwidth.

Tone Probe, Tone Masker

At one time, perhaps because of the demonstrated power of the Fourier transform in the analysis of linear time-invariant systems, the sine wave was considered to be the “natural” signal to be used in studies of human hearing. Much of the earliest work on masking dealt with the masking of one tone by another [42]. Typical results are shown in Fig. 39.8 ([3], Fig. 1). Similar results appear in Wegel and Lane [42]. The abscissa is probe frequency and the ordinate is masking in dB, the elevation of masked over absolute threshold (15 dB SPL for 400-Hz tone). Three curves are shown, for 400-Hz maskers at 40, 60, and 80 dB SPL.

Masking is greatest for probe frequencies slightly above or below the masker frequency of 400 Hz. Maximum probe-to-masker ratios are -19 dB for an 80 dB SPL masker (probe intensity elevated 46 dB above the absolute threshold of 15 dB SPL), -15 dB for a 60 dB SPL masker, and -14 dB for a 40 dB SPL masker.

Masking decreases as probe frequency gets closer to 400 Hz. The probe frequencies closest to 400 Hz are 397 and 403 Hz, and at these frequencies the threshold probe-to-masker ratio is -26 dB for an 80 dB SPL masker, -23 dB for a 60 dB SPL masker, and -21 dB for a 40 dB SPL masker.

Masking also decreases as probe frequency gets further away from masker frequency. For the 40 dB SPL masker this selectivity is nearly symmetric in log frequency, but as the masker intensity increases the masking becomes more and more asymmetric so that the 400-Hz masker produces much more masking at higher frequencies than at lower.

The irregularities seen near probe frequencies of 400, 800, and 1200 Hz are the result of interactions between masker and probe. When masker and probe frequencies are close, beating results. Even when

FIGURE 39.8: Masking of tones by a 400-Hz tone at 40, 60, and 80 dB SPL. (Source: Egan, J.P. and Hake, H.W., On the masking pattern of a simple auditory stimulus, *J. Acoust. Soc. Am.*, 22: 622-630, 1950).

their frequencies are far apart, nonlinear effects in the auditory system result in complex interactions. These irregularities provided incentive to use narrow bands of noise, rather than pure tones, as maskers.

Tone Probe, Noise Masker

Fletcher and Munson [8] were among the first to use bands of noise as maskers. Figure 39.9 ([3], Fig. 2) shows typical results. The conditions are similar to those for Fig. 39.8 except that now the masker is a band of noise 90 Hz wide centered at 410 Hz. The maximum probe-to-masker ratios occur for probe frequencies slightly above the center frequency of the masker, and they are much greater than they were for the tone maskers shown in Fig. 39.8. Maximum probe-to-masker ratios are -4 dB for an 80 dB SPL masker and -3 dB for 60 and 40 dB SPL maskers. The frequency selectivity and upward spread of masking seen in Fig. 39.8 appear in Fig. 39.9 as well, but the irregularities seen at harmonics of the masker frequency are greatly reduced.

An important effect that occurs in connection with masking of a tone probe by a band of noise is the relationship between masker bandwidth and amount of masking. This relationship can be presented in many ways, but the results can be described to a reasonable degree of accuracy by saying that noise energy within a narrow band of frequencies surrounding the probe contributes to masking while noise energy outside this band of frequencies does not. This is one manifestation of the *critical band* described in Section 39.2.6 (**Critical Bands and Peripheral Auditory Filters**).

Figure 39.10 ([2], Fig. 6) shows results from a series of experiments designed to determine the widths of critical bands. We are most concerned here with the closed symbols and the associated solid and dotted straight lines. These show an expanded and elaborated repeat of a test Fletcher reported in 1940 to measure the width of critical bands, and the results shown here are similar to Fletcher's results ([7], Fig. 124). The closed symbols show threshold level of probe signals at frequencies ranging from 500 Hz to 8 kHz in dB relative to the intensity of a masking band of noise centered at the frequency of the test signal and with the bandwidth shown on the abscissa. The intensity of the masking noise is 60 dB SPL per 1/3 octave. Note that for narrow-band maskers the probe-to-masker

FIGURE 39.9: Masking of tones by a 90-Hz wide band of noise centered at 410 Hz at 40, 60, and 80 dB SPL (Source: Egan, J.P. and Hake, H.W., On the masking pattern of a simple auditory stimulus, *J. Acoust. Soc. Am.*, 22: 622-630, 1950).

ratio is nearly independent of bandwidth, while for wide-band maskers the probe-to-masker ratio decreases at approximately 3 dB per doubling of bandwidth. This result indicates that above a certain bandwidth, approximated in this figure as the intersection of the asymptotic narrow-band horizontal line and the asymptotic wide-band sloping lines, noise energy outside of this band does not contribute to masking.

The results shown in Fig. 39.10 are from only one of many studies of masking of pure tones by noise bands of varying bandwidths that lead to similar conclusions. The list includes Feldtkeller and Zwicker [5] and Greenwood [13]. Scharf [33] provides additional references.

Noise Probe, Tone or Noise Masker

Masking of bands of noise, either by tone or noise maskers, has received relatively little attention. This is unfortunate for the designer who is concerned with masking wide-band coding noise. Masking of noise by tones is touched on in Zwicker [47], but the earliest study that gives actual data points appears to be Hellman [15]. The threshold probe-to-masker ratios for a noise probe approximately one critical band wide were -21 dB for a 60 dB SPL masker and -28 dB for a 90 dB SPL masker. Threshold probe-to-masker ratios for an octave-band probe were -55 dB for 1-kHz maskers at 80 and 100 dB SPL. A 1-kHz masker at 90 dB SPL produced practically no masking of a wide-band probe.

Hall [34] measured threshold intensity for noise bursts one-half, one, and two critical bands wide

FIGURE 39.10: Threshold level of probe signals from 500 Hz to 8 kHz relative to overall level of noise masker at bandwidth shown on the abscissa. (Modified from Bos, C.E. and de Boer, E., Masking and discrimination, *J. Acoust. Soc. Am.*, 39: 708-715, 1966. With permission).

with various center frequencies in the presence of 80 dB SPL pure-tone maskers ranging from an octave below to an octave above the center frequency. Figure 39.11 shows results for a critical-band 1-kHz probe. The threshold probe-to-masker ratio for a 1-kHz masker is -24 dB, in agreement with Hellman's results, and the figure shows the same upward spread of masking that appears in Figs. 39.8 and 39.9. (Note that in Figs. 39.8 and 39.9 the masker is fixed and the abscissa is probe frequency, while in Fig. 39.11 the probe is fixed and the abscissa is masker frequency.) A tone below 1 kHz produces more masking than a tone above 1 kHz.

Masking of noise by noise is confounded by the question of phase relationships between probe and masker. If masker and probe are identical in bandwidth and phase, then as we saw in Section 39.2.5 (**Masked Threshold**) the masked threshold becomes identical to the differential threshold. Miller's [21] Weber fraction $\Delta I/I$ of 0.099 for intensity discrimination of wide-band noise, phrased in terms of intensity of the just-detectable increment, leads to a probe-to-masker ratio of -26.3 dB.

More recently, Hall [14] measured threshold intensity for various combinations of probe and masker bandwidths. These experiments differ from earlier experiments in that phase relationships between probe and masker were controlled: all stimuli were generated by adding together equal-amplitude random phase sinusoidal components, and components common to probe and masker had identical phase. Results for one subject are shown in Fig. 39.12. Masker bandwidth appears on the abscissa, and the parameter is probe bandwidth: $A \Rightarrow 0$ Hz, $B \Rightarrow 4$ Hz, $C \Rightarrow 16$ Hz, and $D \Rightarrow 64$ Hz. All stimuli were centered at 1 kHz and the overall intensity of the masker was 70 dB SPL.

FIGURE 39.11: Threshold intensity for a 923-1083 Hz band of noise masked by an 80-dB SPL tone at the frequency shown on the abscissa. (Source: Schroeder, M.R. et al., Optimizing digital speech coders by exploiting masking properties of the human ear, *J. Acoust. Soc. Am.*, 66: 1647-1652, 1979. With permission).

This figure differs from Figs. 39.8 through 39.11 in that the vertical scale shows intensity increment between masker alone and masker plus just-detectable probe rather than intensity of the just-detectable probe, and the results look quite different. For all probe bandwidths shown, the intensity increment varies only slightly so long as the masker is at least as wide as the probe. The intensity increment decreases when the probe is wider than the masker.

Asymmetry of Masking

Inspection of Figs. 39.8– 39.11 reveals large variation of threshold probe-to-masker intensity ratios depending on the relative bandwidth of probe and masker. Tone maskers produce threshold probe-to-masker ratios of -14 to -26 dB for tone probes, depending on the intensity of the masker and the frequency of the probe (Fig. 39.8), and threshold probe-to-masker ratios of -21 to -28 dB for critical-band noise probes ([15]; also Fig. 39.11). On the other hand, a tone masked by a band of noise is audible only at much higher probe-to-masker ratios, in the neighborhood of 0 dB (Figs. 39.9 and 39.10). This *asymmetry of masking* (the term is due to Hellman, [15]) is of central importance in the design of perceptual coders because of the different masking properties of noise-like and tone-like portions of the coded signal [19]. Current perceptual models do not handle this asymmetry well, so it is a subject we must examine closely.

The logical conclusion to be drawn from the numbers in the preceding paragraph at first appears to be that a band of noise is a better masker than a tone, for both noise and tone probes. In fact, the correct conclusion may be completely different. It can be argued that so long as the masker bandwidth is at least as wide as the probe bandwidth, tones or bands of noise are equally effective maskers and the psychophysical data can be described satisfactorily by current energy-based perceptual models, properly applied. It is only when the bandwidth of the probe is greater than the bandwidth of the masker that energy-based models break down and some criterion other than average energy must be applied.

Figure 39.13 shows Egan and Hake's results for 80 dB SPL tone and noise maskers superimposed on each other. Results for the tone masker are shown as a solid curve and results for the noise masker are shown as a dashed curve. (These curves are not identical to the corresponding curves in Figs. 39.8 and 39.9: They are average results from five subjects, while Figs. 39.8 and 39.9 were for a single

FIGURE 39.12: Intensity increment between masker alone and masker plus just-detectable probe. Probe bandwidth 0 Hz (A); 4 Hz (B); 16 Hz (C); 64 Hz (D). Frequency components common to probe and masker have identical phase. (Source: Hall, J.L., Asymmetry of masking revisited: generalization of masker and probe bandwidth, *J. Acoust. Soc. Am.*, 101: 1023–1033, 1997. With permission).

subject.) The maximum amount of masking produced by the band of noise is 61 dB, while the tone masker produces only 37 dB of masking for a 397-Hz probe.

The difference between tone and noise maskers may be more apparent than real, and for masking of a tone the auditory system may be similarly affected by tone and noise maskers. What is plotted in this figure is the elevation in threshold intensity of the probe tone by the masker, but the discrimination the subject makes is in fact between masker alone and masker plus probe. As was discussed above in Section 39.2.5 (**Masked Threshold**), since coherence between tone probe and masker depends on the bandwidth of the masker, a probe tone of a given intensity can produce a much greater change in intensity of probe plus masker for a tone masker than for a noise masker.

The stimulus in the Egan and Hake experiment with a 400-Hz masker and a 397-Hz probe is identical to the stimulus Riesz used to measure intensity JND (see Section 47 **Differential Thresholds: Intensity**, above). As Egan and Hake observe “... When the frequency of the masked stimulus is 397 or 403 c.p.s. [Hz], the amount of masking is evidently determined by the value of the differential threshold for intensity at 400 c.p.s.” ([3], p. 624). Specifically, for the results shown in Fig. 39.13, the threshold intensity of a 397-Hz tone is 52 dB SPL. This leads to a Weber fraction $\Delta I/I$ (power at envelope maximum minus power at envelope minimum, divided by power at envelope minimum) of 0.17, which is only slightly higher than values obtained by Riesz and by Jesteadt et al. shown in Fig. 39.7.

The situation with noise masker is more difficult to analyze because of the random nature of the masker. The effective intensity increment between masker alone and masker plus probe depends on the phase relationship between probe and 400-Hz component of the masker, which are uncontrolled in the Egan and Hake experiment, and also on the effective time constant and bandwidth of the analyzing auditory filter, which are unknown. However, for the experiment shown in Fig. 39.12 the maskers were computer-generated repeatable stimuli, so that the intensity of masker plus probe could be computed. The results shown in Fig. 39.12 lead to a Weber fraction $\Delta I/I$ of 0.15 for tone masked by tone and 0.10 for tone masked by 64-Hz wide noise. Results are similar for noise masked by noise, so long as the masker is at least as wide as the probe. Weber fractions for the 64-Hz wide masker in Fig. 39.12 range from 0.18 for a 4-Hz wide probe to 0.15 for a 64-Hz wide probe.

Our understanding of the factors leading to the results shown in Fig. 39.12 is obviously very limited, but these results appear to be consistent with the view that to a first-order approximation the relevant variable for masking is the Weber fraction $\Delta I/I$, the intensity of masker plus probe relative to the

FIGURE 39.13: Masking produced by a 400-Hz masker at 80 dB SPL and a 90-Hz wide band of noise centered at 410 Hz. (Source: Egan, J.P. and Hake, H.W., On the masking pattern of a simple auditory stimulus, *J. Acoust. Soc. Am.*, 22: 622-630, 1950).

intensity of the masker, so long as the masker is at least as wide as the probe. This is true for both tone and noise maskers. Because of changes in coherence between probe and masker as masker bandwidth changes, the corresponding probe intensity at threshold can be much lower for a tone masker than for a probe masker, as is shown in Fig. 39.13.

The asymmetry that Hellman was primarily concerned with in her 1972 paper is the striking difference between the threshold of a band of noise masked by a tone and of a tone masked by a band of noise. It appears that this is a completely different effect than the asymmetry shown in Fig. 39.13 and one that cannot be accounted for by current energy-based models of masking. The difference between the -5 to $+5$ dB threshold probe-to-masker ratios seen in Figs. 39.9 and 39.10 for tones masked by noise and the -21 to -28 dB threshold probe-to-masker ratios for noise masked by tone reported by Hellman and seen in Fig. 39.11 is due in part to the random nature of the noise masker and to the change in coherence between masker and probe that we have already discussed. Even when these factors are controlled, as in Fig. 39.12, decrease of masker bandwidth for a 64-Hz wide band of noise results in a decrease of threshold intensity increment. (The situation is complicated by the possibility of off-frequency listening. As we have already seen, neither a tone nor a noise masker masks remote frequencies effectively. The 64-Hz band is narrow enough that off-frequency listening is not a factor.) These and similar results lead to the conclusion that present-day models operating on signal power are inadequate and that some envelope-based measure, such as the envelope maximum or ratio of envelope maximum to minimum, must be considered [10, 11, 38].

Temporal Aspects of Masking

Up until now, we have discussed masking effects with simultaneous masker and probe. In order to be able to deal effectively with a dynamically varying signal such as speech, we need to consider nonsimultaneous masking as well. When the probe follows the masker, the effect is referred to as *forward masking*. When the masker follows the probe, it is referred to as *backward masking*. Effects have also been measured with a brief probe near the beginning or the end of a longer-duration masker. These effects have been referred to as *forward* or *backward fringe masking*, respectively ([44], p. 162).

The various kinds of simultaneous and non-simultaneous masking are nicely illustrated in

FIGURE 39.14: Masking of tone by ongoing wide-band noise with silent interval of 25, 50, 200, or 500 msec. This figure shows simultaneous, forward, backward, forward fringe, and backward fringe masking. (Source: Elliott, L.L., Masking of tones before, during, and after brief silent periods in noise, *J. Acoust. Soc. Am.*, 45: 1277-1279, 1969. With permission).

Fig. 39.14 ([4], Fig. 1). The masker was wideband noise at an overall level of 70 dB SPL and the probe was a brief 1.9-kHz tone burst. The masker was on continuously except for a silent interval of 25, 50, 200, or 500 msec. beginning at the 0-msec point on the abscissa. The four sets of data points show thresholds for probes presented at various times relative to the gap for the four gap durations. Probe thresholds in silence and in continuous noise are indicated on the ordinate by the symbols “Q” and “CN”.

Forward masking appears as the gradual drop of probe threshold over a duration of more than 100 msec following the cessation of the masker. Backward masking appears as the abrupt increase of masking, over a duration of a few tens of msec, immediately before the reintroduction of the masker. Forward fringe masking appears as the more than 10-dB overshoot of masking immediately following the reintroduction of the masker, and backward fringe masking appears as the smaller overshoot immediately preceding the cessation of the masker. Backward masking is an important effect for the designer of coders for acoustic signals because of its relationship to audibility of pre-echo. It is a puzzling effect, because it is caused by a masker that begins only after the probe has been presented. Stimulus-related electrophysiological events can be recorded in the cortex several tens of msec after presentation of the stimulus, so there may be some physiological basis for backward masking. It is an unstable effect, and there is some evidence that backward masking decreases with practice [20], ([23], p. 119).

Forward masking is a more robust effect, and it has been studied extensively. It is a complex function of stimulus parameters, and we do not have a comprehensive model that predicts amount of forward masking as a function of frequency, intensity, and time course of masker and of probe. The following two examples illustrate some of its complexity.

Figure 39.15 ([17], Fig. 1) is from a study of the effects of masker frequency and intensity on forward

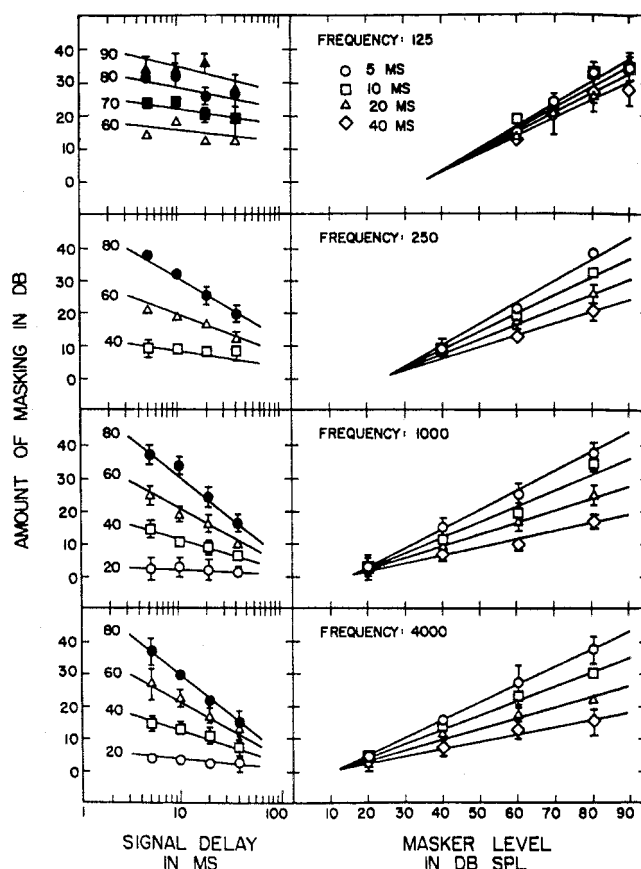

FIGURE 39.15: Forward masking with identical masker and probe frequencies, as a function of frequency, delay, and masker level (Source: Jesteadt, W. et al., Forwarding masking as a function of frequency, masker level, and signal delay, *J. Acoust. Soc. Am.*, 71: 950-962, 1982. With permission).

masking. Masker and probe were of the same frequency. The left and right columns show the same data, plotted on the left against probe delay with masker intensity as a parameter and plotted on the right against masker intensity with probe delay as a parameter. The amount of masking depends in an orderly way on masker frequency, masker intensity, and probe delay. Jesteadt et al. were able to fit these data with a single equation with three free constants. This equation, with minor modification, was later found to give a satisfactory fit to data obtained with forward masking by wide-band noise [25].

Striking effects can be observed when probe and masker frequencies differ. Figure 39.16 (modified from [22], Fig. 8) superimposes simultaneous (open symbols) and forward (filled symbols) masking curves for a 6-kHz probe at 36 dB SPL, 10 dB above the absolute threshold of 26 dB SPL. Rather than showing the amount of masking for a fixed masker, this figure shows masker level, as a function of masker frequency, sufficient to just mask the probe. It is clear that simultaneous and forward masking differ, and that the difference depends on the relative frequency of masker and probe. Results such as those shown in Fig. 39.16 are of interest to the field of auditory physiology because of similarities between forward masking results and frequency selectivity of primary auditory neurons.

FIGURE 39.16: Simultaneous (open symbols) and forward (closed symbols) masking of a 6-kHz probe tone at 36 dB SPL. Masker frequency appears on the abscissa, and masker intensity just sufficient to mask the probe appears on the abscissa. (Modified from Moore, B.C.J., Psychophysical tuning curves measured in simultaneous and forward masking, *J. Acoust. Soc. Am.*, 63: 524-532, 1978. With permission).

39.4 Conclusions

Notwithstanding the successes obtained to date with perceptual coders for speech and audio [16, 19, 27, 36], there is still a great deal of room for further advancement. The most widely applied perceptual models today apply an energy-based criterion to some critical-band transformation of the signal and arrive at a prediction of acceptable coding noise. These models are essentially refinements of models first described by Fletcher and his co-workers and further developed by Zwicker and others [34]. These models do a good job describing masking and loudness for steady-state bands of noise, but they are less satisfactory for other signals. We can identify two areas in which there seem to be great room for improvement. One of these areas presents a challenge jointly to the designer of coders and to the auditory psychophysicist, and the other area presents a challenge primarily to the auditory psychophysicist.

One area for additional research has to do with asymmetry of masking. Noise is a more effective masker than tones, and this difference is not handled well by present-day perceptual models. Present-day coders first compute a measure of tonality of the signal and then use this measure empirically to obtain an estimate of masking. This empirical approach has been applied successfully to a variety of signals, but it is possible that an approach that is less empirical and more based on a comprehensive model of auditory perception would be more robust.

As discussed in Section 39.3.3 (Masking: Asymmetry of Masking), there is evidence that there are two separate factors contributing to this asymmetry of masking. The difference between noise and tone maskers for narrow-band coding noise appears to result from problems with signal definition rather than a difference in processing by the auditory system, and it may be that an effective way of dealing with it will result not from an improved understanding of auditory perception but rather from changes in the coder. A feedforward prediction of acceptable coding noise based on the energy of the signal does not take into account phase relationships between signal and noise. What may be required is a feedback, analysis-by-synthesis approach, in which a direct comparison is made between the original signal and the proposed coded signal. This approach would require a more complex encoder but leave the decoder complexity unchanged [27]. The difference between narrow-band and wide-band coding noise, on the other hand, appears to call for a basic change in models of

auditory perception. For largely historical reasons, the idea of signal energy as a perceptual measure is deeply ingrained in present-day perceptual models. There is increasing realization that under some conditions signal energy is not the relevant measure but that some envelope-based measure may be required.

A second area in which additional research may prove fruitful is in the area of temporal aspects of masking. As is discussed in Section 39.3.3 (**Masking: Temporal Aspects of Masking**), the situation with time-varying signal and noise is more complex than the steady-state situation. There is an extensive body of psychophysical data on various aspects of nonsimultaneous masking, but we are still lacking a satisfactory comprehensive perceptual model. As is the case with asymmetry of masking, present-day coders deal with this problem at an empirical level, in some cases very effectively. However, as with asymmetry of masking, an approach based on fundamental properties of auditory perception would perhaps be better able to deal with a wide variety of signals.

40.1 Introduction

PCM Bit Rates

Typical audio signal classes are telephone speech, wideband speech, and wideband audio, all of which differ in bandwidth, dynamic range, and in listener expectation of offered quality. The quality of telephone-bandwidth speech is acceptable for telephony and for some videotelephony and video-conferencing services. Higher bandwidths (7 kHz for wideband speech) may be necessary to improve the intelligibility and naturalness of speech. Wideband (high fidelity) audio representation including multichannel audio needs bandwidths of at least 15 kHz.

The conventional digital format for these signals is PCM, with sampling rates and amplitude resolutions (PCM bits per sample) as given in Table 40.1.

The *compact disc* (CD) is today's *de facto standard* of digital audio representation. On a CD with its 44.1 kHz sampling rate the resulting stereo net bit rate is $2 \times 44.1 \times 16 \times 1000 \equiv 1.41$ Mb/s (see Table 40.2). However, the CD needs a significant overhead for a runlength-limited line code, which maps 8 information bits into 14 bits, for synchronization and for error correction, resulting in a 49-bit representation of each 16-bit audio sample. Hence, the total stereo bit rate is $1.41 \times 49/16 = 4.32$ Mb/s. Table 40.2 compares bit rates of the compact disc and the *digital audio tape* (DAT).

TABLE 40.1 Basic Parameters for Three Classes of Acoustic Signals

	Frequency range in Hz	Sampling rate in kHz	PCM bits per sample	PCM bit rate in kb/s
Telephone speech	300 - 3,400 ^a	8	8	64
Wideband speech	50 - 7,000	16	8	128
Wideband audio (stereo)	10 - 20,000	48 ^b	2 × 16	2 × 768

^a Bandwidth in Europe; 200 to 3200 Hz in the U.S.
^b Other sampling rates: 44.1 kHz, 32 kHz.

TABLE 40.2 CD and DAT Bit Rates

Storage device	Audio rate (Mb/s)	Overhead (Mb/s)	Total bit rate (Mb/s)
Compact disc (CD)	1.41	2.91	4.32
Digital audio tape (DAT)	1.41	1.05	2.46

Note: Stereophonic signals, sampled at 44.1 kHz; DAT supports also sampling rates of 32 kHz and 48 kHz.

For archiving and processing of audio signals, sampling rates of at least 2×44.1 kHz and amplitude resolutions of up to 24 b per sample are under discussion. Lossless coding is an important topic in order not to compromise audio quality in any way [1]. The digital versatile disk (DVD) with its capacity of 4.7 GB is the appropriate storage medium for such applications.

Bit Rate Reduction

Although high bit rate channels and networks become more easily accessible, low bit rate coding of audio signals has retained its importance. The main motivations for low bit rate coding are the need to minimize transmission costs or to provide cost-efficient storage, the demand to transmit over channels of limited capacity such as mobile radio channels, and to support variable-rate coding in packet-oriented networks.

Basic requirements in the design of low bit rate audio coders are first, to retain a high quality of the reconstructed signal with robustness to variations in spectra and levels. In the case of stereophonic and multichannel signals spatial integrity is an additional dimension of quality. Second, robustness against random and bursty channel bit errors and packet losses is required. Third, low complexity and power consumption of the codecs are of high relevance. For example, in broadcast and playback applications, the complexity and power consumption of audio decoders used must be low, whereas constraints on encoder complexity are more relaxed. Additional network-related requirements are low encoder/decoder delays, robustness against errors introduced by cascading codecs, and a graceful degradation of quality with increasing bit error rates in mobile radio and broadcast applications. Finally, in professional applications, the coded bit streams must allow editing, fading, mixing, and dynamic range compression [1].

We have seen rapid progress in bit rate compression techniques for speech and audio signals [2]–[7]. Linear prediction, subband coding, transform coding, as well as various forms of vector quantization and entropy coding techniques have been used to design efficient coding algorithms which can achieve substantially more compression than was thought possible only a few years ago. Recent results in speech and audio coding indicate that an excellent coding quality can be obtained with bit rates of 1 b per sample for speech and wideband speech and 2 b per sample for audio. Expectations over the next decade are that the rates can be reduced by a factor of four. Such reductions shall be based mainly on employing sophisticated forms of adaptive noise shaping controlled by psychoacoustic criteria. In storage and ATM-based applications additional savings are possible by employing variable-rate coding with its potential to offer a time-independent constant-quality performance.

Compressed digital audio representations can be made less sensitive to channel impairments than analog ones if source and channel coding are implemented appropriately. Bandwidth expansion has often been mentioned as a disadvantage of digital coding and transmission, but with today's

data compression and multilevel signaling techniques, channel bandwidths can be reduced actually, compared with analog systems. In broadcast systems, the reduced bandwidth requirements, together with the error robustness of the coding algorithms, will allow an efficient use of available radio and TV channels as well as “taboo” channels currently left vacant because of interference problems.

MPEG Standardization Activities

Of particular importance for digital audio is the standardization work within the International Organization for Standardization (ISO/IEC), intended to provide international standards for audio-visual coding. ISO has set up a Working Group WG 11 to develop such standards for a wide range of communications-based and storage-based applications. This group is called MPEG, an acronym for *Moving Pictures Experts Group*.

MPEG’s initial effort was the MPEG Phase 1 (MPEG-1) coding standards *IS 11172* supporting bit rates of around 1.2 Mb/s for video (with video quality comparable to that of today’s analog video cassette recorders) and 256 kb/s for two-channel audio (with audio quality comparable to that of today’s compact discs) [8].

The more recent MPEG-2 standard *IS 13818* provides standards for high quality video (including High Definition TV) in bit rate ranges from 3 to 15 Mb/s and above. It provides also new audio features including low bit rate digital audio and multichannel audio [9].

Finally, the current MPEG-4 work addresses standardization of audiovisual coding for applications ranging from mobile access low complexity multimedia terminals to high quality multichannel sound systems. MPEG-4 will allow for interactivity and universal accessibility, and will provide a high degree of flexibility and extensibility [10].

MPEG-1, MPEG-2, and MPEG-4 standardization work will be described in Sections 40.3 to 40.5 of this paper. *Web information about MPEG* is available at different addresses. The official MPEG Web site offers crash courses in MPEG and ISO, an overview of current activities, MPEG requirements, workplans, and information about documents and standards [11]. Links lead to collections of frequently asked questions, listings of MPEG, multimedia, or digital video related products, MPEG/Audio resources, software, audio test bitstreams, etc.

40.2 Key Technologies in Audio Coding

First proposals to reduce wideband audio coding rates have followed those for speech coding. Differences between audio and speech signals are manifold; however, audio coding implies higher sampling rates, better amplitude resolution, higher dynamic range, larger variations in power density spectra, stereophonic and multichannel audio signal presentations, and, finally, higher listener expectation of quality. Indeed, the high quality of the CD with its 16-b per sample PCM format has made digital audio popular.

Speech and audio coding are similar in that in both cases quality is based on the properties of human auditory perception. On the other hand, speech can be coded very efficiently because a *speech production model* is available, whereas nothing similar exists for audio signals.

Modest reductions in audio bit rates have been obtained by instantaneous companding (e.g., a conversion of uniform 14-bit PCM into a 11-bit nonuniform PCM presentation) or by forward-adaptive PCM (block companding) as employed in various forms of *near-instantaneously companded audio multiplex* (NICAM) coding [ITU-R, Rec. 660]. For example, the British Broadcasting Corporation (BBC) has used the NICAM 728 coding format for digital transmission of sound in several European broadcast television networks; it uses 32-kHz sampling with 14-bit initial quantization followed by a compression to a 10-bit format on the basis of 1-ms blocks resulting in a total stereo bit rate of 728 kb/s [12]. Such adaptive PCM schemes can solve the problem of providing a sufficient dynamic range for audio coding but they are not efficient compression schemes because they do not exploit

statistical dependencies between samples and do not sufficiently remove signal irrelevancies.

Bit rate reductions by fairly simple means are achieved in the interactive CD (CD-i) which supports 16-bit PCM at a sampling rate of 44.1 kHz and allows for three levels of adaptive differential PCM (ADPCM) with switched prediction and noise shaping. For each block there is a multiple choice of fixed predictors from which to choose. The supported bandwidths and b/sample-resolutions are 37.8 kHz/8 bit, 37.8 kHz/4 bit, and 18.9 kHz/4 bit.

In recent audio coding algorithms *four key technologies* play an important role: perceptual coding, frequency domain coding, window switching, and dynamic bit allocation. These will be covered next.

40.2.1 Auditory Masking and Perceptual Coding

Auditory Masking

The inner ear performs short-term critical band analyses where frequency-to-place transformations occur along the basilar membrane. The power spectra are not represented on a linear frequency scale but on limited frequency bands called *critical bands*. The auditory system can roughly be described as a bandpass filterbank, consisting of strongly overlapping bandpass filters with bandwidths in the order of 50 to 100 Hz for signals below 500 Hz and up to 5000 Hz for signals at high frequencies. Twenty-five critical bands covering frequencies of up to 20 kHz have to be taken into account.

Simultaneous masking is a frequency domain phenomenon where a low-level signal (the maskee) can be made inaudible (masked) by a simultaneously occurring stronger signal (the masker), if masker and maskee are close enough to each other in frequency [13]. Such masking is greatest in the critical band in which the masker is located, and it is effective to a lesser degree in neighboring bands. A *masking threshold* can be measured below which the low-level signal will not be audible. This masked signal can consist of low-level signal contributions, quantization noise, aliasing distortion, or transmission errors. The masking threshold, in the context of source coding also known as *threshold of just noticeable distortion* (JND) [14], varies with time. It depends on the sound pressure level (SPL), the frequency of the masker, and on characteristics of masker and maskee. Take the example of the masking threshold for the SPL = 60 dB narrowband masker in Fig. 40.1: around 1 kHz the four maskees will be masked as long as their individual sound pressure levels are below the masking threshold. The slope of the masking threshold is steeper towards lower frequencies, i.e., higher frequencies are more easily masked. It should be noted that the distance between masker and masking threshold is smaller in noise-masking-tone experiments than in tone-masking-noise experiments, i.e., noise is a better masker than a tone. In MPEG coders both thresholds play a role in computing the masking threshold.

Without a masker, a signal is inaudible if its sound pressure level is below the *threshold in quiet* which depends on frequency and covers a dynamic range of more than 60 dB as shown in the lower curve of Figure 40.1.

The qualitative sketch of Fig. 40.2 gives a few more details about the masking threshold: a critical band, tones below this threshold (darker area) are masked. The distance between the level of the masker and the masking threshold is called *signal-to-mask ratio* (SMR). Its maximum value is at the left border of the critical band (point A in Fig. 40.2), its minimum value occurs in the frequency range of the masker and is around 6 dB in noise-masks-tone experiments. Assume a m-bit quantization of an audio signal. Within a critical band the quantization noise will not be audible as long as its signal-to-noise ratio SNR is higher than its SMR. Noise and signal contributions *outside* the particular critical band will also be masked, although to a lesser degree, if their SPL is below the masking threshold.

Defining SNR(m) as the signal-to-noise ratio resulting from an m-bit quantization, the perceivable distortion in a given subband is measured by the *noise-to-mask ratio*

$$\text{NMR (m)} = \text{SMR} - \text{SNR (m)} \text{ (in dB)}.$$

FIGURE 40.1: Threshold in quiet and masking threshold. Acoustical events in the shaded areas will not be audible.

The noise-to-mask ratio $NMR(m)$ describes the difference in dB between the signal-to-*mask* ratio and the signal-to-*noise* ratio to be expected from an m -bit quantization. The NMR value is also the difference (in dB) between the level of quantization noise and the level where a distortion may just become audible in a given subband. Within a critical band, coding noise will not be audible as long as $NMR(m)$ is negative.

We have just described masking by only one masker. If the source signal consists of many simultaneous maskers, each has its own masking threshold, and a *global masking threshold* can be computed that describes the threshold of just noticeable distortions as a function of frequency.

In addition to simultaneous masking, the time domain phenomenon of *temporal masking* plays an important role in human auditory perception. It may occur when two sounds appear within a small interval of time. Depending on the individual sound pressure levels, the stronger sound may mask the weaker one, even if the maskee precedes the masker (Fig. 40.3)!

Temporal masking can help to mask pre-echoes caused by the spreading of a sudden large quantization error over the actual coding block. The duration within which *pre-masking* applies is significantly less than one tenth of that of the *post-masking* which is in the order of 50 to 200 ms. Both pre- and postmasking are being exploited in MPEG/Audio coding algorithms.

Perceptual Coding

Digital coding at high bit rates is dominantly waveform-preserving, i.e., the amplitude-vs.-time waveform of the decoded signal approximates that of the input signal. The difference signal between input and output waveform is then the basic error criterion of coder design. Waveform coding principles have been covered in detail in [2]. At lower bit rates, facts about the production and perception of audio signals have to be included in coder design, and the error criterion has to be in favor of an output signal that is useful to the human receiver rather than favoring an output signal that follows and preserves the input waveform. Basically, an efficient source coding algorithm will (1) remove redundant components of the source signal by exploiting correlations between its

FIGURE 40.2: Masking threshold and signal-to-mask ratio (SMR). Acoustical events in the shaded areas will not be audible.

samples and (2) remove components that are irrelevant to the ear. Irrelevancy manifests itself as unnecessary amplitude or frequency resolution; portions of the source signal that are masked do not need to be transmitted.

The dependence of human auditory perception on frequency and the accompanying perceptual tolerance of errors can (and should) directly influence encoder designs; *noise-shaping techniques* can emphasize coding noise in frequency bands where that noise perceptually is not important. To this end, the noise shifting must be dynamically adapted to the actual short-term input spectrum in accordance with the signal-to-mask ratio which can be done in different ways. However, frequency weightings based on linear filtering, as typical in speech coding, cannot make full use of results from psychoacoustics. Therefore, in wideband audio coding, noise-shaping parameters are dynamically controlled in a more efficient way to exploit simultaneous masking and temporal masking.

Figure 40.4 depicts the structure of a *perception-based coder* that exploits auditory masking. The

FIGURE 40.3: Temporal masking. Acoustical events in the shaded areas will not be audible.

encoding process is controlled by the SMR vs. frequency curve from which the needed amplitude resolution (and hence the bit allocation and rate) in each frequency band is derived. The SMR is typically determined from a high resolution, say, a 1024-point FFT-based spectral analysis of the audio block to be coded. Principally, any coding scheme can be used that can be dynamically controlled by such perceptual information. Frequency domain coders (see next section) are of particular interest because they offer a direct method for noise shaping. If the frequency resolution of these coders is high enough, the SMR can be derived directly from the subband samples or transform coefficients without running a FFT-based spectral analysis in parallel [15, 16].

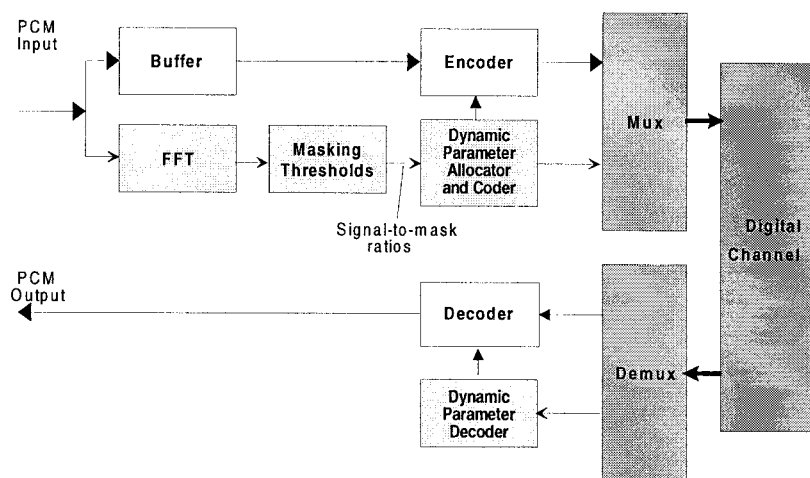

FIGURE 40.4: Block diagram of perception-based coders.

If the necessary bit rate for a complete masking of distortion is available, the coding scheme will be perceptually transparent, i.e., the decoded signal is then subjectively indistinguishable from the source signal. In practical designs, we cannot go to the limits of just noticeable distortion because postprocessing of the acoustic signal by the end-user and multiple encoding/decoding processes in transmission links have to be considered. Moreover, our current knowledge about auditory masking is very limited. Generalizations of masking results, derived for simple and stationary maskers and for limited bandwidths, may be appropriate for most source signals, but may fail for others. Therefore, as an additional requirement, we need a sufficient safety margin in practical designs of such perception-based coders. It should be noted that the MPEG/Audio coding standard is open for better encoder-located psychoacoustic models because such models are not normative elements of the standard (see Section 40.3).

40.2.2 Frequency Domain Coding

As one example of dynamic noise-shaping, quantization noise feedback can be used in predictive schemes [17, 18]. However, frequency domain coders with dynamic allocations of bits (and hence of quantization noise contributions) to subbands or transform coefficients offer an easier and more accurate way to control the quantization noise [2, 15].

In all frequency domain coders, redundancy (the non-flat short-term spectral characteristics of the source signal) and irrelevancy (signals below the psychoacoustical thresholds) are exploited to

reduce the transmitted data rate with respect to PCM. This is achieved by splitting the source spectrum into frequency bands to generate nearly uncorrelated spectral components, and by quantizing these separately. Two coding categories exist, *transform coding* (TC) and *subband coding* (SBC). The differentiation between these two categories is mainly due to historical reasons. Both use an analysis filterbank in the encoder to decompose the input signal into subsampled spectral components. The spectral components are called subband samples if the filterbank has low frequency resolution, otherwise they are called spectral lines or transform coefficients. These spectral components are recombined in the decoder via synthesis filterbanks.

In *subband coding*, the source signal is fed into an analysis filterbank consisting of M bandpass filters which are contiguous in frequency so that the set of subband signals can be recombined additively to produce the original signal or a close version thereof. Each filter output is critically decimated (i.e., sampled at twice the nominal bandwidth) by a factor equal to M , the number of bandpass filters. This decimation results in an aggregate number of subband samples that equals that in the source signal. In the receiver, the sampling rate of each subband is increased to that of the source signal by filling in the appropriate number of zero samples. Interpolated subband signals appear at the bandpass outputs of the synthesis filterbank. The sampling processes may introduce aliasing distortion due to the overlapping nature of the subbands. If perfect filters, such as two-band quadrature mirror filters or polyphase filters, are applied, aliasing terms will cancel and the sum of the bandpass outputs equals the source signal in the absence of quantization [19]–[22]. With quantization, aliasing components will not cancel ideally; nevertheless, the errors will be inaudible in MPEG/Audio coding if a sufficient number of bits is used. However, these errors may reduce the original dynamic range of 20 bits to around 18 bits [16].

In *transform coding*, a block of input samples is linearly transformed via a discrete transform into a set of near-uncorrelated transform coefficients. These coefficients are then quantized and transmitted in digital form to the decoder. In the decoder, an inverse transform maps the signal back into the time domain. In the absence of quantization errors, the synthesis yields exact reconstruction. Typical transforms are the Discrete Fourier Transform or the Discrete Cosine Transform (DCT), calculated via an FFT, and modified versions thereof. We have already mentioned that the decoder-based inverse transform can be viewed as the synthesis filterbank, the impulse responses of its bandpass filters equal the basis sequences of the transform. The impulse responses of the analysis filterbank are just the time-reversed versions thereof. The finite lengths of these impulse responses may cause so-called block boundary effects. State-of-the-art transform coders employ a *modified DCT* (MDCT) filterbank as proposed by Princen and Bradley [21]. The MDCT is typically based on a 50% overlap between successive analysis blocks. Without quantization they are free from block boundary effects, have a higher transform coding gain than the DCT, and their basis functions correspond to better bandpass responses. In the presence of quantization, block boundary effects are deemphasized due to the doubling of the filter impulse responses resulting from the overlap.

Hybrid filterbanks, i.e., combinations of discrete transform and filterbank implementations, have frequently been used in speech and audio coding [23, 24]. One of the advantages is that different frequency resolutions can be provided at different frequencies in a flexible way and with low complexity. A high spectral resolution can be obtained in an efficient way by using a cascade of a filterbank (with its short delays) and a linear MDCT transform that splits each subband sequence further in frequency content to achieve a high frequency resolution. MPEG-1/Audio coders use a subband approach in layers I and II, and a hybrid filterbank in layer III.

40.2.3 Window Switching

A crucial part in frequency domain coding of audio signals is the appearance of *pre-echoes*, similar to copying effects on analog tapes. Consider the case that a silent period is followed by a percussive sound, such as from castanets or triangles, within the same coding block. Such an onset (“attack”) will cause

comparably large instantaneous quantization errors. In TC, the inverse transform in the *decoding* process will distribute such errors over the block; similarly, in SBC, the decoder bandpass filters will spread such errors. In both mappings pre-echoes can become distinctively audible, especially at low bit rates with comparably high error contributions. Pre-echoes can be masked by the time domain effect of pre-masking if the time spread is of short length (in the order of a few milliseconds). Therefore, they can be reduced or avoided by using blocks of short lengths. However, a larger percentage of the total bit rate is typically required for the transmission of side information if the blocks are shorter. A solution to this problem is to switch between block sizes of different lengths as proposed by Edler (*window switching*) [25], typical block sizes are between $N = 64$ and $N = 1024$. The small blocks are only used to control pre-echo artifacts during nonstationary periods of the signal, otherwise the coder switches back to long blocks. It is clear that the block size selection has to be based on an analysis of the characteristics of the actual audio coding block. Figure 40.5 demonstrates the effect in transform coding: if the block size is $N = 1024$ [Fig. 40.5(b)] pre-echoes are clearly (visible and) audible whereas a block size of 256 will reduce these effects because they are limited to the block where the signal attack and the corresponding quantization errors occur [Fig. 40.5(c)]. In addition, pre-masking can become effective.

FIGURE 40.5: Window switching. (a) Source signal, (b) reconstructed signal with block size $N = 1024$, and (c) reconstructed signal with block size $N = 256$. (Source: Iwadare, M., Sugiyama, A., Hazu, F., Hirano, A., and Nishitani, T., IEEE J. Sel. Areas Commun., 10(1), 138-144, Jan. 1992.)

40.2.4 Dynamic Bit Allocation

Frequency domain coding significantly gains in performance if the number of bits assigned to each of the quantizers of the transform coefficients is adapted to short-term spectrum of the audio coding block on a block-by-block basis. In the mid-1970s, Zelinski and Noll introduced *dynamic bit allocation* and demonstrated significant SNR-based and subjective improvements with their adaptive transform coding (ATC, see Fig. 40.6 [15, 27]). They proposed a DCT mapping and a dynamic bit allocation algorithm which used the DCT transform coefficients to compute a DCT-based short-term spectral envelope. Parameters of this spectrum were coded and transmitted. From these parameters, the short-term spectrum was estimated using linear interpolation in the log-domain. This estimate was then used to calculate the optimum number of bits for each transform coefficient, both in the encoder and decoder.

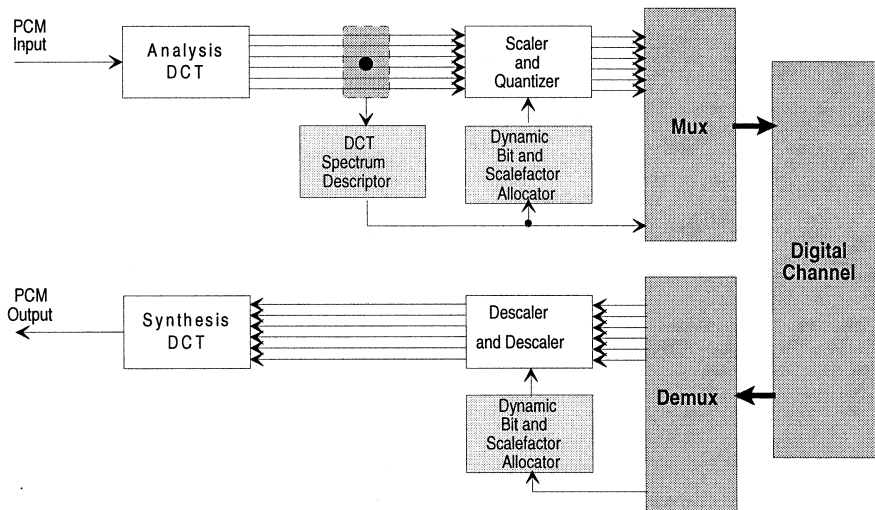

FIGURE 40.6: Conventional adaptive transform coding (ATC).

That ATC had a number of shortcomings, such as block boundary effects, pre-echoes, marginal exploitation of masking, and insufficient quality at low bit rates. Despite these shortcomings, we find many of the features of the conventional ATC in more recent frequency domain coders.

MPEG/Audio coding algorithms, described in detail in the next section, make use of the above key technologies.

40.3 MPEG-1/Audio Coding

The MPEG-1/Audio coding standard [8], [28]–[30] is about to become a universal standard in many application areas with totally different requirements in the fields of consumer electronics, professional audio processing, telecommunications, and broadcasting [31]. The standard combines features of *MUSICAM* and *ASPEC coding algorithms* [32, 33]. Main steps of development towards the MPEG-1/Audio standard have been described in [30, 34]. The MPEG-1/Audio standard represents the state of the art in audio coding. Its subjective quality is equivalent to CD quality (16-bit PCM) at stereo rates given in Table 40.3 for many types of music. Because of its high dynamic range, MPEG-1/audio

has potential to exceed the quality of a CD [31, 35].

TABLE 40.3 Approximate MPEG-1 Bit Rates for Transparent Representations of Audio Signals and Corresponding Compression Factors (Compared to CD Bit Rate)

MPEG-1 audio coding	Approximate stereo bit rates for transparent quality	Compression factor
Layer I	384 kb/s	4
Layer II	192 kb/s	8
Layer III	128 kb/s ^a	12

^a Average bit rate; variable bit rate coding assumed.

40.3.1 The Basics

Structure

The basic structure follows that of perception-based coders (see Fig. 40.4). In the first step, the audio signal is converted into spectral components via an analysis filterbank; layers I and II make use of a subband filterbank, layer III employs a hybrid filterbank. Each spectral component is quantized and coded with the goal to keep the quantization noise below the masking threshold. The number of bits for each subband and a scalefactor are determined on a block-by-block basis, each block has 12 (layer I) or 36 (layers II and III) subband samples (see Section 40.2). The number of quantizer bits is obtained from a dynamic bit allocation algorithm (layers I and II) that is controlled by a *psychoacoustic model* (see below). The subband codewords, scalefactor, and bit allocation information are multiplexed into one bitstream, together with a header and optional ancillary data. In the decoder, the synthesis filterbank reconstructs a block of 32 audio output samples from the demultiplexed bitstream.

MPEG-1/Audio supports sampling rates of 32, 44.1, and 48 kHz and bit rates between 32 kb/s (mono) and 448 kb/s, 384 kb/s, and 320 kb/s (stereo; layers I, II, and III, respectively). Lower sampling rates (16, 22.05, and 24 kHz) have been defined in MPEG-2 for better audio quality at bit rates at, or below, 64 kb/s per channel [9]. The corresponding maximum audio bandwidths are 7.5, 10.3, and 11.25 kHz. The syntax, semantics, and coding techniques of MPEG-1 are maintained except for a small number of parameters.

Layers and Operating Modes

The standard consists of three layers I, II, and III of increasing complexity, delay, and subjective performance. From a hardware and software standpoint, the higher layers incorporate the main building blocks of the lower layers (Fig. 40.7). A standard *full MPEG-1/Audio decoder* is able to decode bit streams of all three layers. The standard also supports MPEG-1/Audio *layer X decoders* ($X = \text{I, II, or III}$). Usually, a layer II decoder will be able to decode bitstreams of layers I and II, a layer III decoder will be able to decode bitstreams of all three layers.

Stereo Redundancy Coding

MPEG-1/Audio supports four *modes*: mono, stereo, dual with two separate channels (useful for bilingual programs), and joint stereo. In the optimal joint stereo mode, interchannel dependencies are exploited to reduce the overall bit rate by using an irrelevancy reducing technique called *intensity stereo*. It is known that above 2 kHz and within each critical band, the human auditory system bases its perception of stereo imaging more on the temporal envelope of the audio than on its temporal fine structure. Therefore, the MPEG audio compression algorithm supports a stereo redundancy

FIGURE 40.7: Hierarchy of layers I, II, and III of MPEG-1/Audio.

coding mode called *intensity stereo coding* which reduces the total bit rate without violating the spatial integrity of the stereophonic signal.

In intensity stereo mode, the encoder codes some upper-frequency subband outputs with a single sum signal $L + R$ (or some linear combination thereof) instead of sending independent left (L) and right (R) subband signals. The decoder reconstructs the left and right channels based only on the single $L + R$ signal and on independent left and right channel scalefactors. Hence, the spectral shape of the left and right outputs is the same within each intensity-coded subband but the magnitudes are different [36]. The optional joint stereo mode will only be effective if the required bit rate exceeds the available bit rate, and it will only be applied to subbands corresponding to frequencies of around 2 kHz and above.

Layer III has an additional option: in the mono/stereo (M/S) mode the left and right channel signals are encoded as middle ($L + R$) and side ($L - R$) channels. This latter mode can be combined with the joint stereo mode.

Psychoacoustic Models

We have already mentioned that the adaptive bit allocation algorithm is controlled by a psychoacoustic model. This model computes SMR taking into account the short-term spectrum of the audio block to be coded and knowledge about noise masking. The model is only needed in the encoder which makes the decoder less complex; this asymmetry is a desirable feature for audio playback and audio broadcasting applications.

The normative part of the standard describes the decoder and the meaning of the encoded bitstream, but the encoder is not standardized thus leaving room for an evolutionary improvement of the encoder. In particular, *different psychoacoustic models can be used* ranging from very simple (or none at all) to very complex ones based on quality and implementability requirements. Information about the short-term spectrum can be derived in various ways, for example, as an accurate estimate from an FFT-based spectral analysis of the audio input samples or, less accurate, directly from the spectral components as in the conventional ATC [15]; see also Fig. 40.6. Encoders can also be optimized for a certain application. All these encoders can be used with complete compatibility with all existing MPEG-1/Audio decoders.

The informative part of the standard gives two examples of FFT-based models; see also [8, 30, 37]. Both models identify, in different ways, tonal and non-tonal spectral components and use the corresponding results of tone-masks-noise and noise-masks-tone experiments in the calculation of the global masking thresholds. Details are given in the standard, experimental results for both psychoacoustic models are described in [37]. In the informative part of the standard a 512-point FFT is proposed for layer I, and a 1024-point FFT for layers II and III. In both models, the audio input samples are Hann-weighted. *Model 1*, which may be used for layers I and II, computes for

each masker its individual masking threshold, taking into account its frequency position, power, and tonality information. The global masking threshold is obtained as the sum of all individual masking thresholds and the absolute masking threshold. The SMR is then the ratio of the maximum signal level within a given subband and the minimum value of the global masking threshold in that given subband (see Fig. 40.2).

Model 2, which may be used for all layers, is more complex: tonality is assumed when a simple prediction indicates a high prediction gain, the masking thresholds are calculated in the cochlea domain, i.e., properties of the inner ear are taken into account in more detail, and, finally, in case of potential pre-echoes the global masking threshold is adjusted appropriately.

40.3.2 Layers I and II

MPEG layer I and II coders have very similar structures. The layer II coder achieves a better performance, mainly because the overall scalefactor side information is reduced exploiting redundancies between the scalefactors. Additionally, a slightly finer quantization is provided.

Filterbank

Layer I and II coders map the digital audio input into 32 subbands via equally spaced bandpass filters (Figs. 40.8 and 40.9). A polyphase filter structure is used for the frequency mapping; its filters have 512 coefficients. Polyphase structures are computationally very efficient because a DCT can be used in the filtering process, and they are of moderate complexity and low delay. On the negative side, the filters are equally spaced, and therefore the frequency bands do not correspond well to the critical band partition (see Section 40.2.1). At 48-kHz sampling rate, each band has a width of $24000/32 = 750$ Hz; hence, at low frequencies, a single subband covers a number of adjacent critical bands. The subband signals are resampled (critically decimated) at a rate of 1500 Hz. The impulse response of subband k , $h_{\text{sub}(k)}(n)$, is obtained by multiplication of the impulse response of a single *prototype lowpass filter*, $h(n)$, by a modulating function which shifts the lowpass response to the appropriate subband frequency range:

$$h_{\text{sub}(k)}(n) = h(n) \cos \left[\frac{(2k+1)\pi n}{2M} + \varphi(k) \right] ;$$

$$M = 32 ; k = 0, 1, \dots, 31 ; n = 0, 1, \dots, 511$$

The prototype lowpass filter has a 3-dB bandwidth of $750/2 = 375$ Hz, and the center frequencies are at odd multiples thereof (all values at 48 kHz sampling rate). The subsampled filter outputs exhibit a significant overlap. However, the design of the prototype filter and the inclusion of appropriate phase shifts in the cosine terms result in an aliasing cancellation at the output of the decoder synthesis filterbank. Details about the coefficients of the prototype filter and the phase shifts $\varphi(k)$ are given in the ISO/MPEG standard. Details about an efficient implementation of the filterbank can be found in [16] and [37], and, again, in the standardization documents.

Quantization

The number of quantizer levels for each spectral component is obtained from a dynamic bit allocation rule that is controlled by a psychoacoustic model. The bit allocation algorithm selects one uniform midtread quantizer out of a set of available quantizers such that both the bit rate requirement and the masking requirement are met. The iterative procedure minimizes the NMR in each subband. It starts with the number of bits for the samples and scalefactors set to zero. In each iteration step, the quantizer SNR(m) is increased for the one subband quantizer producing the largest value of the NMR at the quantizer output. (The increase is obtained by allocating one more bit). For that purpose, $\text{NMR}(m) = \text{SMR} - \text{SNR}(m)$ is calculated as the difference (in dB) between the actual quantization

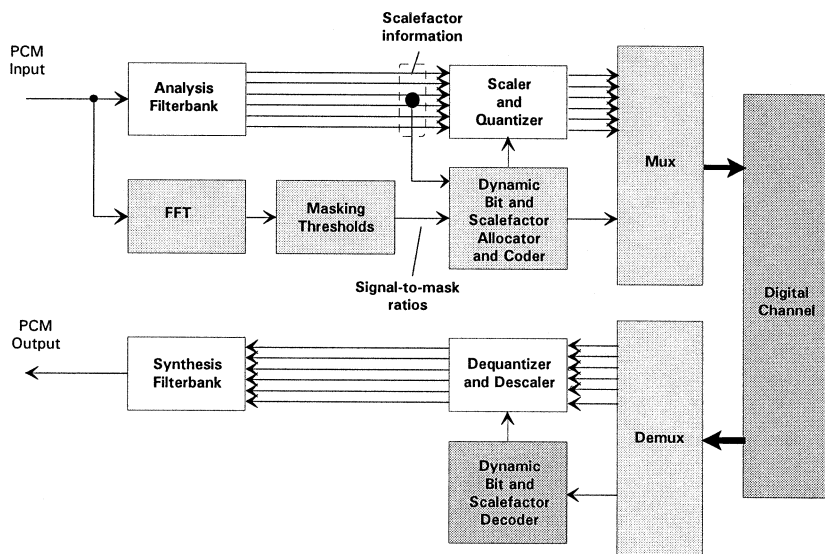

FIGURE 40.8: Structure of MPEG-1/Audio encoder and decoder, layers I and II.

noise level and the minimum global masking threshold. The standard provides tables with estimates for the quantizer SNR(m) for a given m .

Block companding is used in the quantization process, i.e., blocks of decimated samples are formed and divided by a *scalefactor* such that the sample of largest magnitude is unity. In *layer I* blocks of 12 decimated and scaled samples are formed in each subband (and for the left and right channel) and there is one bit allocation for each block. At 48-kHz sampling rate, 12 subband samples correspond to 8 ms of audio. There are 32 blocks, each with 12 decimated samples, representing $32 \times 12 = 384$ audio samples.

In *layer II* in each subband a 36-sample *superblock* is formed of three consecutive blocks of 12 decimated samples corresponding to 24 ms of audio at 48 kHz sampling rate. There is one bit allocation for each 36-sample superblock. All 32 superblocks, each with 36 decimated samples, represent, altogether, $32 \times 36 = 1152$ audio samples. As in layer I, a scalefactor is computed for each 12-sample block. A redundancy reduction technique is used for the transmission of the scalefactors: depending on the significance of the changes between the three consecutive scalefactors, one, two, or all three scalefactors are transmitted, together with a 2-bit *scalefactor select information*. Compared with layer I, the bit rate for the scalefactors is reduced by around 50% [30]. Figure 40.9 indicates the block companding structure.

The scaled and quantized spectral subband components are transmitted to the receiver together with scalefactor, scalefactor select (layer II), and bit allocation information. Quantization with block companding provides a very large dynamic range of more than 120 dB. For example, in layer II uniform midtrearad quantizers are available with 3, 5, 7, 9, 15, 31, . . . , 65535 levels for subbands of low index (low frequencies). In the mid and high frequency region, the number of levels is reduced significantly. For subbands of index 23 to 26 there are only quantizers with 3, 5, and 65535 (!) levels available. The 16-bit quantizers prevent overload effects. Subbands of index 27 to 31 are not transmitted at all. In order to reduce the bit rate, the codewords of three successive subband samples resulting from quantizing with 3-, 5, and 9-step quantizers are assigned one common codeword. The savings in bit rate is about 40% [30].

Figure 40.10 shows the time-dependence of the assigned number of quantizer bits in all subbands

FIGURE 40.9: Block companding in MPEG-1/Audio coders.

for a layer II encoded high quality speech signal. Note, for example, that quantizers with ten or more bits resolution are only employed in the lowest subbands, and that no bits have been assigned for frequencies above 18 kHz (subbands of index 24 to 31).

FIGURE 40.10: Time-dependence of assigned number of quantizer bits in all subbands for a layer II encoded high quality speech signal.

Decoding

The decoding is straightforward: the subband sequences are reconstructed on the basis of blocks of 12 subband samples taking into account the decoded scalefactor and bit allocation information. If a subband has no bits allocated to it, the samples in that subband are set to zero. Each time the subband samples of all 32 subbands have been calculated, they are applied to the *synthesis filterbank*, and 32 consecutive 16-bit PCM format audio samples are calculated. If available, as in bidirectional communications or in recorder systems, the encoder (analysis) filterbank can be used in a reverse mode in the decoding process.

40.3.3 Layer III

Layer III of the MPEG-1/Audio coding standard introduces many new features (see Fig. 40.11), in particular a switched hybrid filterbank. In addition, it employs an analysis-by-synthesis approach, an advanced pre-echo control, and nonuniform quantization with entropy coding. A buffer technique, called *bit reservoir*, leads to further savings in bit rate. Layer III is the only layer that provides mandatory decoder support for variable bit rate coding [38].

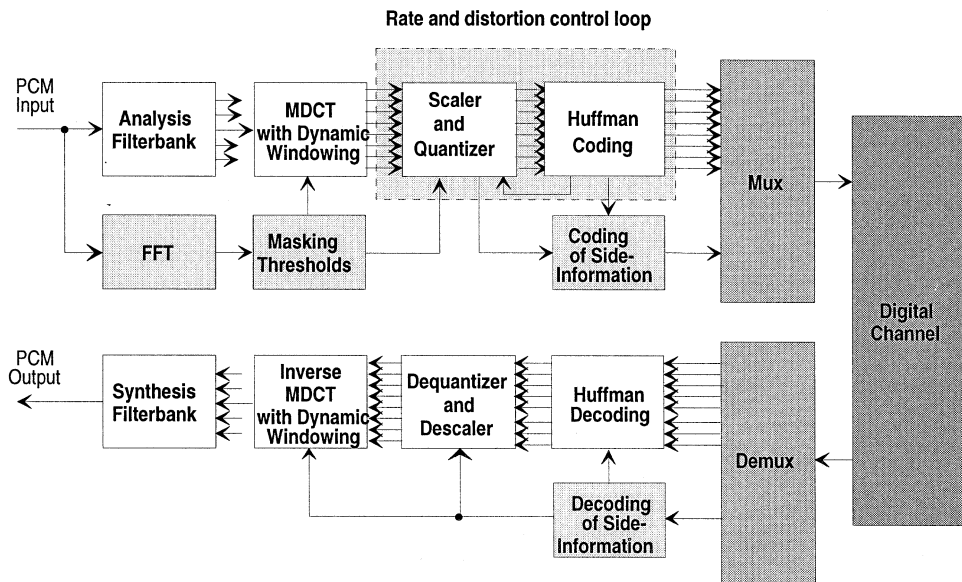

FIGURE 40.11: Structure of MPEG-1/Audio encoder and decoder, layer III.

Switched Hybrid Filterbank

In order to achieve a higher frequency resolution closer to critical band partitions, the 32 subband signals are subdivided further in frequency content by applying, to each of the subbands, a 6- or 18-point modified DCT block transform, with 50% overlap; hence, the windows contain, respectively, 12 or 36 subband samples. The maximum number of frequency components is $32 \times 18 = 576$ each representing a bandwidth of only $24000/576 = 41.67$ Hz. Because the 18-point block transform provides better frequency resolution, it is normally applied, whereas the 6-point block transform provides better time resolution and is applied in case of expected pre-echoes (see Section 40.2.3). In principle, a pre-echo is assumed, when an instantaneous demand for a high number of bits occurs. Depending on the nature of potential, all pre-echoes or a smaller number of transforms are switched. Two special MDCT windows, a start window and a stop window, are needed in case of transitions between short and long blocks and vice versa to maintain the time domain alias cancellation feature of the MDCT [22, 25, 37]. Figure 40.12 shows a typical sequence of windows.

Quantization and Coding

The MDCT output samples are nonuniformly quantized thus providing both smaller mean-squared errors and masking because larger errors can be tolerated if the samples to be quantized

FIGURE 40.12: Typical sequence of windows in adaptive window switching.

are large. Huffman coding, based on 32 code tables, and additional run-length coding are applied to represent the quantizer indices in an efficient way. The encoder maps the variable wordlength codewords of the Huffman code tables into a constant bit rate by monitoring the state of a bit reservoir. The bit reservoir ensures that the decoder buffer neither underflows nor overflows when the bitstream is presented to the decoder at a constant rate.

In order to keep the quantization noise in all critical bands below the global masking threshold (noise allocation) an *iterative analysis-by-synthesis method* is employed whereby the process of scaling, quantization, and coding of spectral data is carried out within two nested iteration loops. The decoding follows that of the encoding process.

40.3.4 Frame and Multiplex Structure

Frame Structure

Figure 40.13 shows the frame structure of MPEG-1/Audio coded signals, both for layer I and layer II. Each frame has a header; its first part contains 12 synchronisation bits, 20 bit system information, and an optional 16-bit cyclic redundancy check code. Its second part contains side information about the bit allocation and the scalefactors (and, in layer II, scalefactor information). As main information, a frame carries a total of 32×12 subband samples (corresponding to 384 PCM audio input sample — equivalent to 8 ms at a sampling rate of 48 kHz) in layer I, and a total of 32×36 subband samples in layer II (corresponding to 1152 PCM audio input samples — equivalent to 24 ms at a sampling rate of 48 kHz). Note that the layer I and II frames are autonomous: each frame contains all information necessary for decoding. Therefore, each frame can be decoded independently from previous frames, it defines an entry point for audio storage and audio editing applications. Please note that the lengths of the frames are not fixed, due to (1) the length of the main information field, which depends on bit-rate and sampling frequency, (2) the side information field which varies in layer II, and (3) the ancillary data field, the length of which is not specified.

FIGURE 40.13: MPEG-1 frame structure and packetization. Layer I: 384 subband samples; layer II: 1152 subband samples; packets P: 4-byte header; 184-byte payload field (see also Fig. 40.14).

Multiplex Structure

We have already mentioned that the systems part of the MPEG-1 coding standard IS 11172 defines a *packet structure for multiplexing* audio, video, and ancillary data bitstreams in one stream. The variable-length MPEG frames are broken down into packets. The packet structure uses 188-byte packets consisting of a 4-byte header followed by 184 bytes of payload (see Fig. 40.14). The header

FIGURE 40.14: MPEG packet delivery.

includes a sync byte, a 13-bit field called packet identifier to inform the decoder about the type of data, and additional information. For example, a *1-bit payload unit start indicator* indicates if the payload starts with a frame header. No predetermined mix of audio, video, and ancillary data bitstreams is required, the mix may change dynamically, and services can be provided in a very flexible way. If additional header information is required, such as for periodic synchronization of audio and video timing, a variable-length *adaptation header* can be used as part of the 184-byte payload field.

Although the lengths of the frames are not fixed, the interval between frame headers is constant (within a byte) throughout the use of padding bytes. The MPEG systems specification describes how MPEG-compressed audio and video data streams are to be multiplexed together to form a single data stream. The terminology and the fundamental principles of the systems layer are described in [39].

40.3.5 Subjective Quality

The standardization process included extensive subjective tests and objective evaluations of parameters such as complexity and overall delay. The MPEG (and equivalent ITU-R) listening tests were carried out under very similar and carefully defined conditions with around 60 experienced listeners, approximately 10 test sequences were used, and the sessions were performed in stereo with both loudspeakers and headphones. In order to detect even small impairments, the 5-point ITU-R impairment scale was used in all experiments. Details are given in [40] and [41]. *Critical test items were chosen in the tests to evaluate the coders by their worst case (not average) performance.* The subjective evaluations, which have been based on triple stimulus/hidden reference/double blind tests, have shown very similar and stable evaluation results. In these tests the subject is offered three signals, A,B, and C (triple stimulus). A is always the unprocessed source signal (the reference). B and C, or C and B, are the reference and the system under test (hidden reference). The selection is neither known to the subjects nor to the conductors(s) of the test (double blind test). The subjects have to decide if B or C is the reference and have to grade the remaining one.

The MPEG-1/Audio coding standard has shown an excellent performance for all layers at the

rates given in Table 40.3. It should be mentioned again that the standard leaves room for encoder-based improvements by using better psychoacoustic models. Indeed, many improvements have been achieved since the first subjective results had been carried out in 1991.

40.4 MPEG-2/Audio Multichannel Coding

A logical further step in digital audio is the definition of a multichannel audio representation system to create a convincing, lifelike soundfield both for audio-only applications and for audiovisual systems, including video conferencing, videophony, multimedia services, and electronic cinema. Multichannel systems can also provide multilingual channels and additional channels for visually impaired (a verbal description of the visual scene) and for hearing impaired (dialog with enhanced intelligibility). ITU-R has recommended a five-channel loudspeaker configuration, referred to as 3/2-stereo, with a left and a right channel (L and R), an additional center channel C, two side/rear surround channels (LS and RS) augmenting the L and R channels, see Fig. 40.15 [ITU-R Rec. 775]. Such a configuration offers an improved realism of auditory ambience with a stable frontal sound image and a large listening area.

Multichannel digital audio systems support p/q presentations with p front and q back channels, and also provide the possibilities of transmitting two independent stereophonic programs and/or a number of commentary or multilingual channels. Typical combinations of channels include.

- 1 channel 1/0-configuration: centre (mono)
- 2 channels 2/0-configuration: left, right (stereophonic)
- 3 channels 3/0-configuration: left, right, centre
- 4 channels: 3/1-configuration left, right, centre, mono-surround
- 5 channels: 3/2-configuration: left, right, centre, surround left, surround right

FIGURE 40.15: 3/2 Multichannel loudspeaker configuration.

ITU-R Recommendation 775 provides a set of downward mixing equations if the number of loudspeakers is to be reduced (*downward compatibility*). An additional *low frequency enhancement (LFE-or subwoofer-) channel* is particularly useful for HDTV applications, it can be added, optionally, to any of the configurations. The LFE channel extends the low frequency content between 15 and 120 Hz in terms of both frequency and level.

One or more loudspeakers can be positioned freely in the listening room to reproduce this LFE signal. (Film industry uses a similar system for their digital sound systems).¹

In order to reduce the overall bit rate of multichannel audio coding systems, redundancies and irrelevancy, such as interchannel dependencies and interchannel masking effects, respectively, may be exploited. In addition, stereophonic-irrelevant components of the multichannel signal, which do not contribute to the localization of sound sources, may be identified and reproduced in a monophonic format to further reduce bit rates. State-of-the-art multichannel coding algorithms make use of such effects. A careful design is needed, otherwise such joint coding may produce artifacts.

40.4.1 MPEG-2/Audio Multichannel Coding

The second phase of MPEG, labeled MPEG-2, includes in its audio part two multichannel audio coding standards, one of which is forward- and backward-compatible with MPEG-1/Audio [8], [42]–[45]. *Forward compatibility* means that an MPEG-2 multichannel decoder is able to properly decode MPEG-1 mono or stereophonic signals, *backward compatibility* (BC) means that existing MPEG-1 stereo decoders, which only handle two-channel audio, is able to reproduce a meaningful basic 2/0 stereo signal from a MPEG-2 multichannel bit stream so as to serve the need of users with simple mono or stereo equipment. *Non-backward compatible* (NBC) multichannel coders will not be able to feed a meaningful bit stream into a MPEG-1 stereo decoder. On the other hand, NBC codecs have more freedom in producing a high quality reproduction of audio signals.

With backward compatibility, it is possible to introduce multichannel audio at any time in a smooth way without making existing two-channel stereo decoders obsolete. An important example is the European Digital Audio Broadcast system, which will require MPEG-1 stereo decoders in the first generation but may offer multichannel audio at a later point.

40.4.2 Backward-Compatible (BC) MPEG-2/Audio Coding

BC implies the use of compatibility matrices. A down-mix of the five channels (“matrixing”) delivers a correct basic 2/0 stereo signal, consisting of a left and a right channel, LO and RO , respectively. A typical set of equations is

$$\begin{aligned} LO &= \alpha (L + \beta \cdot C + \delta \cdot LS) \\ RO &= \alpha (R + \beta \cdot C + \delta \cdot RS) \end{aligned} \quad \alpha = \frac{1}{1+\sqrt{2}}; \beta = \delta = \sqrt{2}$$

Other choices are possible, including $LO = L$ and $RO = R$. The factors α , β , and δ attenuate the signals to avoid overload when calculating the compatible stereo signal (LO , RO). The signals LO and RO are transmitted in MPEG-1 format in transmission channels $T1$ and $T2$. Channels $T3$, $T4$, and $T5$ together form the *multichannel extension signal* (Fig. 40.16). They have to be chosen such that the decoder can recompute the complete 3/2-stereo multichannel signal. Interchannel redundancies and masking effects are taken into account to find the best choice. A simple example is $T3 = C$, $T4 = LS$, and $T5 = RS$. In MPEG-2 the matrixing can be done in a very flexible and even time-dependent way.

BC is achieved by transmitting the channels LO and RO in the subband-sample section of the MPEG-1 audio frame and all multichannel extension signals $T3$, $T4$, and $T5$ in the first part of the MPEG-1/Audio frame reserved for ancillary data. This ancillary data field is ignored by MPEG-1

¹ A 3/2-configuration with five high-quality full-range channels plus a subwoofer channel is often called a 5.1 system.

FIGURE 40.16: Compatibility of MPEG-2 multichannel audio bit streams.

decoders (see Fig. 40.17). The length of the ancillary data field is not specified in the standard. If the decoder is of type MPEG-1, it uses the 2/0-format front left and right down-mix signals, LO' and RO' , directly (see Fig. 40.18). If the decoder is of type MPEG-2, it recomputes the complete 3/2-stereo multichannel signal with its components L' , R' , C' , LS' , and RS' via “dematrixing” of LO' , RO' , $T3'$, $T4'$, and $T5'$ (see Fig. 40.16).

FIGURE 40.17: Data format of MPEG audio bit streams. a.) MPEG-1 audio frame; b.) MPEG-2 audio frame, compatible with MPEG-1 format.

Matrixing is obviously necessary to provide BC; however, if used in connection with perceptual coding, “unmasking” of quantization noise may appear [46]. It may be caused in the dematrixing process when sum and difference signals are formed. In certain situations, such a masking sum or difference signal component can disappear in a specific channel. Since this component was supposed to mask the quantization noise in that channel, this noise may become audible. Note that the masking signal will still be present in the multichannel representation but it will appear on a different loudspeaker. Measures against “unmasking” effects have been described in [47].

MPEG-1 decoders have a bit rate limitation (384 kb/s in layer II). In order to overcome this limitation, the MPEG-2 standard allows for a second bit stream, the extension part, to provide

FIGURE 40.18: MPEG-1 stereo decoding of MPEG-2 multichannel bit stream.

compatible multichannel audio at higher rates. Figure 40.19 shows the structure of the bit stream with extension.

FIGURE 40.19: Data format of MPEG-2 audio bit stream with extension part.

40.4.3 Advanced/MPEG-2/Audio Coding (AAC)

A second standard within MPEG-2 supports applications that do not request compatibility with the existing MPEG-1 stereo format. Therefore, matrixing and dematrixing are not necessary and the corresponding potential artifacts disappear (see Fig. 40.20). The advanced multichannel coding mode will have the sampling rates, audio bandwidth, and channel configurations of MPEG-2/Audio, but shall be capable of operating at bit rates from 32kb/s up to a bit rate sufficient for high quality audio.

The last two years have seen extensive activities to optimize and standardize a MPEG-2 AAC algorithm. Many companies around the world contributed advanced audio coding algorithms in a collaborative effort to come up with a flexible high quality coding standard [44]. The MPEG-2 AAC standard employs high resolution filter banks, prediction techniques, and Huffman coding.

Modules

The MPEG-2 AAC standard is based on recent evaluations and definitions of basic modules each having been selected from a number of proposals. The self-contained modules include:

- optional preprocessing
- time-to-frequency mapping (filterbank)

FIGURE 40.20: Non-backward-compatible MPEG-2 multichannel audio coding (advanced audio coding).

- psychoacoustic modeling
- prediction
- quantization and coding
- noiseless coding
- bit stream formatter

Profiles

In order to serve different needs, the standard will offer three profiles:

1. main profile
2. low complexity profile
3. sampling-rate-scaleable profile

For example, in its main profile, the filter bank is a modified discrete cosine transform of blocklength 2048 or 256, it allows for a frequency resolution of 23.43 Hz and a time resolution of 2.6 ms (both at a sampling rate of 48 kHz). In the case of the long blocklength, the window shape can vary dynamically as a function of the signal; a temporal noise shaping tool is offered to control the time dependence of the quantization noise; time domain prediction with second order backward-adaptive linear predictors reduces the bit rate for coding subsequent subband samples in a given subband; iterative non-uniform quantization and noiseless coding are applied.

The low complexity profile does not employ temporal noise shaping and time domain prediction, whereas in the sampling-rate-scaleable profile a preprocessing module is added that allows for sampling rates of 6, 12, 18, and 24 kHz. The default configurations of MPEG-2 AAC include 1.0, 2.0, and 5.1 (mono, stereo, and five channel with LFE-channel). However, 16 configurations can be defined in the encoder. A detailed description of the MPEG-2 AAC multichannel standard can be found in the literature [44].

The above listed selected modules define the MPEG-2/AAC standard which became International Standard in April 1997 as an extension to MPEG-2 (*ISO/MPEG 13818 - 7*). The standard offers high quality at lowest possible bit rates between 320 and 384 kb/s for five channels, it will find many applications, both for consumer and professional use.

40.4.4 Simulcast Transmission

If bit rates are not of high concern, a *simulcast transmission* may be employed where a full MPEG-1 bitstream is multiplexed with the full MPEG-2 AAC bit stream in order to support BC without matrixing techniques (Fig. 40.21).

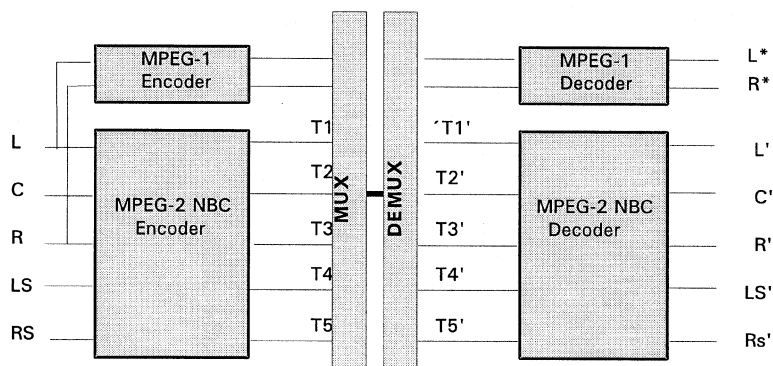

FIGURE 40.21: BC MPEG-2 multichannel audio coding (simulcast mode).

40.4.5 Subjective Tests

First subjective tests, independently run at German Telekom and BBC (UK) under the umbrella of the MPEG-2 standardization process had shown a satisfactory average performance of NBC and BC coders. The tests had been carried out with experienced listeners and critical test items at low bit rates (320 and 384 kb/s). However, all codecs showed deviations from transparency for some of the test items [48, 49]. Very recently [50], extensive formal subjective tests have been carried out to compare MPEG-2 AAC coders, operating, respectively, at 256 and 320 kb/s, and a BC MPEG-2 layer II coder,² operating at 640 kb/s. All coders showed a very good performance, with a slight advantage of the 320 kb/s MPEG-2 AAC coder compared with the 640 kb/s MPEG-2 layer II BC coder. The performances of those coders are indistinguishable from the original in the sense of the EBU definition of *indistinguishable quality* [51].

40.5 MPEG-4/Audio Coding

Activities within MPEG-4 aim at proposals for a broad field of applications including multimedia. MPEG-4 will offer higher compression rates, and it will merge the whole range of audio from high fidelity audio coding and speech coding down to synthetic speech and synthetic audio. In order to represent, integrate, and exchange pieces of audio-visual information, MPEG-4 offers standard tools which can be combined to satisfy specific user requirements [52]. A number of such configurations may be standardized. A syntactic description will be used to convey to a decoder the choice of tools made by the encoder. This description can also be used to describe new algorithms and download their configuration to the decoding processor for execution. The current toolset supports audio and speech compression at monophonic bit rates ranging from 2 to 64 kb/s. Three *core coders* are used:

1. a parametric coding scheme for low bit rate speech coding
2. an analysis-by-synthesis coding scheme for medium bit rates (6 to 16 kb/s)
3. a subband/transform-based coding scheme for higher bit rates.

These three coding schemes have been integrated into a so-called verification model that describes the operations both of encoders and decoders, and that is used to carry out simulations and optimizations.

²A 1995 version of this latter coder was used, therefore its test results do not reflect any subsequent enhancements.

In the end, the verification model will be the embodiment of the standard [52]. Let us also note that MPEG-4 will offer new functionalities such as time scale changes, pitch control, edibility, database access, and scalability, which allows extraction from the transmitted bitstream of a subset sufficient to generate audio signals with lower bandwidth and/or lower quality depending on channel capacity or decoder complexity. MPEG-4 will become an international standard in November 1998.

40.6 Applications

MPEG/Audio compression technologies will play an important role in consumer electronics, professional audio, telecommunications, broadcasting, and multimedia. A few, but typical application fields are described in the following.

Main applications will be based on delivering digital audio signals over terrestrial and satellite-based digital *broadcast and transmission systems* such as subscriber lines, program exchange links, cellular mobile radio networks, cable-TV networks, local area networks, etc. [53]. For example, in narrowband *Integrated Services Digital Networks* (ISDN) customers have physical access to one or two 64-kb/s B channels and one 16-kb/s D channel (which supports signaling but can also carry user information). Other configurations are possible including $p \times 64$ kb/s ($p = 1, 2, 3, \dots$) services. ISDN rates offer useful channels for a practical distribution of stereophonic and multichannel audio signals.

Because ISDN is a bidirectional service, it also provides upstream paths for future on-demand and interactive audiovisual *just-in-time audio* services. The backbone of digital telecommunication networks will be broadband (B-) ISDN with its cell-oriented structure. Cell delays and cell losses are sources of distortions to be taken into account in designs of digital audio systems [54].

Lower bit rates than those given by the 16-bit PCM format are mandatory if audio signals are to be stored efficiently on *storage media*—although the upcoming digital versatile disk (DVD) with its capacity of 4.7 GB relieves the pressure for extreme compression factors. In the field of digital storage on digital audio tape and (re-writeable) disks, a number of MPEG-based consumer products have recently reached the audio market. Of these products, Philips *Digital Compact Cassette* (DCC) essentially makes use of layer I of the MPEG-1/Audio coder employing its 384 kb/s stereo rate; its audio coding algorithm is called PASC (*Precision Audio Subband Coding*) [16]. The DCC encoder obtains an estimate of the short-term spectrum directly from the 32 subbands.

In the movie theater world, a 7.1-channel configuration is becoming popular due to an improved front-back stability of the stereo image and an improved impression of spaciousness. A scalable 7.1-channel reproduction is applied in the digital video disc (DVD). It is based on the MPEG-1 and MPEG-2 standards by down-mixing the 7-channel signal into a 5-channel signal, and a subsequent down-mixing of the latter one into a 2-channel signal [55]. The 2-channel signal, three contributions from the 5-channel signal, and two contributions from the 7-channel signal can then be transmitted or stored. The decoder uses the 2-channel signal directly, or it employs matrixing to reconstruct 5- or 7-channel signals. Other formats are possible, such as storing a 5-channel signal and an additional stereo signal in simulcast mode, without down-mixing the stereo signal from the multichannel signal.

A further example is solid state audio playback systems (e.g., for announcements) with the compressed data stored on chip-based memory cards or smart cards. One example is NEC's prototype *Silicon Audio Player* which uses a one-chip MPEG-1/Audio layer II decoder and offers 24 min of stereo at its recommended stereo bit rate of 192 kb/s [56].

A number of decisions concerning the introduction of *digital audio broadcast* (DAB) and digital video broadcast (DVB) services have been made recently. In Europe, a project group named Eureka 147 has worked out a DAB system able to cope with the problems of digital broadcasting [57]–[59]. ITU-R has recommended the MPEG-1/Audio coding standard after it had made extensive subjective tests. Layer II of this standard is used for program emission, the Layer III version is recommended

for commentary links at low rates. The sampling rate is 48 kHz in all cases, the ancillary data field is used for program associated data (PAD information). The DAB system has a significant bit rate overhead for error correction based on punctured convolutional codes in order to support *source-adapted channel coding*, i.e., an unequal error protection that is in accordance with the sensitivity of individual bits or a group of bits to channel errors [60]. Additionally, error concealment techniques will be applied to provide a *graceful degradation* in case of severe errors. In the U.S. a standard has not yet been defined. Simulcasting analog and digital versions of the same audio program in the FM terrestrial band (88 to 108 MHz) is an important issue (whereas the European solution is based on new channels) [61].

As examples of satellite-based digital broadcasting, we mention the Hughes DirecTV satellite subscription television system and ADR (Astra Digital Radio) both of which make use of MPEG-1 layer II. As a further example, the Eutelsat SaRa system will be based on layer III coding.

Advanced digital TV systems provide HDTV delivery to the public by terrestrial broadcasting and a variety of alternate media and offer full-motion high resolution video and high quality multichannel surround audio. The overall bit rate may be transmitted within the bandwidth of an analog UHF television channel. The U.S. *Grand Alliance HDTV* system and the European *Digital Video Broadcast (DVB)* system both make use of the MPEG-2 video compression system and of the MPEG-2 transport layer which uses a flexible ATM-like packet protocol with headers/descriptors for multiplexing audio and video bit streams in one stream with the necessary information to keep the streams synchronized when decoding. The systems differ in the way the audio signal is compressed: the Grand Alliance system will use Dolby's AC-3 transform coding technique [62]–[64], whereas the DVB system will use the MPEG-2/Audio algorithm.

40.7 Conclusions

Low bit rate digital audio is applied in many different fields, such as consumer electronics, professional audio processing, telecommunications, and broadcasting. Perceptual coding in the frequency domain has paved the way to high compression rates in audio coding. ISO/MPEG-1/Audio coding with its three layers has been widely accepted as an international standard. Software encoders, single DSP chip implementations, and computer extensions are available from a number of suppliers.

In the area of broadcasting and mobile radio systems, services are moving to portable and handheld devices, and new, third generation mobile communication networks are evolving. Coders for these networks must not only operate at low bit rates but must be stable in burst-error and packet- (cell-) loss environments. Error concealment techniques will play a significant role. Due to the lack of available bandwidth, traditional channel coding techniques may not be able to sufficiently improve the reliability of the channel.

MPEG/Audio coders are controlled by psychoacoustic models which may be improved thus leaving room for an evolutionary improvement of codecs. In the future, we will see new solutions for encoding. A better understanding of binaural perception and of stereo presentation will lead to new proposals.

Digital multichannel audio improves stereophonic images and will be of importance both for audio-only and multimedia applications. MPEG-2/audio offers both BC and NBC coding schemes to serve different needs. Ongoing research will result in enhanced multichannel representations by making better use of interchannel correlations and interchannel masking effects to bring the bit rates further down. We can also expect solutions for special presentations for people with impairments of hearing or vision which can make use of the multichannel configurations in various ways.

Emerging activities of the ISO/MPEG expert group aim at proposals for audio coding which will offer higher compression rates, and which will merge the whole range of audio from high fidelity audio coding and speech coding down to synthetic speech and synthetic audio (ISO/IEC MPEG-4).

Because the basic audio quality will be more important than compatibility with existing or upcoming standards, this activity will open the door for completely new solutions.

41.1 Overview

In order to more efficiently transmit or store high-quality audio signals, it is often desirable to reduce the amount of information required to represent them. In the case of digital audio signals, the amount of binary information needed to accurately reproduce the original pulse code modulation (PCM) samples may be reduced by applying compression algorithm. A primary goal of audio compression algorithms is to maximally reduce the amount of digital information (bit-rate) required for conveyance of an audio signal while rendering differences between the original and decoded signals inaudible.

Digital audio compression is useful wherever there is an economic benefit realized by reducing the bit-rate. Typical applications are in satellite or terrestrial audio broadcasting, delivery of audio over electrical or optical cables, or storage of audio on magnetic, optical, semiconductor, or other storage media. One application which has received considerable attention in the United States is digital television (DTV). Audio and video compression are both necessary in DTV to meet the requirement that one high-definition DTV channel fit within the 6 MHz transmission bandwidth occupied by one preexisting NTSC (analog) channel. In December 1996, the United States Federal Communications Commission adopted the ATSC standard for DTV which is consistent with a consensus agreement developed by a broad cross-section of parties, including the broadcasting and computer industries. The audio technology used in the ATSC digital audio compression standard [1] is Dolby AC-3.

Dolby AC-3 is an audio compression technology capable of encoding a range of audio channel formats into a bit stream ranging from 32 kb/s to 640 kb/s. AC-3 technology is primarily targeted toward delivery of multiple discrete channels intended for simultaneous presentation to consumers. Channel formats range from 1 to 5.1 channels, and may include a number of associated audio

services. The 5.1 channel format consists of five full bandwidth (20 kHz) channels plus an optional low frequency effects (lfe or subwoofer) channel.

A typical application of the algorithm is shown in Fig. 41.1. In this example, a 5.1 channel audio program is converted from a PCM representation requiring more than 5 Mbps ($6 \text{ channels} \times 48 \text{ kHz} \times 18 \text{ bits} = 5.184 \text{ Mbps}$) into a 384 kbps serial bit stream by the AC-3 encoder. Satellite transmission equipment converts this bit stream to an RF transmission which is directed to a satellite transponder. The amount of bandwidth and power required by the transmission has been reduced by more than a factor of 13 by the AC-3 digital compression. The signal received from the satellite is demodulated back into the 384 kbps serial bit stream, and decoded by the AC-3 decoder. The result is the original 5.1 channel audio program.

FIGURE 41.1: Example application of satellite transmission using AC-3.

There are a diverse set of requirements for a coder intended for widespread application. While the most critical members of the audience may be anticipated to have complete 6-speaker multi-channel reproduction systems, most of the audience may be listening in mono or stereo, and still others will have three front channels only. Some of the audience may have matrix-based (e.g., Dolby Surround) multi-channel reproduction equipment without discrete channel inputs, thus requiring a dual-channel matrix-encoded output from the AC-3 decoder. Most of the audience welcomes a restricted dynamic range reproduction, while a few in the audience will wish to experience the full dynamic range of the original signal. The visually and hearing impaired wish to be served. All of these and other diverse needs were considered early in the AC-3 design process. Solutions to these requirements have been incorporated from the beginning, leading to a self-contained and efficient system.

As an example, one of the more important listener features built-in to AC-3 is dynamic range compression. This feature allows the program provider to implement subjectively pleasing dynamic range reduction for most of the intended audience, while allowing individual members of the audience

the option to experience more (or all) of the original dynamic range. At the discretion of the program originator, the encoder computes dynamic range control values and places them into the AC-3 bit stream. The compression is actually applied in the decoder, so the encoded audio has full dynamic range. It is permissible (under listener control) for the decoder to fully or partially apply the dynamic range control values. In this case, some of the dynamic range will be limited. It is also permissible (again under listener control) for the decoder to ignore the control words, and hence reproduce full-range audio. By default, AC-3 decoders will apply the compression intended by the program provider.

Other user features include decoder downmixing to fewer channels than were present in the bit stream, dialog normalization, and Dolby Surround compatibility. A complete description of these features and the rest of the ATSC Digital Audio Compression Standard is contained in [1].

AC-3 achieves high coding gain (the ratio of the encoder input bit-rate to the encoder output bit-rate) by quantizing a frequency domain representation of the audio signal. A block diagram of this process is shown in Fig. 41.2. The first step in the encoding process is to transform the representation of audio from a sequence of PCM signal sample blocks into a sequence of frequency coefficient blocks. This is done in the analysis filter bank as follows. Signal sample blocks of length 512 are multiplied by a set of window coefficients and then transformed into the frequency domain. Each sample block is overlapped by 256 samples with the two adjoining blocks. Due to the overlap, every PCM input sample is represented in two adjacent transformed blocks. The frequency domain representation includes decimation by an extra factor of two so that each frequency block contains only 256 coefficients. The individual frequency coefficients are then converted into a binary exponential notation as a binary exponent and a mantissa. The set of exponents is encoded into a coarse representation of the signal spectrum which is referred to as the spectral envelope. This spectral envelope is processed by a bit allocation routine to calculate the amplitude resolution required for encoding each individual mantissa. The spectral envelope and the quantized mantissas for 6 audio blocks (1536 audio samples) are formatted into one AC-3 synchronization frame. The AC-3 bit stream is a sequence of consecutive AC-3 frames.

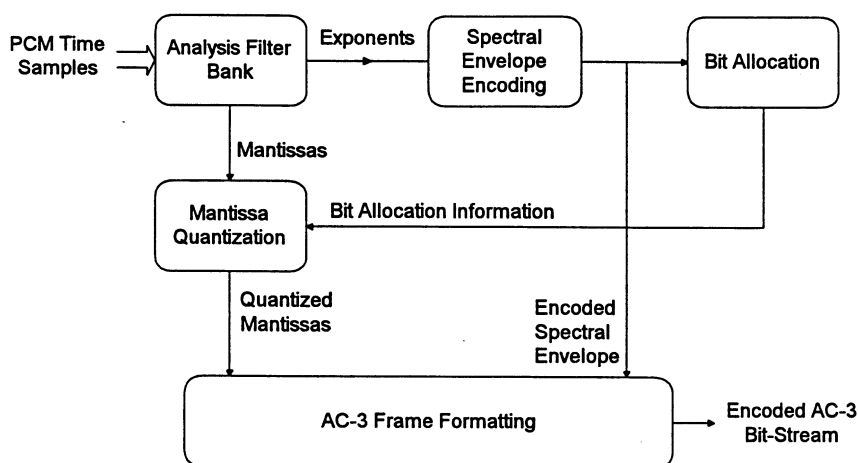

FIGURE 41.2: The AC-3 Encoder.

The decoding process is essentially a mirror-inverse of the encoding process. The decoder, shown in Fig. 41.3, must synchronize to the encoded bit stream, check for errors, and deformat the various types

of data such as the encoded spectral envelope and the quantized mantissas. The spectral envelope is decoded to reproduce the exponents. The bit allocation routine is run and the results used to unpack and dequantize the mantissas. The exponents and mantissas are recombined into frequency coefficients, which are then transformed back into the time domain to produce decoded PCM time samples. Figs. 41.2 and 41.3 present a somewhat simplified, high-level view of an AC-3 encoder and decoder.

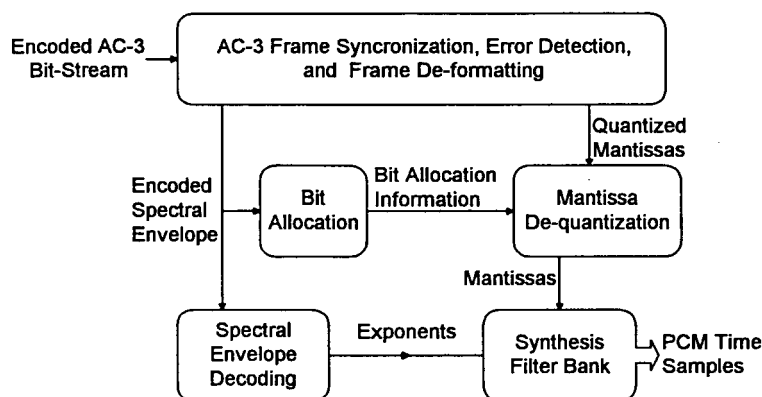

FIGURE 41.3: The AC-3 Decoder.

Table 41.1 presents the different channel formats that are accommodated by AC-3. The three-bit control variable *acmod* is embedded in the bit stream to convey the encoder channel configuration to the decoder. If *acmod* is '000', then two completely independent program channels (dual mono) are encoded into the bit stream (referenced as Ch1, Ch2). The traditional mono and stereo formats are denoted when *acmod* equals '001' and '010', respectively. If *acmod* is greater than '100', the bit stream format includes one or more surround channels. The optional lfe channel is enabled/disabled by a separate control bit called *lfeon*.

TABLE 41.1 AC-3 Audio Coding Modes

<i>acmod</i>	Audio coding mode	Number of full bandwidth channels	Channel array ordering
'000'	1 + 1	2	Ch1, Ch2
'001'	1/0	1	C
'010'	2/0	2	L, R
'011'	3/0	3	L, C, R
'100'	2/1	3	L, R, S
'101'	3/1	4	L, C, R, S
'110'	2/2	4	L, R, SL, SR
'111'	3/2	5	L, C, R, SL, SR

Table 41.2 presents the different bit-rates that are accommodated by AC-3. The six-bit control variable *frmsizecod* is embedded in the bit stream to convey the encoder bit-rate to the decoder. In principle, it is possible to use the bit-rates in Table 41.2 with any of the channel formats from Table 41.1. However, in high-quality applications employing the best known encoder, the typical bit-rate for 2 channels is 192 kb/s, and for 5.1 channels is 384 kb/s. As AC-3 encoding technologies mature in the future, these bit-rates can be expected to drop farther.

TABLE 41.2 AC-3 Audio Coding Bit-Rates

frmsizecod	Nominal bit-rate (kb/sec)	frmsizecod	Nominal bit-rate (kb/sec)	frmsizecod	Nominal bit-rate (kb/sec)
0	32	14	112	28	384
2	40	16	128	30	448
4	48	18	160	32	512
6	56	20	192	34	576
8	64	22	224	36	640
10	80	24	256		
12	96	26	320		

41.2 Bit Stream Syntax

An AC-3 serial coded audio bit stream is composed of a contiguous sequence of synchronization frames. A synchronization frame is defined as the minimum-length bit stream unit which can be decoded independently of any other bit stream information. Each synchronization frame represents a time interval corresponding to 1536 samples of digital audio (for example, 32 ms at a sampling rate of 48 kHz). All of the synchronization codes, preamble, coded audio, error correction, and auxiliary information associated with this time interval is completely contained within the boundaries of one audio frame.

Figure 41.4 presents the various bit stream elements within each synchronization frame. The five different components are: SI (Synchronization Information), BSI (Bit Stream Information), AB (Audio Block), AUX (Auxiliary Data Field), and CRC (Cyclic Redundancy Code). The SI and CRC fields are of fixed-length, while the length of the other four depends upon programming parameters such as the number of encoded audio channels, the audio coding mode, and the number of optionally-conveyed listener features. The length of the AUX field is adjusted by the encoder such that the CRC element falls on the last 16-bit word of the frame. A summary of the bit stream elements and their purpose is provided in Table 41.3.

FIGURE 41.4: AC-3 synchronization frame.

The number of bits in a synchronization frame (frame length) is a function of sampling rate and total bit-rate. In a conventional encoding scenario, these two parameters are fixed, resulting in synchronization frames of constant length. However, AC-3 also supports variable-rate audio applications, as will be discussed shortly.

Each Audio Block contains coded information for 256 samples from each input channel. Within one synchronization frame, the AC-3 encoder can change the relative size of the six Audio Blocks depending on audio signal bit demand. This feature is particularly useful when the audio signal is non-stationary over the 1536-sample synchronization frame. Audio Blocks containing signals with a high bit demand can be weighted more heavily than others in the distribution of the available bits (bit pool) for one frame. This feature provides one mechanism for local variation of bit-rate while keeping the overall bit-rate fixed.

TABLE 41.3 AC-3 Bit Stream Elements

Bit stream element	Purpose	Length (bits)
SI	Synchronization information — Header at the beginning of each frame containing information needed to acquire and maintain bit stream synchronization.	40
BSI	Bit stream information — Preamble following SI containing parameters describing the coded audio service, e.g., number of input channels (acmod), dynamic compression control word (dynrng), and program time codes (timecod1, timecod2).	Variable
AB	Audio block — Coded information pertaining to 256 quantized samples of audio from all input channels. There are six audio blocks per AC-3 synchronization frame.	Variable
Aux	Auxiliary data field — Block used to convey additional information not already defined in the AC-3 bit stream syntax.	Variable
CRC	Frame error detection field — Error check field containing a CRC word for error detection. An additional CRC word is located in the SI header, the use of which is optional.	17

In applications such as digital audio storage, an improvement in audio quality can often be achieved by varying the bit-rate on a long-term basis (more than one synchronization frame). This can also be realized in AC-3 by adjusting the bit-rate of different synchronization frames on a signal-dependent basis. In regions where the audio signal is less bit-demanding (for example, during quiet passages), the frame bit-rate (frmsizecod) is reduced. As the audio signal becomes more demanding, the frame bit-rate is increased so that coding distortion remains inaudible. Frame-to-frame bit-rate changes selected by the encoder are automatically tracked by the decoder.

41.3 Analysis/Synthesis Filterbank

The design of an analysis/synthesis filterbank is fundamental to any frequency-domain audio coding system. The frequency and time resolution of the filterbank play critical roles in determining the achievable coding gain. Of significant importance as well are the properties of critical sampling and overlap-add reconstruction. This section discusses these properties in the context of the AC-3 multichannel audio coding system.

Of the many considerations involved in filterbank design, two of the most important for audio coding are the window shape and the impulse response length. The window shape affects the ability to resolve frequency components which are in close proximity, and the impulse response length affects the ability to resolve signal events which are short in time duration. For transform coders, the impulse response length is determined by the transform block length.

A long transform length is most suitable for input signals whose spectrum remains stationary, or varies only slowly with time. A long transform length provides greater frequency resolution, and hence improved coding performance for such signals. On the other hand, a shorter transform length, possessing greater time resolution, is more effective for coding signals that change rapidly in time. The best of both cases can be obtained by dynamically adjusting the frequency/time resolution of the transform depending upon spectral and temporal characteristics of the signal being coded. This behavior is very similar to that known to occur in human hearing, and is embodied in AC-3.

The transform selected for use in AC-3 is based on a 512-point Modified Discrete Cosine Transform (MDCT) [2]. In the encoder, the input PCM block for each successive transform is constructed by taking 256 samples from the last half of the previous audio block and concatenating 256 new samples from the current block. Each PCM block is therefore overlapped by 50% with its two neighbors. In the decoder, each inverse transform produces 512 new PCM samples, which are subsequently windowed, 50% overlapped, and added together with the previous block. This approach has the desirable property of crossfade reconstruction, which reduces waveform discontinuities (and audible distortion) at block boundaries.

41.3.1 Window Design

To achieve perfect-reconstruction with a unity-gain MDCT transform filterbank, the shape of the analysis and synthesis windows must satisfy two design constraints. First of all, the analysis/synthesis windows for two overlapping transform blocks must be related by:

$$a_i(n + N/2)s_i(n + N/2) + a_{i+1}(n)s_{i+1}(n) = 1, \quad n = 0, \dots, N/2 - 1 \quad (41.1)$$

where $a_i(n)$ is the analysis window, $s_i(n)$ is the synthesis window, n is the sample number, N is the transform block length, and i is the transform block index. This is the well-known condition that the analysis/synthesis windows must add so that the result is flat [3]. The second design constraint is:

$$a_i(N/2 - n - 1)s_i(n) - a_i(n)s_i(N/2 - n - 1) = 0, \quad n = 0, \dots, N/2 - 1 \quad (41.2)$$

This constraint must be satisfied so that the time-domain alias distortion introduced by the forward transform is completely canceled during synthesis.

To design the window used in AC-3, a convolution technique was employed which guarantees that the resultant window satisfies Eq. (41.1). Equation (41.2) is then satisfied by choosing the analysis and synthesis windows to be equal. The procedure consists of convolving an appropriately chosen symmetric kernel window with a rectangular window. The window obtained by taking the square root of the result satisfies Eq. (41.1). Tradeoffs between the width of the window main-lobe and the ultimate rejection can be made simply by choosing different kernel windows. This method provides a means for transforming a kernel window having desirable spectral analysis properties (such as in [4]) into one satisfying the MDCT window design constraints.

The window generation technique is based on the following equation:

$$a_i(n) = s_i(n) = \sqrt{\frac{\sum_{j=L}^M [w(j)r(n-j)]}{\sum_{j=0}^K [w(j)]}} \quad \text{for } n = 0, \dots, N-1, \text{ where} \quad (41.3)$$

$$L = \begin{cases} 0 & 0 \leq n < N-K \\ n - N + K + 1 & N-K \leq n < N \end{cases}$$

$$M = \begin{cases} n & 0 \leq n < K \\ K & K \leq n < N \end{cases}$$

In this equation, $w(n)$ is the kernel window of length $K+1$, $r(n)$ is a rectangular window of length $N-K$, N is the transform sample block length, and K is the width of the (non-flat) transition region in the resulting window (note that K must satisfy $0 \leq K \leq N/2$). The rectangular window is defined as:

$$r(n) = \begin{cases} 0 & 0 \leq n < (N/2 - K)/2 \text{ and } (3N/2 - K)/2 \leq n < N - K \\ 1 & (N/2 - K)/2 \leq n < (3N/2 - K)/2 \end{cases} \quad (41.4)$$

The rectangular window is defined to contain $(N/2 - K)/2$ zeros, followed by $N/2$ unity samples, followed by another $(N/2 - K)/2$ zeros. The AC-3 window uses $K = N/2$, implying the transition region length is one-half the total window length.

The Kaiser-Bessel window is used as the kernel in designing the AC-3 analysis/synthesis windows because of its near-optimal transition band slope and good ultimate rejection characteristic. A scalar

parameter α in the Kaiser-Bessel window definition can be adjusted to vary this ratio. The AC-3 window uses $\alpha = 5$.

The selection of the Kaiser-Bessel window function and alpha factor used for the AC-3 algorithm is determined by considering the shape of masking template curves. A useful criterion is to use a filter response which is at or below the worst-case combination of all masking templates [5]. Such a filter response is advantageous in reducing the number of bits required for a given level of audio quality. When the filter response is at or below the worst-case combination of all masking templates, the number of bits assigned to transform coefficients adjacent to each tonal component is reduced.

41.3.2 Transform Equations

The transform employed in AC-3 is an extension of the oddly-stacked TDAC (OTDAC) filter bank reported by Princen and Bradley [2]. The extension involves the capability to switch transform block length from $N = 512$ to 256 for audio signals with rapid amplitude changes. As originally formulated by Princen, the filter bank operates with a time-invariant block-length, and therefore has constant time/frequency resolution. An adaptive time/frequency resolution transform can be implemented by changing the time offset of the transform basis functions during short blocks. The time offset is selected to preserve critical sampling and perfect reconstruction before, during, and following transform length changes.

Prior to transforming the audio signal from time to frequency dimension, the encoder performs an analysis of the spectral and/or temporal nature of the input signal and selects the appropriate block length. A one-bit code per channel per Audio Block is embedded in the bit stream which conveys length information: (blksw = 0 or 1 for 512 or 256 samples, respectively). The decoder uses this information to deformat the bit stream, reconstruct the mantissa data, and apply the appropriate inverse transform equations.

Transforming a long block (512 samples) produces 256 unique transform coefficients. Short blocks are constructed starting with 512 windowed audio samples and splitting them into two abutting subblocks of length 256. Each subblock is transformed independently, producing 128 unique non-zero transform coefficients. Hence, the total number of transform coefficients produced in the short-block mode is identical to that produced in long-block mode, but with doubly improved temporal resolution. Transform coefficients from the two subblocks are interleaved together on a coefficient-by-coefficient basis. This block is quantized and transmitted identically to a single long block.

A similar, mirror image procedure is applied in the decoder. Quantized transform coefficients for the two short transforms arrive in the decoder interleaved in frequency. The decoder processes the interleaved sequences identically to long-block sequences, except during the inverse transformation as described below.

A definition of the AC-3 forward transform equation for long and short blocks is:

$$X(k) = 1/N \sum_{n=0}^{N-1} x(n) \cos((2\pi/N)(k + 1/2)(n + n_0)), \quad k = 0, 1, \dots, N-1, \quad (41.5)$$

where n is the sample index, k is the frequency index, $x(n)$ is the windowed sequence of N audio samples, and $X(k)$ is the resulting sequence of transform coefficients.

The corresponding inverse transform equation for long and short blocks is:

$$y(n) = \sum_{k=0}^{N-1} X(k) \cos((2\pi/N)(k + 1/2)(n + n_0)), \quad n = 0, 1, \dots, N-1 \quad (41.6)$$

Parameter n_0 represents a time offset of the modulator basis vectors used in the transform kernel. For long blocks, and for the second of each short block pair, $n_0 = 257/2$. For the first short block, $n_0 = 1/2$.

When $x(n)$ in Eq. (41.5) is real, $X(k)$ is odd-symmetric for the MDCT. Therefore, only $N/2$ unique non-zero transform coefficients are generated for each new block of N samples. Accordingly, some information is lost during the transform, which ultimately leads to an alias component in $y(n)$. However, with an appropriate choice of n_0 , and in the absence of transform coefficient quantization, the aliasing is completely canceled during the window/overlap/add procedure following the inverse transform. Hence, the AC-3 filterbank has the properties of critical sampling and perfect reconstruction. A fundamental advantage of this approach is that 50% frame overlap is achieved without increasing the required bit-rate. Any non-zero overlap used with conventional transforms (such as the DFT or standard DCT) precludes critical sampling, generally resulting in a higher bit-rate for the same level of subjective quality.

Several memory and computation-efficient techniques are available for implementing the AC-3 forward and inverse transforms (for example, see [6]). The most efficient ones can be derived by rewriting Eqs. (41.5) and (41.6) in the form of an N -point DFT and IDFT, respectively, combined with two complex vector multiplies. The DFT and IDFT can be efficiently computed using an FFT and IFFT, respectively. Two properties further reduce the fast transform length. First, the input signal is real, and second, the N -length sequence $y(n)$ contains only $N/2$ unique samples. When these two properties are combined, the result is an $N/4$ -point complex FFT or IFFT. The AC-3 decoder filter bank computation rate is about 13 multiply-accumulate operations per sample per channel, including the window/overlap/add. This computation rate remains virtually unchanged during block length changes.

41.4 Spectral Envelope

The most basic form of audio information conveyed by an AC-3 bit stream consists of quantized frequency coefficients. The coefficients are delivered in floating-point form, whereby each consists of an exponent and a mantissa. The exponents from one audio block provide an estimate of the overall spectral content as a function of frequency. This representation is often termed a spectral envelope. This section describes spectral envelope coding strategies in AC-3, and explores an important relationship between exponent coding and mantissa bit allocation.

Due to the inherent variety of audio spectra within one frame, the AC-3 spectral envelope coding scheme contains significant degrees of freedom. In essence, the six spectral envelopes contained in one frame represent a two-dimensional signal, varying in time (block index) and frequency. AC-3 spectral envelope coding provides for variable coarseness of representation in both dimensions. In the frequency dimension, either one, two, or four mantissas can be shared by one floating-point exponent. In the time dimension, any two or more consecutive audio blocks from one frame can share common set of exponents.

The concepts of spectral envelope coding and bit allocation are closely linked in AC-3. More specifically, the effectiveness with which mantissa bits are utilized can depend greatly upon the encoder's choice of spectral envelope coding. To see this, note that the dominant contributors to the total bit-rate for a frame are the audio exponents and mantissas. Sharing exponents in either the time or frequency dimension, or both, reduces the total cost of exponent transmission for one frame. More liberal use of exponent sharing therefore frees more bits for mantissa quantization. Conversely, retransmitting exponents increases the total cost of exponent transmission for one frame relative to mantissa quantization. Furthermore, the block positions at which exponents are retransmitted can significantly alter the effectiveness of mantissa bit assignments among the various audio blocks. As will be seen later in Section 41.6, bit assignments are derived in part from the coded spectral envelope.

In summary, the encoder decisions regarding when to use frequency or time exponent sharing, and when to retransmit exponents depend upon signal conditions. Collectively, these decisions are called exponent strategy.

For short-term stationary signals, the signal spectrum remains substantially invariant from block-to-block. In this case, the AC-3 encoder transmits exponents once in audio block 0, and then typically reuses them for blocks 1-5. The resulting bit allocation would generally be identical for all 6 blocks, which is appropriate for these signal conditions.

For short-term non-stationary signals, the signal spectrum changes significantly from block-to-block. In this case, the AC-3 encoder transmits exponents in block 0 and typically in one or more other blocks as well. In this case, exponent retransmission produces a time trajectory of coded spectral envelopes which better matches dynamics of the original signal. Ultimately, this results in a quality improvement if the cost of exponent retransmission is less than the benefit of redistributing mantissa bits among blocks.

Exponent strategy decisions can be based, for example, on a cost-benefit analysis for each frame. The objective of such an analysis would be to minimize a cost-benefit ratio by considering encoding parameters such as total available bit-rate, audibility of quantization noise (noise-to-mask ratio), exponent coding mode for each audio block (reuse, D15, D25, or D45), channel coupling on/off, and reconstructed audio bandwidth.

The block(s) at which bit assignment updates occur is governed by several different parameters, but primarily by the exponent strategy fields. AC-3 bit streams contain coded exponents for up to five independent channels, and for the coupling and low frequency effects channels (when enabled). The respective exponent strategy fields are called *chexpstr[ch]*, *cplexpstr*, and *lfeexpstr*. Bit allocation updates are triggered if the state of any one or more strategy flags is D15, D25, or D45; however, updates can be triggered in between shared exponent block boundaries as well.

Exponents are 5-bit values which indicate the number of leading zeros in the binary representation of a frequency coefficient. For the D15 exponent strategy, the unsigned integer exponent $e(i)$ represents a scale factor for the i th mantissa, equal to $2^{-e(i)}$. Frequency coefficients are normalized in the encoder by multiplying by $2^{e(i)}$, and denormalized in the decoder by multiplying by $2^{-e(i)}$. Exponent values are allowed to range from 0 (for the largest value coefficients with no leading zeros) to 24. Exponents for coefficients which have more than 24 leading zeros are fixed at 24, and the corresponding mantissas are allowed to have leading zeros. Exponents require 5 bits in order to represent all allowed values.

AC-3 exponent transmission employs differential coding, in which the exponents for a channel are differentially coded across frequency. The first exponent of a full bandwidth or lfe channel is always sent as a 4-bit absolute value, ranging from 0-15. The value indicates the number of leading zeros of the first (DC term) transform coefficient. Successive exponents (ascending in frequency) are sent as differential values which must be added to the prior exponent value in order to form the next absolute value.

The differential exponents are combined into groups in the audio block. The grouping is done by one of three methods, D15, D25, or D45. The number of grouped differential exponents placed in the audio block for a particular channel depends on the exponent strategy and on the frequency bandwidth information for that channel. The number of exponents in each group depends only on the exponent strategy.

Exponent strategy information for every channel is included in every AC-3 audio block. Information is never shared across frames, so block 0 will always contain a strategy indication for each channel.

The three exponent strategies provide a tradeoff between bit-rate required for exponents, and their frequency resolution. The overall exponent bit-rate for a frame depends on the exponent strategy, the number of blocks over which the exponents are shared, and the audio signal bandwidth. Table 41.4 presents the per-coefficient bit-rate required to transmit the spectral envelope for each strategy, and

for each block share interval. The D15 mode provides the finest frequency resolution (one exponent per frequency coefficient), while the D45 mode consumes the lowest per-coefficient bit-rate.

TABLE 41.4 Exponent Bit-Rate for Different Exponent Strategies

Exponent strategy	Share interval (number of audio blocks)					
	1	2	3	4	5	6
D15	2.33	1.17	0.78	0.58	0.47	0.39
D25	1.17	0.58	0.39	0.29	0.23	0.19
D45	0.58	0.29	0.19	0.15	0.12	0.10

Note: Bits per frequency coefficient

The absolute exponents found in the bit stream at the beginning of the differentially coded exponent sets are sent as 4-bit values which have been limited in either range or resolution in order to save one bit. For full bandwidth and lfe channels, the initial 4-bit absolute exponent represents a value from 0 to 15. Exponent values larger than 15 are limited to a value of 15. For the coupled channel, the 5-bit absolute exponent is limited to even values, and the least significant bit is not transmitted. The resolution has been limited to valid values of 0, 2, 4,..., 24. Each differential exponent can take on one of five values: -2 , -1 , 0 , $+1$, $+2$. This allows deltas of up to ± 2 (± 12 dB) between exponents. These five values are mapped into the values 0, 1, 2, 3, 4 before being grouped, as shown in Table 41.5.

TABLE 41.5 Mapping of Differential Exponent Values

Differential exponent	Mapped value, M_i
+2	4
+1	3
0	2
-1	1
-2	0

In D15 mode, the above mapping is applied to each individual differential exponent for coding into the bit stream. In D25 mode, each pair of differential exponents is represented by a single mapped value in the bit stream. In this mode, the differential exponent is used once to compute an exponent that is shared between two consecutive frequency coefficients.

The D45 mode is similar to D25 mode except that quadruplets of differential exponents are represented by a single mapped value. Again, the differential exponent is used once to compute an exponent that is shared between four consecutive frequency coefficients.

For all modes, sets of three adjoining (in frequency) mapped values (M_1 , M_2 and M_3) are grouped together and coded as a 7-bit unsigned integer I according to the following relation:

$$I = 25M_1 + 5M_2 + M_3. \quad (41.7)$$

Following the exponent strategy fields in the bit stream is a set of 6-bit channel bandwidth codes, chbwcod[ch]. These are only present for independent channels (not in coupling) that have new exponents in the current block. The channel bandwidth code defines the end mantissa bin number for that channel according to the following:

$$\text{endmant}[\text{ch}] = ((\text{chbwcod}[\text{ch}] + 12)3) + 37 \quad (41.8)$$

Exponent strategy for each full bandwidth channel and the lfe channel can be updated independently. Lfe channel exponents are restricted only to reuse or D15 mode. If a full bandwidth channel is in coupling, exponents up to the start coupling frequency are transmitted. If the full bandwidth channel is not in coupling, exponents up to the channel bandwidth code are transmitted. If coupling is on for any full bandwidth channel, a separate and independent set of exponents is transmitted for the coupling channel. Coupling start and end frequencies are transmitted as 4-bit indices.

41.5 Multichannel Coding

In the context of AC-3, multichannel audio is defined as two or more full bandwidth channels that are intended for simultaneous presentation to a listener. Multichannel audio coding offers new opportunities in bit-rate reduction beyond those commonly employed in monophonic coders. The goal of multichannel coding is to compress an audio program by exploiting redundancy between the channels and irrelevancy in the signal while preserving both sound clarity and spatial characteristics of the original program. AC-3 achieves this goal by preserving listener cues which affect perceived directionality of hearing (localization).

The motivation for multichannel audio coding is provided by an understanding of how the ear extracts directional information from an incident sound wave. Hearing research suggests that the auditory system does not evaluate every detail of the complicated interaural signal differences, but rather derives what information is needed from definite, easily recognizable attributes [7]. For example, localization of signals are generally distinguished by:

1. Interaural time differences (ITD)
2. Interaural level differences (ILD)

The ITD cues are caused by the difference between the time of arrival of a sound at both ears. ILD cues are sound pressure level differences caused by a different acoustic transfer functions from the acoustic source to the two ears. Most authors agree ITD is the most important attribute of the audio signal relating to the formation of lateral displacements [7]. For tones below about 800 Hz, perceived lateral displacement is approximately linear as a function of the difference in the time of arrival for the two ears, up to an ITD of 600 μsec . Full lateral displacement is obtained with an ITD of approximately 630 μsec . At any given time, the auditory event corresponding to the shorter time of arrival is dominant.

The ear is able to evaluate spectral components of the ear input signals individually with respect to ITD. Lateral displacement of the auditory event attainable for pure tones is most perceptible below 800 Hz. However, for some non-tonal signals above 800 Hz, such as narrowband noise, the ear is still able to detect ITDs. In this case, the interaural temporal displacement of the energy envelope of the signal is generally regarded as the criterion involved. Experiments have indicated that the ITD of the signal's fine temporal structure contributes negligibly to localization; instead, the ear evaluates only the energy envelopes. The processing occurs individually in each of a multiplicity of spectral bands. The spectrum is dissected to a degree determined by the finite spectral resolution of the inner ear. Then, the envelopes of the separate spectral components are evaluated individually. These experimental results form the basis for the use of channel coupling in AC-3.

41.5.1 Channel Coupling

Channel coupling is a method for reducing the bit-rate of multichannel programs by summing two or more correlated channel spectra in the encoder. Frequency coefficients for the single combined (coupled) channel are transmitted in place of the individual channel spectra, together with additional side information. The side information consists of a unique set of coupling coefficients for each

channel. In the decoder, frequency coefficients for each output channel are computed by multiplying the coupled channel frequency coefficients by the coupling coefficients for that channel. Coupling coefficients are computed in the encoder in a manner which preserves the short-time energy envelope of the original signals, thereby preserving spatialization cues used by the listener.

Coupling is active only above the coupling start frequency; below this boundary, frequency coefficients are coded independently. The coupling start frequency can be changed from one audio block to the next, and coupling can be disabled if desired. Any combination of two or more full bandwidth channels can be coupled; each channel has an associated channel-in-coupling bit to indicate if it has been included in the coupling channel.

Channel coupling is intended for use only when independent channel coding at the given bit-rate and desired audio bandwidth would result in audible artifacts. As the audio bit-rate is lowered with a fixed bandwidth of 20 kHz, a point is eventually reached where audible coding errors will occur for critical signals. In these circumstances, channel coupling reduces the need for encoders to take more drastic measures to eliminate artifacts, such as lowering the audio bandwidth.

A diagram depicting the encoder coupling procedure for the case of three input channels is depicted in Fig. 41.5. The coupling channel is formed as the vector summation of frequency coefficients from all channels in coupling. An optional signal-dependent phase adjustment is applied to the frequency coefficients prior to summation so that phase cancellation does not occur. For each input channel in coupling, the AC-3 encoder then calculates the power of the original signal and the coupled signal. The power summation is performed individually on a number of bands. For the simplified case of Fig. 41.5, there are two such bands. In a typical application the number of bands is 14, but can vary between 1 and 18. Next, the power ratio between the original signal and the coupled channel is computed for each input channel and each band. Denoted a coupling coordinate, these ratios are quantized and transmitted to the decoder.

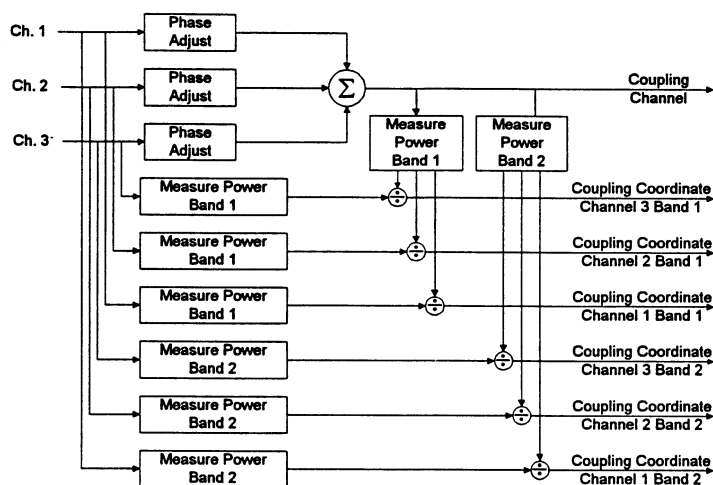

FIGURE 41.5: Block diagram of encoder coupling for three input channels.

To reconstruct the spectral coefficients corresponding to one channel's worth of transform data, quantized spectral coefficients representing the uncoupled portion of the transform block are prepended to a set of scaled coupling channel spectral coefficients. The scaled coupling channel coefficients are generated for each channel by multiplying the coupling coordinates for each band by the received coupling channel coefficients, as shown in Fig. 41.6.

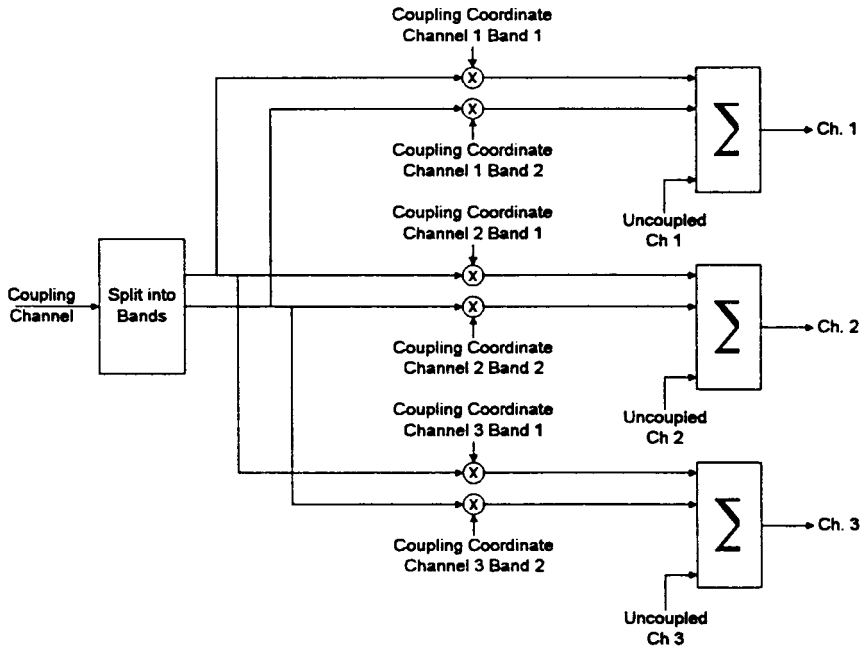

FIGURE 41.6: Block diagram of decoder coupling for three input channels.

Coupling parameters, such as the coupling start/end frequencies and which channels are in coupling, are always transmitted in block 0. They are also optionally transmitted in blocks 1 through 5. Typically only channels with similar spectral shapes are coupled. Level differences between channels are accounted for by the coupling coefficients. It is noteworthy that if in-band spectral differences between coupled input channels are due to level only, the original input channels can still be recovered exactly in the decoder, in the absence of frequency coefficient quantization.

The coupling coefficient dynamic range is -132 to $+18$ dB, with step sizes varying between 0.28 and 0.53 dB. The lowest coupling start frequency is 3.42 kHz at a 48 kHz sampling frequency.

41.5.2 Rematrixing

Rematrixing in AC-3 is a channel combining technique in which sum and difference signals of highly correlated channels are coded rather than the original channels themselves. That is, rather than code and pack left and right (L and R) in a two channel coder, the encoder constructs:

$$\begin{aligned} L' &= (L + R)/2 \\ R' &= (L - R)/2. \end{aligned} \quad (41.9)$$

The usual quantization and data packing operations are then performed on L' and R' .

In the decoder, the original L and R signals are reconstructed using the inverse equations:

$$\begin{aligned} L &= L' + R' \\ R &= L' - R'. \end{aligned} \quad (41.10)$$

Clearly, if the original stereo signal were identical in both channels (i.e., two-channel mono), L' is identical to L and R , and R' is identically zero. Therefore, the R' channel can be coded with very

few bits, increasing accuracy in the more important L' channel. Rematrixing is only applicable in the 2/0 encoding mode (acmod = '010').

Rematrixing is particularly important when conveying Dolby Surround encoded programs. Consider again a two channel mono source signal. A Dolby Pro Logic decoder will steer all in-phase information to the center channel, and all out-of-phase information to the surround channel. Without rematrixing, the Pro Logic decoder will receive the signals:

$$\begin{aligned} Q(L) &= L + n_1 \\ Q(R) &= R + n_2 \end{aligned} \quad (41.11)$$

where n_1 and n_2 are uncorrelated quantization noise sequences added by the process of bit-rate reduction. The Pro Logic decoder will then construct the center and surround channels as:

$$\begin{aligned} C &= ((L + n_1) + (R + n_2))/2 \\ S &= ((L + n_1) - (R + n_2))/2 \end{aligned} \quad (41.12)$$

In the case of the center channel, n_1 and n_2 add, but remain masked by, the dominant $L + R$ signal. In the surround channel, however, $L - R$ cancels to zero, and the surround speakers reproduce the difference in the quantization noise sequences ($n_1 - n_2$).

If rematrixing is active, the left and right channels will be reproduced as:

$$\begin{aligned} L &= (L' + n_3) + (R' + n_4) \cong L + n_3 \\ R &= (L' + n_3) - (R' + n_4) \cong R + n_3, \end{aligned} \quad (41.13)$$

where the approximation is made since the quantization noise $n_3 \gg n_4$. More importantly, the center and surround channels will be more faithfully reproduced as:

$$\begin{aligned} C &\cong ((L + n_3) + (R + n_3))/2 = (L + R)/2 + n_3 \\ S &\cong ((L + n_3) - (R + n_3))/2 = (L - R)/2. \end{aligned} \quad (41.14)$$

In this case, the quantization noise in the surround channel is much lower in level.

In AC-3, rematrixing is performed independently in separate frequency bands. There are two to four contiguous bands with boundary locations dependent on coupling information. At a sampling rate of 48 kHz, bands 0 and 1 start at 1.17 and 2.30 kHz, respectively. Bands 2 and 3 start at 3.42 and 5.67 kHz. If coupling is not in use, band 3 stops at a frequency given by the channel bandwidth code. The band boundaries scale proportionally for other sampling frequencies.

Rematrixing is never used in the coupling channel. If coupling and rematrixing are simultaneously in use, the highest rematrixing band ends at the coupling start frequency.

41.6 Parametric Bit Allocation

The process of distributing a finite number of bits B to a block of M frequency bands so as to minimize a suitable distortion criterion is called bit allocation. The result is a bit assignment $b(k)$, $k = 0, 1, \dots, M - 1$, which defines the word length of the frequency coefficient(s) transmitted in the k th band. The bit assignment is performed subject to the constraint:

$$\sum_{k=0}^{M-1} b(k) = B. \quad (41.15)$$

B is determined from the transmission channel capacity, expressed in bits/sec, the block length, and other parameters as well. Performance gains may be realized by allowing B to vary from block to block depending on signal characteristics.

41.6.1 Bit Allocation Strategies

In applications such as digital audio broadcasting and high definition television, one encoder typically distributes programs to many decoders. In these situations, it is advantageous to make the encoder as flexible as possible. If quality improvements are possible even after the decoder design is standardized, the useful life of the coding algorithm can be extended. The bit allocation strategy is a natural candidate for improvement because it plays a crucial role in determining the ultimate quality achievable by a coding algorithm.

One approach to achieving flexibility is to use a forward-adaptive bit allocation strategy, in which the bit assignment $b(k)$ for all bands is explicitly conveyed in the bit stream as side information. A second strategy is termed backward-adaptive allocation, in which $b(k)$ is computed in the encoder and then recomputed in the decoder. Since the computation is based upon quantized information which is transmitted to the decoder anyway, the side information to convey $b(k)$ is not required. The bits that are saved can be used to encode the frequency coefficients themselves.

AC-3 employs an alternative approach [8]. Called parametric bit allocation, the technique combines the advantages of forward and backward-adaptive strategies. It employs a hearing model combining elements from [9] with new features based on more recent psychoacoustic experiments. The term “parametric” refers to the notion that the model is defined by several key variables that influence the masking curve shape and amplitude, and hence the bit assignment. A difference between AC-3 and previous coders is that both the encoder and decoder contain the model, eliminating the need to transmit $b(k)$ explicitly. Only the essential model parameters (psychoacoustic features) are conveyed to the decoder. These parameters can be transmitted with significantly fewer bits than $b(k)$ itself. Furthermore, an improvement path is provided since the specific parameter values are selected by the encoder.

Equally significant, the parametric approach provides latitude for the encoder to adjust the time and frequency resolution of $b(k)$. Bit allocation updates are always present in block 0, and are optionally transmitted in blocks 1 through 5. The frequency resolution of $b(k)$ can be adjusted from 2.7 to 10.7 bands/kHz (one bit assignment every 94 to 375 Hz). The AC-3 encoder typically makes these adjustments in accordance with spectral and temporal changes in the audio signal itself, in a manner similar to the human ear.

Secondary strategy information which also affects block-to-block changes in bit assignment is the bit allocation information, coupling strategy, and SNR offset. This information is always transmitted in block 0, and is optionally transmitted in each subsequent audio block. The presence/absence of the information is controlled by the respective “exists” bits *baie*, *cplstre*, and *snroffste*. The exists bits are set to 1 in blocks 1 to 5 only when a change in strategy results in better audio quality than would be obtained by reusing parameters from the preceding block.

Signal conditions may arise in which the masking curve, and therefore $b(k)$, cannot be sufficiently optimized using the built-in parametric model. Therefore, AC-3 encoders contain a provision for adjusting the masking curve in accordance with an independent psychoacoustic analysis. This is accomplished by transmitting additional bit stream codes, designated as *deltas*, which convey differences between the two masking curves.

41.6.2 Spreading Function Shape

In Schroeder’s model for computing a masking threshold [9], one of the key variables influencing the degree of masking of one spectral component by another is the shape of the spreading function. If the spreading function is a unit impulse, the excitation function (and therefore the masking curve) will be identical in shape to the input signal spectrum. This corresponds to the case where no masking whatsoever is assumed, with the result that all frequency coefficients receive the same bit assignment, and the quantization noise spectrum will conform in shape to the input signal spectrum. As the

spreading function is broadened, progressively greater degrees of masking are modeled. This yields a noise spectrum which, in general, contains peaks and valleys that are aligned with features of the input signal spectrum, but broadened in character. As the spreading function is flattened further, eventually a limit is reached where the noise spectrum will be white, corresponding to the minimum mean-square error bit assignment. This noise shaping behavior is identical to the concept of [10, 11].

Since the spreading function strongly influences the level and extent of assumed masking, a parametric description is provided in AC-3. The parametric spreading function is one mechanism available to an AC-3 encoder for making compatible adjustments to the masking model.

The range of spreading function parameter variation was obtained by distilling a family of prototype functions from the available masking data [8]. The variation in shape of the four composite masking curves for 0.5, 1, 2, and 4 kHz tones is shown in Fig. 41.7. We have approximated the envelope of upward masking for each composite curve by two linear segments. The spreading function is defined as the point-by-point maximum of the two segments across frequency. In the example shown in Fig. 41.7, the composite curves can be reasonably approximated by choosing an appropriate slope and vertical offset for each linear segment. Hence, four parameters are transmitted in the bit stream to define the spreading function shape.

41.6.3 Algorithm Description

The AC-3 bit allocation strategy places the majority of computation in the encoder. For example, the encoder can trade off reconstructed signal bandwidth vs. quantization noise power, change the degree of upward masking of one spectral component by another, modify the bit assignment as a function of acoustic signal level, and adaptively control total harmonic distortion. The bit assignment can also be adjusted according to an arbitrary second masking model, as outlined later in the section describing “Delta Bit Allocation”. The encoder iteratively converges on an optimal solution. On the other hand, the decoder makes only one pass through the received parameters and exponent data, and is therefore considerably simpler. The bit assignment is reconstructed in the decoder using only basic two’s complement operators: add, compare, arithmetic left/right shift, and table lookup.

Frequency Banding

The first step in the masking curve computation is to convert a block of power spectrum samples, taken at equidistant frequency intervals, into a Bark spectrum. This is accomplished by subdividing the power spectrum into multiple frequency bands and then integrating the spectrum samples within each band. The bands are non-uniform in width and derived from the critical-bandwidths defined by Zwicker [12]. The psychoacoustic basis for this procedure is that each critical band corresponds to a fixed distance along the basilar membrane, and therefore to a constant number of auditory nerve fibers.

The summation of the power spectrum samples during linear to Bark frequency conversion requires a linear summation. However, the logarithm of those quantities is most readily available in AC-3. Therefore, a log-adder is employed. The log-addition of two quantities $\log(a)$ and $\log(b)$ is computed using the relation:

$$\log(a + b) = \max(\log(a), \log(b)) + \log(1 + e^d) \quad (41.16)$$

where e is the logarithm base, and

$$d = |\log(a) - \log(b)|. \quad (41.17)$$

The second term on the right side of the equation is implemented as a subtraction $\log(a) - \log(b)$, followed by absolute value and a table lookup. The contents of the table at address d is: $\log(1 + e^d)$. Therefore, the complete log-addition is performed with only add, compare, and table lookup instructions.

FIGURE 41.7: Comparison between 500 Hz to 4 kHz masking templates and the two slope spreading function.

Masking Convolution

The technique for modeling masking effects developed by Schroeder specifies convolution. At every frequency point, masking contributions from all other spectral components are weighted and summed. The output of a linear recursive (e.g., IIR) filter may also be viewed as a weighted summation of input samples. Therefore, the convolution of the spreading function with the *linear*-amplitude critical band density in Schroeder's model can be approximated by applying a time-varying linear recursive filter to the spectral components. Upward masking is modeled by filtering the frequency samples from low to high frequency. Downward masking is modeled by filtering input samples in the reverse order. The filter order and coefficients are determined from the desired spreading function. To compute the excitation function using the *logarithmic*-amplitude critical band density used in AC-3, the linear recursive filter is replaced with an equivalent filter which processes logarithmic spectral samples.

The conversion of the linear recursive filter to an equivalent log-domain filter is straightforward. By writing out the difference equation for an IIR filter and taking the logarithm of both sides of the equation, an expression relating the log excitation function with the log power spectrum can be derived. The multiplies and additions of the IIR filter are replaced with additions and log-additions, respectively, in the log domain filter. To implement the two-slope spreading function, two filters are connected in parallel. Each filter implements the characteristic of one of the segments, and the overall excitation value $E(k)$ at band k is computed as the larger of the two filter output samples. The log-domain equations for computing $E(k)$ are:

$$\begin{aligned} x_0 &= (x_0 - d_0) \oplus (P(k) - g_0) \\ x_1 &= (x_1 - d_1) \oplus (P(k) - g_1) \\ E(k) &= \max(x_0, x_1) \end{aligned} \quad (41.18)$$

where $P(k)$ is the log-amplitude power spectrum, d_0 and d_1 are the dB spreading function decay values for the first and second segment, respectively, g_0 and g_1 are the dB offsets of the two spreading function segments, and the \oplus symbol denotes log-addition as defined previously. For each of 50

bands, the value of two accumulators x_0 and x_1 is computed by performing a log-addition of the previous accumulator value, decayed by d_0 or d_1 , and the current power spectrum value scaled by the gain g_0 or g_1 . In AC-3, log-addition is replaced by a maximum operator to reduce computation. This is also more conservative in that additive masking is not assumed.

Compensation for Decoder Selectivity

One basis for determining the bit assignments $b(k)$ in a perception-based allocation strategy is to compute the difference between the signal spectrum and the predicted masking curve. An implicit assumption of this technique is that quantization noise in one particular band is independent of bit assignments in neighboring bands. This is not always a reasonable assumption because the finite frequency selectivity and the high degree of overlap between bands in the decoder filter bank cause localized spreading of the error spectrum (leakage from one band into neighboring bands). The effect is predominant at low frequencies where the slope of the masking curve can equal or exceed the slope of the filter bank transition skirts. Hence, under some conditions, a basis other than the difference between the signal spectrum and masking curve is warranted.

As discussed in [8], decoder selectivity compensation has been found to improve subjective coding performance at low frequencies. Accordingly, the AC-3 masking model employs a straightforward, recursive algorithm for applying compensation from 0 to 2.3 kHz. Although the compensation is a filter bank response correction, not a psychoacoustic effect of human hearing, it can be incorporated into the computation of the excitation curve.

Parameter Variation

The masking computation primarily represents the backward-adaptive portion of the bit allocation strategy. However a number of parameters defining the masking model are transmitted in the compressed data stream. These represent part of the forward-adaptive portion of the bit allocation strategy. As discussed earlier, the shape of the prototype spreading function is controlled by four parameters, where a pair of parameters correspond to each segment. The first linear segment slope is adjustable between -2.95 to -5.77 dB per band, with offsets ranging from -6 to -48 dB. The second segment slope can be adjusted between -0.70 to -0.98 dB per band, with offsets ranging from -49 to -63 dB. The syntax of AC-3 allows the first segment to be controlled independently for each channel. Parameters for the second segment are common to all channels. There are 512 unique spreading function shapes available to an AC-3 encoder.

Delta Bit Allocation

Another forward-adaptive component of the bit allocation strategy is a parametric adjustment that is optionally made to the masking curve computed by the masking model. This adjustment is conveyed to the decoder with the delta bit allocation. For each channel, the encoder can specify nearly arbitrary adjustments to the computed masking curve at a certain cost in bit-rate that otherwise would be used directly to code audio data. Delta bit allocation is used by the encoder to specify a masking curve, and hence a bit assignment, that cannot be generated by the parametric model alone. This feature is useful, for example, if future research points to masking behavior which cannot be simulated by the existing model. In this case, benefits of any new research can be added to an AC-3 encoder by augmenting the parametric model with the improved one.

Determination of the desired delta bit allocation function is straightforward. In an encoder, both the standard AC-3 masking model and the improved one are run in parallel to determine two masking curves. The desired delta bit allocation function is equal to the difference between the masking curves. It may be advantageous to only approximate the desired difference to reduce the required data expenditure. Note that an encoder should first exhaust the flexibility granted by the non-delta parameters before committing any bits to delta bit allocation. The other parameters are

less expensive in terms of bit-rate as they must be transmitted periodically in any case.

The delta function is constrained to have a “stair step” shape. Each tread of the stair step corresponds to the masking level adjustment for an integral number of adjoining one-half Bark bands. Taken together, the stair steps comprise a number of non-overlapping, variable-length segments. The segments are run-length coded for efficient transmission.

41.7 Quantization and Coding

All mantissas are quantized to a fixed level of precision indicated by the corresponding bit allocation pointer (bap). Mantissas quantized to 15 or fewer levels use symmetric quantization. Mantissas quantized to more than 15 levels use asymmetric quantization (a conventional two's complement representation).

Some quantized mantissa values are grouped together and encoded into a common codeword. In the case of the 3-level quantizer, 3 quantized values are grouped together and represented by a 5-bit codeword in the data stream. In the case of the 5-level quantizer, 5 quantized values are grouped and represented by a 7-bit codeword. For the 11-level quantizer, 11 quantized values are grouped and represented by a 7-bit codeword. Groups are filled in the order that the mantissas are processed. If the number of mantissas in an exponent set does not fill an integral number of groups, the groups are shared across exponent sets. The next exponent set in the block continues filling the partial groups.

In the encoder, each frequency coefficient is normalized by applying a left-shift equal to its associated exponent (0 to 24). The mantissa is then quantized to a number of levels indicated by the corresponding bap.

Table 41.6 indicates the assignment between bap number and number of quantizer levels. If a bap equals 0, no bits are sent for the mantissa. For more efficient bit utilization, grouping is used for bap values of 1, 2, and 4 (3, 5, and 11 level quantizers).

TABLE 41.6 Quantizer Levels and Mantissa Bits vs. bap

bap	Quantizer levels	Mantissa bits (group bits / num in group)
0	0	0
1	3	1.67 (5/3)
2	5	2.33 (7/3)
3	7	3
4	11	3.5 (7/2)
5	15	4
6	32	5
7	64	6
8	128	7
9	256	8
10	512	9
11	1024	10
12	2048	11
13	4096	12
14	16,384	14
15	65,536	16

For bit allocation pointer values between 6 and 15, inclusive, asymmetric fractional two's complement quantization is used. No grouping is employed for asymmetrically quantized mantissas.

For bap values of 1 through 5, inclusive, the mantissas are represented by coded values. The coded values are converted to standard 2's complement fractional binary words. The number of bits indicated by a mantissa's bap are extracted from the bit stream and right justified. This coded value is treated as a table index and is used to look up the quantized mantissa value. The resulting mantissa

value is right shifted by the corresponding exponent to generate the transform coefficient value.

The AC-3 decoder may use random noise (dither) values instead of quantized values when the number of bits allocated to a mantissa is zero ($bap = 0$). The decoder substitution of random values for the quantized mantissas with $bap = 0$ is conditional on the value of a bit conveyed in the bit stream (dithflag). There is a separate dithflag bit for each transmitted channel. When dithflag = 1, the random noise value is used. When dithflag = 0, a true zero value is used.

41.8 Error Detection

There are several ways in which the AC-3 data may determine that errors are contained within a frame of data. The decoder may be informed of that fact by the transport system which has delivered the data. Data integrity may be checked using the embedded Cyclic Redundancy Check (CRCs) words. Also, some simple consistency checks on the received data can indicate that errors are present. The decoder strategy when errors are detected is user definable. Possible responses include muting, block repeats, frame repeats, or more elaborate schemes based on waveform interpolation to “fill in” missing PCM samples. The amount of error checking performed, and the behavior in the presence of errors are not specified in the AC-3 ATSC standard, but are left to the application and implementation.

Each AC-3 frame contains two 16-bit CRC words. As discussed in Section 41.2, *crc1* is the second 16-bit word of the frame, immediately following the synchronization word. *crc2* is the last 16-bit word of the frame, immediately preceding the synchronization word of the following frame. *crc1* applies to the first 5/8 of the frame, not including the synchronization word. *crc2* provides coverage for the last 3/8 of the frame as well as for the entire frame (not including the synchronization word). Decoding of CRC word(s) allows errors to be detected.

The following generator polynomial is used to generate both of the 16-bit CRC words in the encoder:

$$x^{16} + x^{15} + x^2 + 1 . \quad (41.19)$$

The CRC calculation may be implemented by one of several standard techniques. A convenient hardware implementation is a linear feedback shift register. Details of this technique are presented in [1].

PAC is a perceptual audio coder that is flexible in format and bitrate, and provides high-quality audio compression over a variety of formats from 16 kb/s for a monophonic channel to 1024 kb/s for a 5.1 format with four or six auxiliary audio channels, and provisions for an ancillary (fixed rate) and auxiliary (variable rate) side data channel. In all of its forms it provides efficient compression of high-quality audio. For stereo audio signals, it provides near compact disk (CD) quality at about 56 to 64 kb/s, with transparent coding at bit rates approaching 128 kb/s.

PAC has been tested both internally and externally by various organizations. In the 1993 ISO-MPEG-2 5-channel test, PAC demonstrated the best decoded audio signal quality available from any algorithm at 320 kb/s, far outperforming all algorithms, including the layer II and layer III backward compatible algorithms. PAC is the audio coder in most of the submissions to the U.S. Digital Audio Radio (DAR) standardization project, at bit rates of 160 kb/s or 128 kb/s for two-channel audio compression. It has been adapted by various vendors for the delivery of high quality music over the Internet as well as ISDN links. Over the years PAC has evolved considerably. In this paper we present an overview for the PAC algorithm including some recently introduced features such as the use of a signal adaptive switched filterbank for efficient encoding of non-stationary signals.

42.1 Introduction

With the overwhelming success of the compact disc (CD) in the consumer audio marketplace, the public's notion of "high quality audio" has become synonymous with "compact disc quality". The CD represents stereo audio at a data rate of 1.4112 Mbps (mega bits per second). Despite continued

growth in the capacity of storage and transmission systems, many new audio and multi-media applications require a lower data rate.

In compression of audio material, human perception plays a key role. The reason for this is that source coding, a method used very successfully in speech signal compression, does not work nearly as well for music. Recent U.S. and international audio standards work (HDTV, DAB, MPEG-1, MPEG-2, CCIR) therefore has centered on a class of audio compression algorithms known as *perceptual coders*. Rather than minimizing analytic measures of distortion, such as signal-to-noise ratio, perceptual coders attempt to minimize perceived distortion. Implicit in this approach is the idea that signal fidelity perceived by humans is a better quality measure than “fidelity” computed by traditional distortion measures. Perceptual coders define “compact disc quality” to mean “listener indistinguishable from compact disc audio” rather than “two channel of 16-bit audio sampled at 44.1 kHz”.

PAC, the Perceptual Audio Coder [10], employs source coding techniques to remove signal redundancy and perceptual coding techniques to remove signal irrelevancy. Combined, these methods yield a high compression ratio while ensuring maximal quality in the decoded signals. The result is a high quality, high compression ratio coding algorithm for audio signals. PAC provides a 20 Hz to 20 kHz signal bandwidth and codes monophonic, stereophonic, and multichannel audio. Even for the most difficult audio material it achieves approximately ten to one compression while rendering the compression effects inaudible. Significantly higher level of compression, e.g., 22 to 1, is achieved with only a little loss in quality.

The PAC algorithm has its roots in a study done by Johnston [7, 8] on the perceptual entropy (PE) vs. the statistical entropy of music. Exploiting the fact that the perceptual entropy (the entropy of that portion of the music signal above the masking threshold) was less than the statistical entropy resulted in the perceptual transform coder (PXFM) [8, 16]. This algorithm used a 2048 point real FFT with 1/16 overlap, which gave good frequency resolution (for redundancy removal) but had some coding loss due to the window overlap.

The next-generation algorithm was ASPEC [2], which used the modified discrete-cosine transform (MDCT) filterbank [15] instead of the FFT, and a more elaborate bit allocation and buffer control mechanism as a means of generating constant-rate output. The MDCT is a critically sampled filterbank, and so does not suffer the 1/16 overlap loss that the PXFM coder did. In addition, ASPEC employed an adaptive window size of 1024 or 256 to control noise spreading resulting from quantization. However, its frequency resolution was half that of PXFM's resulting in some loss in the coding efficiency (c.f., Section 42.3).

PAC as first proposed in [10] is a third-generation algorithm learning from ASPEC and PXFM-Stereo [9]. In its current form, it uses a long transform window size of 2048 for better redundancy removal together with window switching for noise spreading control. It adds composite stereo coding in a flexible and easily controlled form, and introduces improvements in noiseless compression and threshold calculation methods as well. Additional threshold calculations are made for stereo signals to eliminate the problem of binaural noise unmasking.

PAC supports encoders of varying complexity and quality. Broadly speaking, PAC consists of a core codec augmented by various enhancement. The full capability algorithm is sometimes also referred to as *Enhanced PAC* (or EPAC). EPAC is easily configurable to (de)activate some or all of the enhancements depending on the computational budget. It also provides a built-in scheduling mechanism so that some of the enhancements are automatically turned on or off based on averaged short term computational requirement.

One of the major enhancements in the EPAC codec is geared towards improving the quality at lower bit rates of signals with sharp attacks (e.g., castanets, triangles, drums, etc.). Distortion of attacks is a particularly noticeable artifact at lower bit rates. In EPAC, a signal adaptive switched filterbank which switches between a MDCT and a wavelet transform is employed for analysis and synthesis [18]. Wavelet transform offer natural advantages for the encoding of transient signals and

the switched filterbank scheme allows EPAC to merge this advantage with the advantages of MDCT for stationary audio segments.

Real-time PAC encoder and decoder hardware have been provided to standards bodies, as well as business partners. Software implementation of real time decoder algorithm is available on PCs and workstations, as well as low cost general-purpose DSPs, making it suitable for mass-market applications. The decoder typically consumes only a fraction of the CPU processing time (even on a 486-PC). Sophisticated encoders run on current workstations and RISC-PCs; simpler real-time encoders that provide moderate compression or quality are realizable on correspondingly less inexpensive hardware.

In the remainder of this paper we present a detailed overview of the various elements of PACs, its applications, audio quality, and complexity issues. The organization of the chapter is as follows. In Section 42.2, some of applications of PAC and its performance on formalized audio quality evaluation tests is discussed. In Section 42.3, we begin with a look at the defining blocks of a perceptual coding scheme followed by the description of the PAC structure and its key components (i.e., filterbank, perceptual model, stereo threshold, noise allocation, etc.). In this context we also describe the switched MDCT/wavelet filterbank scheme employed in the EPAC codec. Section 42.4 focuses on the multichannel version of PAC. Discussions on bitstream formation and decoder complexity are presented in Sections 42.5 and 42.6, respectively, followed by concluding remarks in Section 42.7.

42.2 Applications and Test Results

In the most recent test of audio quality [4] PAC was shown to be the best available audio quality choice [4] for audio compression applications concerning 5-channel audio. This test evaluated both backward compatible audio coders (MPEG Layer II, MPEG Layer III) and non-backward compatible coders, including PAC. The results of these tests showed that PAC's performance far exceeded that of the next best coder in the test.

Among the emerging applications of PAC audio compression technology, the Internet offers one of the best opportunities. High quality audio on demand is increasingly popular and promises both to make existing Internet services more compelling as well as open avenues for new services. Since most Internet users connect to the network using as low bandwidth modem (14.4 to 28.8 kb/s) or at best an ISDN link, high quality low bit rate compression is essential to make audio streaming (i.e., real time playback) applications feasible. PAC is particularly suitable for such applications as it offers near CD quality stereo sound at the ISDN rates and the audio quality continues to be reasonably good for bit rates as low as 12 to 16 kb/s. PAC is therefore finding increasing acceptance in the Internet world.

Another application currently in the process of standardization is digital audio radio (DAR). In the U.S. this may have one of several realizations: a terrestrial broadcast in the existing FM band, with the digital audio available as an adjunct to the FM signal and transmitted either coincident with the analog FM, or in an adjacent transmission slot; alternatively, it can be a direct broadcast via satellite (DBS), providing a commercial music service in an entirely new transmission band. In each of the above potential services, AT&T and Lucent Technologies have entered or partnered with other companies or agencies, providing PAC audio compression at a stereo coding rate of 128 to 160 kb/s as the audio compression algorithm proposed for that service.

Some other applications where PAC has been shown to be the best audio compression quality choice is compression of the audio portion of television services, such as high-definition television (HDTV) or advanced television (ATV).

Still other potential applications of PAC that require compression but are broadcast over wired channels or dedicated networks are DAR, HDTV or ATV delivered via cable TV networks, public switched ISDN, or local area networks. In the last case, one might even envision an "entertainment

bus” for the home that broadcasts audio, video, and control information to all rooms in a home.

Another application that entails transmitting information from databases of compressed audio are network-based music servers using LAN or ISDN. This would permit anyone with a networked decoder to have a “virtual music catalog” equal to the size of the music server. Considering only compression, one could envision a “CD on a chip”, in which an artist’s CD is compressed and stored in a semiconductor ROM and the music is played back by inserting it into a robust, low-power palm-sized music player. Audio compression is also important for read-only applications such as multi-media (audio plus video/stills/text) on CD-ROM or on a PC’s hard drive. In each case, video or image data compete with audio for the limited storage available and all signals must be compressed.

Finally, there are applications in which point-to-point transmission requires compression. One is radio station studio to transmitter links, in which the studio and the final transmitter amplifier and antenna may be some distance apart. The on-air audio signal might be compressed and carried to the transmitter via a small number of ISDN B-channels. Another application is the creation of a “virtual studio” for music production. In this case, collaborating artists and studio engineers may each be in different studio, perhaps very far apart, but seamlessly connected via audio compression links running over ISDN.

42.3 Perceptual Coding

PAC, as already mentioned, is a “Perceptual Coder” [6], as opposed to a source modelling coder. For typical examples of source, perceptual, and combined source and perceptual coding, see Figs. 42.1, 42.2, and 42.3. Figure 42.1 shows typical block diagrams of source coders, here exemplified by DPCM, ADPCM, LPC, and transform coding [5]. Figure 42.2 illustrates a basic perceptual coder. Figure 42.3 shows a combined source and perceptual coder.

“Source model” coding describes a method that eliminates redundancies in the source material in the process of reducing the bit rate of the coded signal. A source coder can be either lossless, providing perfect reconstruction of the input signal or lossy. Lossless source coders remove no information from the signal; they remove redundancy in the encoder and restore it in the decoder. Lossy coders remove information from (add noise to) the signal; however, they can maintain a constant compression ratio regardless of the information present in a signal. In practice, most source coders used for audio signals are quite lossy [3].

The particular blocks in source coders, e.g., Fig. 42.1, may vary substantially, as shown in [5], but generally include one or more of the following.

- Explicit source model, for example an LPC model.
- Implicit source model, for example DCPM with a fixed predictor.
- Filterbank, in other words a method of isolating the energy in the signal.
- Transform, which also isolates (or “diagonalizes”) the energy in the signal.

All of these methods serve to identify and potentially remove redundancies in the source signal. In addition, some coders may use sophisticated quantizers and information-theoretic compression techniques to efficiently encode the data, and most if not all coders use a bitstream formatter in order to provide data organization. Typical compression methods do not rely on information-theoretic coding alone; explicit source models and filterbanks provide superior source modeling for audio signals.

All perceptual coders are lossy. Rather than exploit mathematical properties of the signal or attempt to understand the producer, perceptual coders model the listener, and attempt to remove irrelevant (undetected) parts of the signal. In some sense, one could refer to it as a “destination” rather than “source” coder. Typically, a perceptual coder will have a lower SNR than an equivalent rate source coder, but will provide superior perceived quality to the listener.

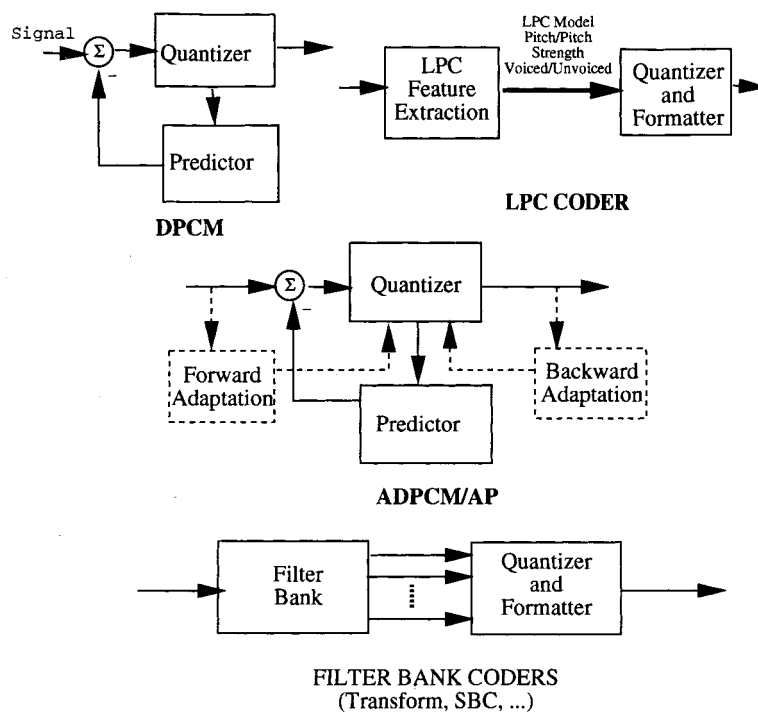

FIGURE 42.1: Block diagrams of selected source-coders.

The perceptual coder shown in Fig. 42.2 has the following functional blocks.

- Filterbank — Converts the input signal into a form suitable for perceptual processing.
- Perceptual model — Determines the irrelevancies in the signal, generating a perceptual threshold.
- Quantization — Applies the perceptual threshold to the output of the filterbank, thereby removing the irrelevancies discovered by the perceptual model.
- Bit stream former — Converts the quantized output and any necessary side information into a form suitable for transmission or storage.

The combined source and perceptual coder shown in Fig. 42.3 has the following functional blocks.

FIGURE 42.2: Block diagrams of a simple perceptual coder.

FIGURE 42.3: Block diagrams of an integrated source-perceptual coder.

- Filterbank — Converts the input signal into a form that extracts redundancies and is suitable for perceptual processing.
- Perceptual model — Determines the irrelevancies in the signal, generates a perceptual threshold, and relates the perceptual threshold to the filterbank structure.
- Fitting of perceptual model to filtering domain — Converts the outputs of the perceptual model into a form relevant to the filter bank.
- Quantization — Applies the perceptual threshold to the output of the filterbank, thereby removing the irrelevancies discovered by the perceptual model.
- Information-theoretic compression — Removes redundancy from the output of the quantizer.
- Bit stream former — Converts the compressed output and any necessary side information into a form suitable for transmission or storage.

Most coders referred to as perceptual coders are combined source and perceptual coders. Combining a filterbank with a perceptual model provides not only a means of removing perceptual irrelevancy, but also, by means of the filterbank, provides signal diagonalization, ergo source coding gain. A combined coder may have the same block diagram as a purely perceptual coder; however, the choice of filterbank and quantizer will be different. PAC is a combined coder, removing both irrelevancy and redundancy from audio signals to provide efficient compression.

42.3.1 PAC Structure

Figure 42.4 shows a more detailed block diagram of the monophonic PAC algorithm, and illustrates the flow of data between the algorithmic blocks. There are five basic parts.

FIGURE 42.4: Block diagram of monophonic PAC encoder.

1. Analysis filterbank — The filterbank converts the time domain audio signal to the short-term frequency domain. Each block is selectively coded by 1024 or 128 uniformly spaced frequency bands, depending on the characteristics of the input signal. PAC's filterbank is used for source coding and cochlear modeling (i.e., perceptual coding).
2. Perceptual model — The perceptual model takes the time domain signal and the output of the filterbank and calculates a frequency domain threshold of masking. A threshold of masking is a frequency dependent calculation of the maximum noise that can be added to the audio material without perceptibly altering it. Threshold values are of the same time and frequency resolution as the filterbank.
3. Noise allocation — Noise is added to the signal in the process of quantizing the filterbank outputs. As mentioned above, the perceptual threshold is expressed as a noise level for each filterbank frequency; quantizers are adjusted such that the perceptual thresholds are met or exceeded in a perceptually gentle fashion. While it is always possible to meet the perceptual threshold in a unlimited rate coder, coding at high compression ratios requires both overcoding (adding less noise to the signal than the perceptual threshold requires) and undercoding (adding more noise to the signal than the perceptual threshold requires). PAC's noise allocation allows for some time buffering, smoothing local peaks and troughs in the bitrate demand.
4. Noiseless compression — Many of the quantized frequency coefficients produced by the noise allocator are zero; the rest have a non-uniform distribution. Information-theoretic methods are employed to provide an efficient representation of the quantized coefficients.
5. Bitstream former — Forms the bitstream, adds any transport layer, and encodes the entire set of information for transmission or storage.

As an example, Fig. 42.5 shows the perceptual threshold and spectrum for a typical (trumpet) signal. The staircase curve is the calculated perceptual threshold, and the varying curve is the short-term spectrum of the trumpet signal. Note that a great deal of the signal is below the perceptual threshold, and therefore redundant. This part of the signal is what we discard in the perceptual coder.

FIGURE 42.5: Example of masking threshold and signal spectrum.

42.3.2 The PAC Filterbank

The filterbank normally used in PAC is referred to as the modified discrete cosine transform (MDCT) [15]. It may be viewed as a modulated, maximally decimated perfect reconstruction filterbank. The sub-band filters in a MDCT filterbank are linear phase FIR filters with impulse responses twice as long as the number of subbands in the filterbank. Equivalently, MDCT is a lapped orthogonal transform with a 50% overlap between two consecutive transform blocks; i.e., the number of transform coefficients is equal to one half the block length. Various efficient forms of this algorithm are detailed in [11]. Previously, Ferreira [10] has created an alternate form of this filterbank where the decimation is done by dropping the imaginary part of an odd-frequency FFT, yielding an even-frequency FFT and an MDCT from the same calculations.

In an audio coder it is quite important to appropriately choose the frequency resolution of the filterbank. During the development of the PAC algorithm, a detailed study of the effect of filterbank resolution for a variety of signals was examined. Two important considerations in perceptual coding, i.e., coding gain and non-stationarity within a block, were examined as a function of block length. In general the coding gain increases with the block length indicating a better signal representation for redundancy removal. However, increasing non-stationarity within a block forces the use of more conservative perceptual masking thresholds to ensure the masking of quantization noise at all times. This reduces the realizable or net coding gain. It was found that for a vast majority of music samples the realizable coding gain peaks at the frequency resolution of about 1024 lines or subbands, i.e., a window of 2048 points (this is true for sampling rates in the range of 32 to 48 kHz). PAC therefore employs a 1024 line MDCT as the normal “long” block representation for the audio signal.

In general, some variation in the time frequency resolution of the filterbank is necessary to adapt to the changes in the statistics of the signal. Using a high frequency resolution filterbank to encode a signal segment with a sharp attack leads to significant coding inefficiencies or *pre-echo* conditions. Pre-echos occur when quantization errors are spread over the block by the reconstruction filter. Since pre-masking by an attack in the audio signal lasts for only about 1 msec (or even less for stereo signals), these reconstruction errors are potentially audible as pre-echos unless significant readjustments in the perceptual thresholds are made resulting in coding inefficiencies.

PAC offers two strategies for matching the filterbank resolution to the signal appropriately. A lower computational complexity version is offered in the form of *window switching* approach whereby the MDCT filterbank is switched to a lower 128 line spectral resolution in the presence of attacks. This approach is quite adequate for the encoding of attacks at moderate to higher bit rates (96 kbps or higher for a stereo pair). Another strategy offered as an enhancement in the EPAC codec is the switched MDCT/wavelet filterbank scheme mentioned earlier. The advantages of using such a scheme as well as its functional details are presented below.

42.3.3 The EPAC Filterbank and Structure

The disadvantage of the window switching approach is that the resulting time resolution is uniformly higher for all frequencies. In other words, one is forced to increase the time resolution at the lower frequencies to increase it to the necessary extent at higher frequencies. The inefficient coding of lower frequencies becomes increasingly burdensome at lower bit rates, i.e., 64 kbps and lower. An ideal filterbank for sharp attacks is a non-uniform structure whose subband matches the critical band scale. Moreover, it is desirable that the high frequency filters in the bank be proportionately shorter. This is achieved in EPAC by employing a high spectral resolution MDCT for stationary portions of the signal and switching to a non-uniform (tree structured) wavelet filterbank (WFB) during non-stationarities.

WFBs are quite attractive for the encoding of attacks [17]. Besides the fact that wavelet representation of such signals is more compact than the representation derived from a high resolution MDCT,

wavelet filters have desirable temporal characteristics. In a WFB, the high frequency filters (with a suitable moment condition as discussed below) typically have a compact impulse response. This prevents excessive time spreading of quantization errors during synthesis.

The overview of an encoder based on the switched filterbank idea is illustrated in Fig. 42.6. This structure entails the design of a suitable WFB which is discussed next.

FIGURE 42.6: Block diagram of the switched filterbank audio encoder.

The WFB in EPAC consists of a tree structured wavelet filterbank which approximates the critical band scale. The tree structure has the natural advantage that the effective support (in time) of the subband filters is progressively smaller with increasing center frequency. This is because the critical bands are wider at higher frequency so fewer cascading stages are required in the tree to achieve the desired frequency resolution. Additionally, proper design of the prototype filters used in the tree decomposition ensures (see below) that the high frequency filters in particular are compactly localized in time.

The decomposition tree is based on sets of prototype filterbanks. These provide two or more bands of split and are chosen to provide enough flexibility to design a tree structure that approximates the critical band partition closely. The three filterbanks were designed by optimizing parametrized para-unitary filterbanks using standard optimization tools and an optimization criterion based on weighted stopband energy [20]. In this design, the *moment* condition plays an important role in achieving desirable temporal characteristics for the high frequency filters. An M band para-unitary filterbank with subband filters $\{H_i\}_{i=1}^M$ is said to satisfy a P th order moment condition if $H_i(e^{j\omega})$ for $i = 2, 3, \dots, M$ has a P th order zero at $\omega = 0$ [20]. For a given support for the filters, K , requiring $P > 1$ in the design yields filters for which the “effective” support decreases with increasing P . In the other words, most of the energy is concentrated in an interval $K' < K$ and K' is smaller for higher P (for a similar stopband error criterion). The improvement in the temporal response of the filters occurs at the cost of an increased transition band in the magnitude response. However, requiring at least a few vanishing moments yields filters with attractive characteristics.

The impulse response of a high frequency *wavelet* filter (in a 4-band split) is illustrated in Fig. 42.7. For comparison, the impulse response of a filter from a modulated filterbank with similar frequency characteristics is also shown. It is obvious that the *wavelet* filter offers superior localization in time.

FIGURE 42.7: High frequency wavelet and cosine-modulated filters.

Switching Mechanism

The MDCT is a lapped orthogonal transform. Therefore, switching to a wavelet filterbank requires orthogonalization in the overlap region. While it is straightforward to set up a general orthogonalization problem, the resulting transform matrix is inefficient computationally. The orthogonalization algorithm can be simplified by noting that a MDCT operation over a block of $2 * N$ samples is equivalent to a symmetry operation on the windowed data (i.e., outer $N/2$ samples from either end of the window are folded into the inner $N/2$ samples) followed by an N point orthogonal block transform Q over these N samples. Perfect reconstruction is ensured irrespective of the choice of a particular block orthogonal transform Q . Therefore, Q may be chosen to be a DCT for one block and a wavelet transform matrix for the subsequent or any other block. The problem with this approach is that the symmetry operation extends the wavelet filter (or its translates) in time and also introduces discontinuities in these filters. Thus, it impairs the temporal as well as frequency characteristics of the wavelet filters. In the present encoder, this impairment is mitigated by the following two steps: (1) start and stop windows are employed to switch between $MDCT$ and WFB (this is similar to the window switching scheme in PAC), and (2) the effective overlap between the transition and wavelet windows is reduced by the application of a new family of *smooth* windows [19]. The resulting switching sequence is illustrated in Fig. 42.8.

The next design issue in the switched filterbank scheme is the design of a $N \times N$ orthogonal matrix Q^{WFB} based on the prototype filters and the chosen tree structure. To avoid circular convolutions, we employ transition filters at the edge of the blocks. Given a subband filter, c_k , of length K a total of $K_1 = (K/M) - 1$ transition filters are needed at the two ends of the block. The number at a particular end is determined by the rank of a $K \times (K_1 + 1)$ matrix formed by the translations

FIGURE 42.8: A filterbank switching sequence.

of c_k . The transition filters are designed through optimization in a subspace constrained by the pre-determined rows of Q^{WFB} .

42.3.4 Perceptual Modeling

Current versions of PAC utilize several perceptual models. Simplest is the monophonic model which calculates an estimated JND in frequency for a single channel. Others add MS (i.e., sum and difference) thresholds and noise-imaging protected thresholds for pairs of channels as well, as “global thresholds” for multiple channels. In this section we discuss the calculation of monophonic thresholds, MS thresholds, and noise-imaging protected thresholds.

Monophonic Perceptual Model

The perceptual model in PAC is similar in method to the model shown as “Psychoacoustic Model II” in the MPEG-1 audio standard annexes [14]. The following steps are used to calculate the masking threshold of a signal.

- Calculate the power spectrum of the signal in 1/3 critical band partitions.
- Calculate the tonal or noiselike nature of the signal in the same partitions, called the tonality measure.
- Calculate the spread of masking energy, based on the tonality measure and the power spectrum.
- Calculate the time domain effects on the masking energy in each partition.
- Relate the masking energy to the filterbank outputs.

Application of Masking to the Filterbank

Since PAC uses the same filterbank for perceptual modeling and source coding, converting masking energy into terms meaningful to the filterbank is straightforward. However, the noise allocator quantizes filterbank coefficients in fixed blocks, called *coder bands*, which differ from the 1/3 critical band partitions used in perceptual modeling. Specifically, 49 coder bands are used for the 1024-line filterbank, and 14 for the 128-line filterbank. Perceptual thresholds are mapped to coder bands by using the minimum threshold that overlaps the band.

In EPAC additional processing is necessary to apply the threshold to the WFB. The thresholds for the quantization of wavelet coefficients are based on an estimate of time-varying *spread* energy in each of the subbands and a tonality measure as estimated above. The spread energy is computed by considering the spread of masking across frequency as well as time. In other words, an inter-frequency as well as a temporal spreading function is employed. The shape of these spreading functions may be derived from the cochlear filters [1]. The temporal spread of masking is frequency dependent and is roughly determined by the (inverse of) bandwidth of the cochlear filter at that frequency. A fixed temporal spreading function for a range of frequencies (wavelet subbands) is employed. The coefficients in a subband are grouped in a *coder band* as above and one threshold value per coderband is used in quantization. The coderband span ranges from 10 msec in the lowest frequency subband to about 2.5 msec in the highest frequency subband.

Stereo Threshold Calculation

Experiments have demonstrated that the monaural perceptual model does not extend trivially to the binaural case. Specifically, even if one signal is masked by both the L (left) and R (right) signals individually, it may not be masked when the L and R signals are presented binaurally. For further details, see the discussion of Binary Masking Level Difference (BLMD) in [12].

In stereo PAC Fig. 42.9, we used a model of BLMD in several ways, all based on the calculation of the M (mono, $L + R$) and S (stereo, $L - R$) thresholds in addition to the independent L and R thresholds. To compute the M and S thresholds, the following steps are added after the computation of the masking energy.

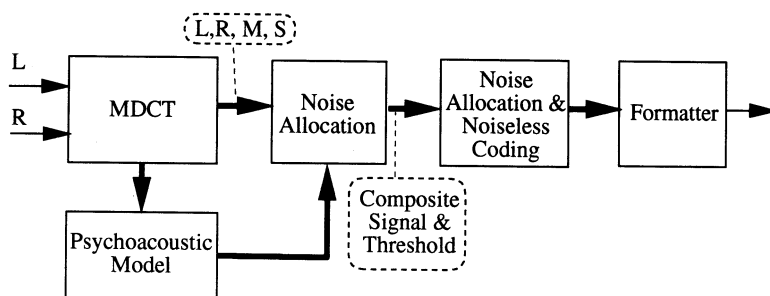

FIGURE 42.9: Stereo PAC block diagram.

- Calculate the spread of masking energy for the other channel, assuming a tonal signal and adding BMLD protection.
- Choose the more restrictive, or smaller, masking energy.

For the L and R thresholds, the following step is added after the computation of the masking energy.

- Calculation of the spread of masking energy for the other channel. If the two masking energies are similar, add BMLD protection to both.

These four thresholds are used for the calculation of quantization, rate, and so on. An example set of spectra and thresholds for a vocal signal are shown in Fig. 42.10. In this figure, compare the threshold values and energy values in the S (or “Difference”) signal. As is clear, even with the BMLD protection, most of the S signal can be coded as zero, resulting in substantial coding gain. Because the signal is more efficiently coded as MS even at low frequencies where the BLMD protection is in effect, that protection can be greatly reduced for the more energetic M channel because the noise will image in the same location as the signal, and not create an unmasking condition for the M signal, even at low frequencies. This provides increases in both audio quality and compression rate.

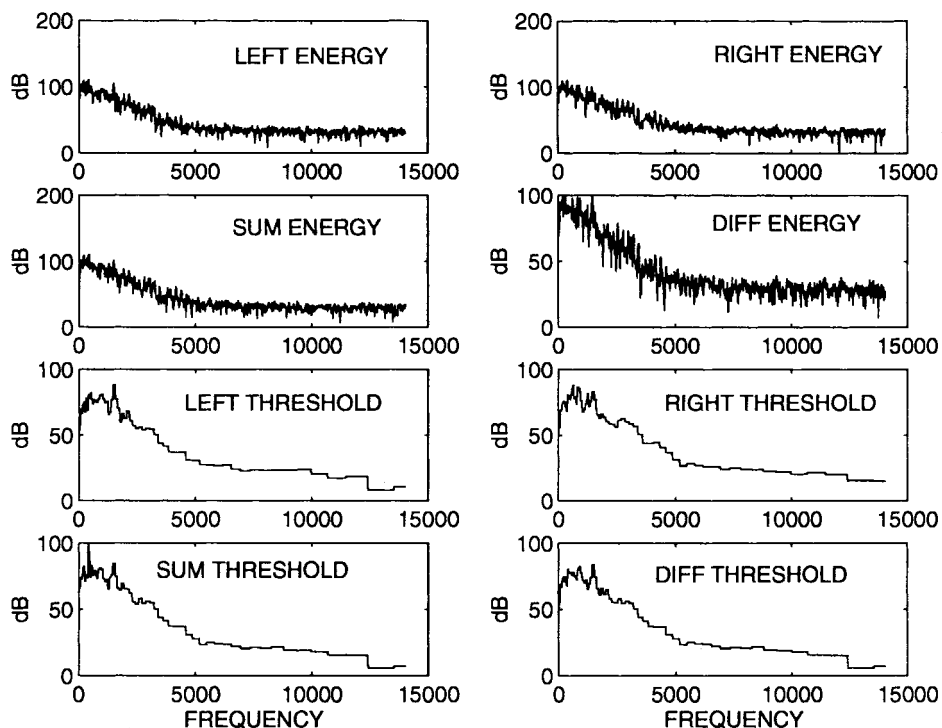

FIGURE 42.10: Examples of stereo PAC thresholds.

42.3.5 MS vs. LR Switching

In PAC, unlike the MPEG Layer III codec [13] MS decisions are made independently for each group of frequencies. For instance, the coder may alternate coding each group as MS or LR, if that proves most efficient. Each of the L, R, M, and S filterbank coefficients are quantized using the appropriate thresholds, and the number of bits required to transmit coefficients is computed. For each group of frequencies, the more efficient of LR or MS is chosen; this information is encoded with a Huffman codebook and transmitted as part of the bitstream.

42.3.6 Noise Allocation

Compression is achieved by quantizing the filter bank outputs into small integers. Each coder band's threshold is mapped onto 1 of 128 exponentially distributed quantizer step sizes, which is used to quantize the filter bank outputs for that coder band.

PAC controls the instantaneous rate of transmission by adjusting the thresholds according to an equal-loudness calculation. Thresholds are adjusted so that the compression ratio is met, plus or minus a small amount to allow for short term irregularities in demand. This noise allocation system is iterative, using a single estimator that represents the absolute loudness of the noise relative to the perceptual threshold. Noise allocation is made across all frequencies for all channels, regardless of stereo coding decision: ergo the bits are allocated in a perceptually effective sense between L, R, M, and S, without regard to any measure of how many bits are assigned to L, R, M, and S.

42.3.7 Noiseless Compression

After the quantizers and quantized coefficients for a block are determined, information-theoretic methods are employed to yield an efficient representation.

Coefficients for each coder band are encoded using one of eight Huffman codebooks. One of the tables encodes only zeros; the rest encode coefficients with increasing absolute value. Each codebook encodes groups of two or four coefficients, with the exception of the zero codebook which encodes all of the coefficients in the band. See Table 42.1 for details. In this table, LAV refers to the largest absolute value in a given codebook, and dimension refers to the number of quantized outputs that are coded together in one codeword. Two codebooks are special, and require further mention. The zero codebook is of indeterminate size, it indicates that all quantized values that the zero codebook applies to are in fact zero, no further information is transmitted about those values. Codebook seven is also a special codebook. It is of size -16:16 by -16:16, but the entry of absolute value 16 is not a data value, it is, rather, an escape indicator. For each escape indicator sent in codebook seven (there can be zero, one, or two per codeword), there is an additional escape word sent immediately after the Huffman codeword. This additional codeword, which is generated by rule, transmits the value of the escaped codeword. This generation by rule is a process that has no bounds; therefore, any quantized value can be transmitted by the use of an escape sequence.

TABLE 42.1 PAC Huffman

Codebooks		
Codebook	LAV	Dimension
0	0	*
1	1	4
2	1	4
3	2	4
4	4	2
5	7	2
6	12	2
7	ESC	2

Communicating the codebook used for each band constitutes a significant overhead; therefore, similar codebooks are grouped together in *sections*, with only one codebook transmitted and used for encoding each section.

Since the possible quantizers are precomputed, the indices of the quantizers are encoded rather than the quantizer values. Quantizer indices for coder bands which have only zero coefficients are discarded; the rest are differentially encoded, and the differences are Huffman encoded.

42.4 Multichannel PAC

The multichannel perceptual audio coder (MPAC) extends the stereo PAC algorithm to the coding of multiple audio channels. In general, the MPAC algorithm is software configurable to operate in 2, 4, 5, and 5.1 channel mode. In this document we will describe the MPAC algorithm as it is applied to a 5-channel system consisting of the five full bandwidth channels: Left (L), Right (R), Center (C), Left Surround (Ls), and Right Surround (Rs).

The MPAC 5-channel audio coding algorithm is illustrated in Fig. 42.11. Below we describe the various modules, concentrating in particular on the ones that are different from the stereo algorithm.

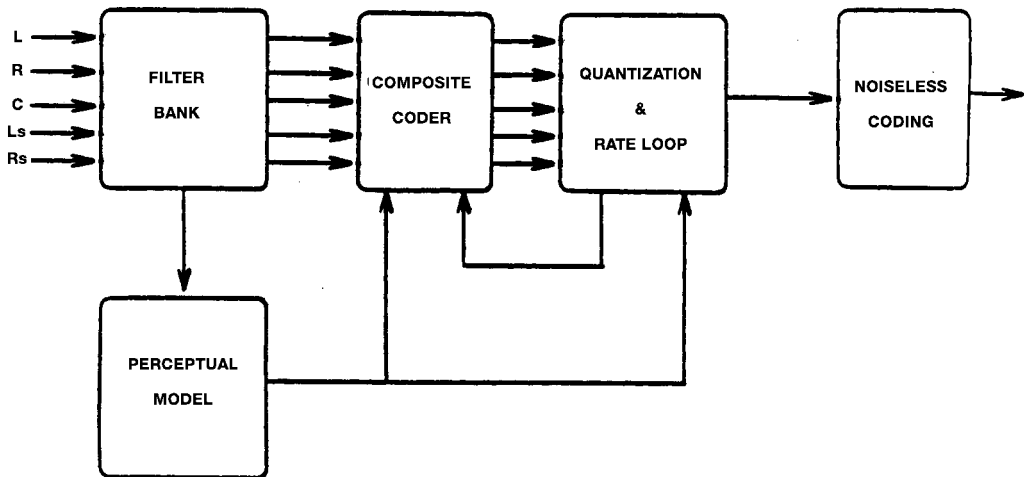

FIGURE 42.11: Block diagram of MPAC.

42.4.1 Filterbank and Psychoacoustic Model

Like the stereo coder, MPAC employs a MDCT filterbank with two possible resolutions, i.e., the usual long block which has 1024 uniformly spaced frequency outputs and a short bank which has 128 uniformly spaced frequency bins. A window switching algorithm, as described above, is used to switch to a short block in the presence of strong non-stationarities in the signal. In the 5-channel setup it is desirable to be able to switch the resolution independently for various subsets of channels. For example, one possible scenario is to apply the window switching algorithm to the front channels (L, R, and C) independently of the surround channels (Ls and Rs). However, this somewhat inhibits the possibilities for composite coding (see below) among the channels. Therefore, one needs to examine the relative gain of independent window switching vs. the gain from a higher level of composite coding. In the present implementation different filterbank resolutions for the front and surround channels are allowed.

The individual masking threshold for the five channels are computed using the PAC psychoacoustic model described above. In addition, the front pair LR and the surround pair Ls/Rs are used to generate two pairs of MS thresholds (c.f., Section "Stereo Threshold Calculation"). The five channels are coded with their individual thresholds excepting in the case where joint stereo coding is being used (either for the front or the surround pair), in which case the appropriate MS thresholds

are used. In addition to the five individual and four stereo thresholds, a joint (or “global”) threshold based on all channels is also computed. The computation and role of the global threshold will be discussed later in this section.

42.4.2 The Composite Coding Methods

The MPAC algorithm extends the MS coding of the stereo algorithm to a more elaborate composite coding scheme. Like the MS coding algorithm, the MPAC algorithm uses adaptive composite coding in both time and frequency: the composite coding mode is chosen separately for each of the coder bands at every analysis instance. This selection is based on a “perceptual entropy” criterion and attempts to minimize the bit rate requirement as well as exercise some control over noise localization. The coding scheme uses two complementary sets of inter-channel combinations as described below:

- MS coding for the front and surround pair
- Inter-channel prediction

MS coding is a basis transformation operation and is therefore performed with the uncoded samples of the corresponding pair of channels. The resulting M or S channel is then coded using its own threshold (which is computed separately from the individual channel threshold). Inter-channel prediction, on the other hand, is performed using the quantized samples of the predicting channel. This is done to prevent the propagation of quantization errors (or “cross-talk”). The predicted value for each channel is subtracted from the channel samples and the resulting difference is encoded using the original channel threshold. It may be noted that the two sets of channel combinations are nested so that either, both, or none may be employed for a particular coder band. The coder currently employs the following possibilities for inter-channel prediction.

For the Front Channels (L, R & C): Front L and R channels are coded as LR or MS. In addition, one of the following two possibilities for inter-channel prediction may be used.

1. Center predicts LR (or M if MS coding mode is on).
2. Front M channel predicts the center.

For the Surround Channels (Ls and Rs): Ls and Rs channels are coded as Ls/Rs or Ms/Ss (where Ms and Ss are, respectively, the surround M and surround S). In addition, one or both of following two modes of interchannel prediction may be employed:

1. Front L, R, M channels predict Ls/Rs or Ms.
2. Center channel predicts Ls/Rs or Ms.

In the present implementation, the predictor coefficients in all of the above inter-channel prediction equations are all fixed to either zero or one.

Note that the possibility of completely independent coding is implicit in the above description, i.e., the possibility of turning off any possible prediction is always included. Furthermore, any of these conditions may be independently used in any of the 49 coder bands (long filter band length) or in the 14 coder bands (short filter band length), for each block of filterbank output. Also note that for the short filterbank where the outputs are grouped into 8 groups of 128 (each group of 128 has 14 bands), each of these 8 groups has independently calculated composite coding.

The decisions for composite coding are based primarily on the “perceptual entropy” criterion; i.e., the composite coding mode is chosen to minimize the bit requirement for the perceptual coding of the filterbank outputs from the five channels. The decision for MS coding (for the front and surround pair) is also governed in part by noise localization considerations. As a consequence, the MPAC coding algorithm ensures that signal and noise images are localized at the same place in the

front and rear planes. The advantage of this coding scheme is that the quantization noise usually remains masked not only in a listening room environment but also during headphone reproduction of a stereo downmix of the five coded channels (i.e., when two downmixed channels of the form $L_c = L + \alpha C + \beta L_s$, and $R_c = R + \alpha C + \beta R_s$ are produced and fed to a headphone).

The method used for composite coding is still in the experimental phase and subject to refinements/modifications in future.

42.4.3 Use of a Global Masking Threshold

In addition to the five individual thresholds and the four MS thresholds, the MPAC coder also makes use of a global threshold to take advantage of masking across the various channels. This is done when the bit demand is consistently high so that the bit reservoir is close to depletion. The global threshold is taken to be the maximum of five individual thresholds minus a “safety margin”. This global threshold is phased in gradually when the bit reservoir is really low (e.g., less than 20%) and in that case it is used as a lower limit for the individual thresholds.

The reason that global threshold is useful is because results in [12] indicate that if the listener is more than a “critical distance” away from the speakers, then the spectrum at either of listener’s ear may be well approximated by the sum of power spectrums due to individual speakers.

The computation of a global threshold also involves a safety margin. This safety margin is frequency dependent and is larger for the lower frequencies and smaller for higher frequencies. The safety margin changes with the bit reservoir state.

42.5 Bitstream Formatter

PAC is a block processing algorithm; each block corresponds to 1024 input samples from each channel, regardless of the number of channels. The encoded filter bank outputs, codebook sections, quantizers, and channel combination information for one 1024-sample chunk or eight 128-sample chunks are packed into one *frame*.

Depending on the application, various extra information is added to first frame or to every frame. When storing information on a reliable media, such as a hard disk, one header indicating version, sample rate, number of channels, and encoded rate is placed at the beginning of the compressed music. For extremely unreliable transmission channels, like DAR, a header is added to each frame. This header contains synchronization, error recovery, sample rate, number of channels, and the transmission bit rate.

42.6 Decoder Complexity

The PAC decoder is of approximately equal complexity to other decoders currently known in the art. Its memory requirements are approximately

- 1100 words each for MDCT and WFB workspace
- 512 words per channel for MDCT memory
- (optional) 1024 words per channel for error mitigation
- 1024 samples per channel for output buffer
- 12 Kbytes ROM for codebooks

The calculation requirements for the PAC decoder are slightly more than doing a 512-point complex FFT per 1024 samples per channel. On an Intel 486 based platform, the decoder executes in real time using up approximately 30 to 40.

42.7 Conclusions

PAC has been tested both internally and externally by various organizations. In the 1993 ISO-MPEG-2 5-channel test, PAC demonstrated the best decoded audio signal quality available from any algorithm at 320 kb/s, far outperforming all algorithms, including the backward compatible algorithms. PAC is the audio coder in three of the submissions to the U.S. DAR project, at bit rates of 160 kb/s or 128 kb/s for two-channel audio compression.

PAC presents innovations in the stereo switching algorithm, the psychoacoustic model, filterbank, the noise-allocation method, and the noiseless compression technique. The combination provides either better quality or lower bit rates than techniques currently on the market.

In summary, PAC offers a single encoding solution that efficiently codes signals from AM bandwidth (5 to 10 kHz) to full CD bandwidth, over dynamic ranges that match the best available analog to digital convertors, from one monophonic channel to a maximum of 16 front, 7 back, 7 auxiliary, and at least 1 effects channel. It operates from 16 kb/s up to a maximum of more than 1000 kb/s for the multiple-channel case. It is currently implemented in 2-channel hardware encoder and decoder, and 5-channel software encoder and hardware decoder. Versions of the bitstream that include an explicit transport layer provide very good robustness in the face of burst-error channels, and methods of mitigating the effects of lost audio data.

In the future, we will continue to improve PAC. Some specific improvements that are already in motion are the improvement of the psychoacoustic threshold for unusual signals, reduction of the overhead in the bitstream at low bit rates, improvements of the filterbanks for higher coding efficiency, and the application of vector quantization techniques.

43.1 Introduction

Kenzo Akagiri

In digital signal processing, manipulating of the signal is defined as an essentially mathematical procedure, while the AD and DA converters, the front end and the final stage devices of the processing, include analog factor/limitation. Therefore, the performance of the devices determines the degradation from the theoretical performance defined by the format of the system.

Until the 1970s, AD and DA converters with around 16-bit resolution, which were fabricated by module or hybrid technology, were very expensive devices for industry applications. At the beginning of the 1980s, the CD (compact disk) player, the first mass-production digital audio product, was introduced, and required low cost and monolithic type DA converters with 16-bit resolution. The two-step dual slope method [1] and the DEM (Dynamic Element Matching) [2] method were

used in the first generation DA converters for CD players. These were methods which relieved the accuracy and matching requirements of the elements to guarantee conversion accuracy by circuit technology. Introducing new ideas on circuit and trimming, like segment decode and laser trimming of the thin film fabricated on monolithic silicon die, for example, classical circuit topologies using binary weighted current source were also used. For AD conversion at same generation, successive approximation topology and the two-step dual slope method were also used.

In the mid-1980s, introductions of the oversampling and the noise shaping technology to the AD and DA converters for audio applications were investigated [3]. The converters using the technologies are the most popular devices for recent audio applications, especially as DA converters.

43.2 Oversampling AD and DA Conversion Principle

M. Katakura

43.2.1 Concept

The concept of the oversampling AD and DA conversion, DS or SD modulation, was known in the 1950s; however, the device technology to fabricate actual devices was impracticable until the 1980s [4].

The oversampling AD and DA conversion is characterized by the following three technologies.

1. oversampling
2. noise shaping
3. fewer bit quantizer (converters used one bit quantizer called the DS or SD type)

It is well known that the quantization noise shown in the next equation is determined by only quantization step D and distributed in bandwidth limited by Nyquist frequency ($2/f_s$), and the spectrum is almost similar to white noise when the step size is smaller than the signal level.

$$V_n = \Delta / \sqrt{12} \quad (43.1)$$

As shown in Fig. 43.1, the oversampling expands a capacity of the quantization noise cavity on the frequency axis and reduces the noise density in the audio band, and the noise shaping moves it to out of the band. Figure 43.2 is first-order noise shaping to show the principle of the noise shaping, in which the quantizer is represented by the adder fed an input $U(n)$ and a quantization noise $Q(n)$. $Y(n)$ and $U(n)$, the output and input signals of the quantizer, respectively, are given as follows:

$$Y(n) = U(n) + Q(n) \quad (43.2)$$

$$U(n) = X(n) + Q(n-1) \quad (43.3)$$

As a result, the output $Y(n)$ is

$$Y(n) = X(n) + \{Q(n) - Q(n-1)\} \quad (43.4)$$

The quantization noise in output $Y(n)$, which is a differentiation of the original quantization noise $Q(n)$ and $Q(n-1)$ shifted a time step, has high frequency boosted spectrum. Equation (43.4) is written as follows using z

$$Y(z) = X(z) + Q(z) (1 - Z^{-1}) \quad (43.5)$$

The oversampling conversion using one bit quantizer is called DS or SD AD/DA converters. Regarding one bit quantizer, a mismatch of the elements does not affect differential error; in other

FIGURE 43.1: Quantization noise of the oversampling conversion.

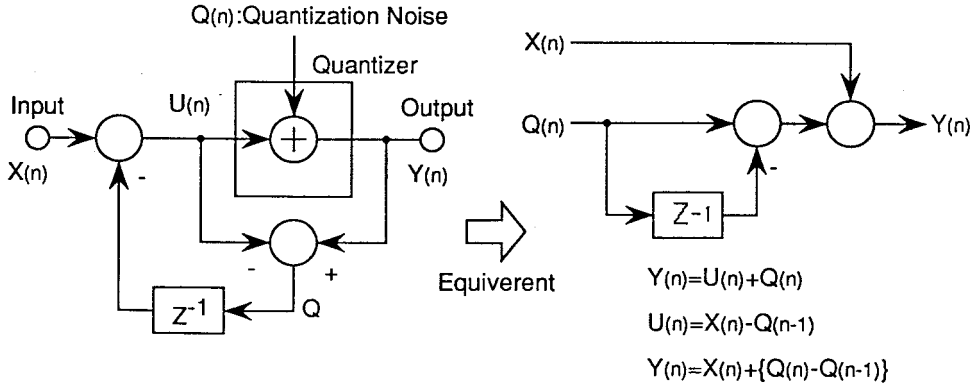

FIGURE 43.2: First-order noise shaping.

words, it has no non-linear error. Assume output swing of the quantizer is $\pm D$, quantization noise $Q(z)$ is white noise, and the magnitude $|Q(Wt)|$ is $D/3$, which corresponds to four times in power of Eq. (43.1) since the step size is twice that. Define θ which is $2\pi \cdot f_{\max} / f_s$, where f_{\max} and f_s are the audio bandwidth and the sampling frequency, respectively, then the in-band noise in Eq. (43.5) becomes

$$\begin{aligned}
 \bar{N}^2 &= |Q(\omega T)|^2 \frac{1}{2\pi} \int_{-\theta}^{\theta} |H(\omega T)|^2 d(\omega T) \\
 &= \frac{\Delta^2}{3} \frac{1}{2\pi} \int_{-\theta}^{\theta} |1 - e^{-j\omega T}|^2 d(\omega T) \\
 &= \frac{\Delta^2}{3} \frac{2}{\pi} (\theta - \sin \theta) \\
 &= \frac{\Delta^2}{9\pi} \theta^3
 \end{aligned} \tag{43.6}$$

The oversampling conversion has the following remarkable advantages compared with traditional methods.

1. It is easy to realize “good” one bit converters without superior device accuracy and matching.
2. Analog anti-aliasing filters with sharp cutoff characteristics are unnecessary due to oversampling.

Using the oversampling converting technology, requirements for analog parts are relaxed; however,

they require large scale digital circuits because interpolation filters in front of the DA conversion, which increase sampling frequency of the input digital signal, and decimation filters after the AD conversion, which reject quantization noise in high frequency and reduce sampling frequency, are required.

Figure 43.3 shows the block diagram of the DA converter including an interpolation filter. Though the scheme of the noise shaper is different from that of Fig. 43.2, the function is equivalent. Figure 43.4 shows the block diagram of the AD converter including a decimation filter. Note that the AD converter is almost the same as with the DA converters regarding the noise shapers; however, the details of the hardware are different depending on whether the block handles analog or digital signal. For example, to handle digital signals the delay units and the adders should use latches and digital adders; on the other hand, to handle analog signals delay units and adders using switched capacitor topology should be used. In the DS type, the quantizer is just reduction data length to one bit for the DA converter, and is a comparator for the AD converter by the same rule.

FIGURE 43.3: Oversampling DA converter.

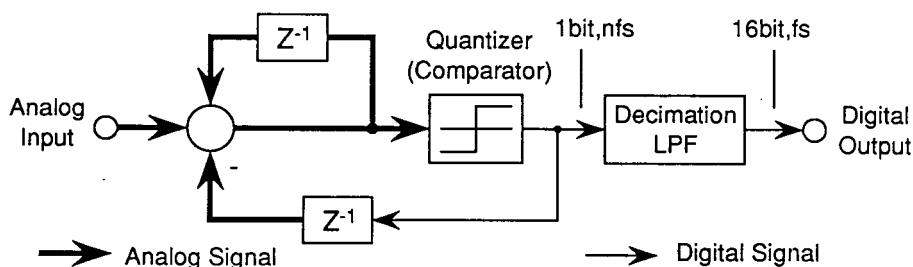

FIGURE 43.4: Oversampling AD converter.

43.2.2 Actual Converters

To achieve resolution of 16 bits or more for digital audio applications, the first-order noise shaping is not acceptable because it requires an extra high oversampling ratio, and the following technologies are actually adopted.

- High-order noise shaping

- Multi-stage (feedforward) noise shaping
- Interpolative conversion

1. High-order noise shaping

Figure 43.5 shows quantization noise spectrum for order of the noise shaping. The third-order noise shaping achieves 16-bit dynamic range using less than an oversampling ratio of 100. Figure 43.6 shows a third-order noise shaping for example of the high order. Order of the noise shaping used is 2 to 5 for audio applications.

FIGURE 43.5: Quantization noise vs. order of noise shaping.

FIGURE 43.6: Third-order noise shaping.

In Fig. 43.6 output $Y(z)$ is given

$$Y(z) = X(z) + Q(z) (1 - Z^{-1})^3 \quad (43.7)$$

The high-order noise shaping has a stability problem because the phase shift of the open loop in more than a third-order noise shaping exceeds 180° . In order to guarantee the stability, an amplitude limiter at the integrator outputs is used, and modification of the loop transfer function is done, although it degrades the noise shaping performance slightly.

2. Multi-stage (feedforward) noise shaping [5]

Multi-stage (feedforward) noise shaping (called MASH) achieves high-order noise shaping transfer functions using not high-order feedback but feedforward, and is shown in Fig. 43.7. Though two-stage (two-order) is shown in Fig. 43.7, three-stage (three-order) is usually used for audio applications.

FIGURE 43.7: Multi-stage noise shaping.

3. Interpolative converters [6]

This is a method which uses a few bit resolution converters instead of one bit. The method reduces the oversampling ratio and order of the noise shaping to guarantee specified dynamic range and improve the loop stability. Since absolute value of the quantization noise becomes small, it is relatively easy to guarantee noise level; however, linearity of large signal conditions affects the linearity error of the AD/DA converters used in the noise shaping loop.

Oversampling conversion has become a major technique in digital audio application, and one of the distinctions is that it does not inherently zero cross distort. For recent device technology, it is not so difficult to guarantee 18-bit accuracy. Thus far, the available maximum dynamic range is slightly less than 20 bit (120 dB) without noise weighting (wide band) due to analog limitation. On the other hand, converters with 20-bit or more resolution have been reported [7] and are expected to improve sound quality in very small signal levels from the standpoint of hearing.

43.4 The SDDS System for Digitizing Film Sound

H. Yamauchi, E. Saito, and M. Kohut

43.4.1 Film Format

There are three basic concepts for developing the SDDS format. They can

1. Provide sound quality similar to CD sound quality. We adapt ATRAC (Adaptive TRansform Acoustic Coding) to obtain good sound quality equivalent to that of CDs. ATRAC is the compression method used in the mini disc (MD) which has been in sale since 1992. ATRAC enables one record digital sound data by compressing about 1/5 of the original sound.
2. Provide enough numbers of sound channels with good surround effects. We have eight discrete channel systems and six channels to the screen in the front and two channels in the rear as surround speakers shown in Fig. 43.8. We have discrete channel systems, making a good channel separation which provides superior surround effects even in a large theater with no sound defects.
3. Be compatible with the current widespread analogue sound system. There are limited spaces between the sprockets, picture frame, and in the external portion of the sprocket hole where the digital sound could be recorded because the analogue sound track is left as usual. As in the cinema scope format, it may be difficult to obtain enough space between picture frames. Because the signal for recording and playback would become intermittent between sprockets, special techniques would be required to process such signals. As shown in Fig. 43.9, we therefore establish track P and track S on a film external portion where continuous recordings are possible and where space can be obtained in the digital sound recording region on the SDDS format.

Data bits are recorded on the film with black and white dot patterns. The size of a bit is decided to overcome the effects caused by film scratch and is able to correct errors. In order to obtain the certainty of reading data, we set a guard band area to the horizontal and track direction.

Now, the method to record digital sound data on these two tracks is to separate eight channels and record four channels each in track P and in track S. A redundant data is also recorded about 18 frames later on the opposite track. By this method, it makes it possible to obtain the equivalent data from track S if any error occurs on track P and the correction is unable to be made, or vice versa. This is called the "Digital Backup System".

Figure 43.10 shows the block structure for the SDDS format. A data compression block of the ATRAC system has 512 bit sound data per film block. A vertical sync region is set at the head of the film block. A film block ID is recorded in this region to reproduce the sound data and picture frame

FIGURE 43.8: Speaker arrangement in theater.

with the right timing and to prevent the “lip sync” offset from discordance; for example, the time accordance between an actor’s/actress’ lip movement and his/her voice. Also, a horizontal sync is set on the left-hand side of the film block and is referred to correctly detect the head of the data in reading with the line sensor.

43.4.2 Playback System for Digital Sound

The digital playback sound system for the SDDS system consists of a reader unit, DFP-R2000, and a decoder unit, DFP-D2000 as shown in Fig. 43.11. The reader unit is set between the supply reel and the projector.

The principle of digital sound reading for the reader unit DFP-R2000 is described in Fig. 43.12. The LED light source is derived from the optical fiber and it scans the data portion recorded on track P and track S of the film. Transparent lights through the film give an image formation on the line sensor through the lens. These optical systems are designed to have the appropriate structures which can hardly be affected by scratches on the film. The output of a sensor signal is transmitted to the decoder after the signal processing such as the wave form equalization is made.

The block diagram of the decoder unit DFP-D2000 is shown in Fig. 43.13. The unit consists of EQ, DEC, DSP, and APR blocks.

In the EQ, signals become digital signals after being equalized. Then the digital signals are transmitted to the DEC together with the regenerated clock signal.

In the DEC, jitters elimination and lip sync control are done by the time base collector circuit, and errors caused by scratches and dust on the film are corrected by the strong error correction algorithm. Also in the DEC, signals for track P and track S which have been compressed by the ATRAC system are decoded. This data is transmitted to the DSP as a linear PCM signal.

In the DSP, the sound field of the theater is adjusted and concealment modes are controlled. A CPU is installed in the DSP to control the entire decoder, and control the front panel display and reception and transmission of external control data.

FIGURE 43.9: SDDS track designation.

Finally in the APR, 10 channels of digital filter including monitors, D/A converter, and line amplifier are installed. Also, it is possible to directly bypass an analogue input signal by relay as necessary. This bypass is prepared to cope with analogue sound if digital sound would not play back.

43.4.3 The SDDS Error Correction Technique

The SDDS system adapts the “Reed Solomon” code for error correction. An error correction technique is essential for maintaining high sound quality and high picture quality for digital recording and playback systems, such as CD, MD, digital VTR, etc. Such C1 parity + C2 parity data necessary for error correction are added and recorded in advance to cope with cases when the correct data are not able to be obtained. It enables recovery of the correct data by using this additional data even if a reading error occurs.

If the error rate is 10^{-4} (1 bit for every 10,000 bits), the error rate for C1 parity after correction would normally be 10^{-11} . In other words, an error would occur only once every 1.3 years if a film were showed 24 hours a day. Errors will be extremely close to “zero” by using C2 parity erasure correction. A strong error correction capability is installed in the SDDS digital sound playback system against random errors.

Other errors besides random errors are

- errors caused by a scratch in the film running direction
- errors caused by dust on the film
- errors caused by splice points of films
- errors caused by defocusing during printing or playback

These are considered burst errors which occur consistently. Scratch errors in particular will increase more and more every time the film is shown. SDDS has the capability of dealing with such burst errors. Therefore, in spite of the scratch on the film width direction, error correction towards the film length would be possible up to 1.27 mm and in spite of the scratch on the film running direction, error correction towards the film width would be possible up to 336 μ m.

FIGURE 43.10: Data block configuration.

43.4.4 Features of the SDDS System

The specification characteristics for the SDDS player are shown in Table 43.1. It is not easy to obtain high fidelity in audio data compression compared to the linear recording system of CDs with regard to a sound quality. By adapting a system with high compression efficiency and making use of the human hearing characteristics, we were able to maintain a sound quality equivalent to CDs by adapting the ATRAC system which restrains deterioration to the minimum.

One of the biggest features of the SDDS is the adaption of a digital backup system. This is a countermeasure system to make up for the damage to the splicing parts of the digital data or the parts of data missing by using the opposite side of the track with a digital data recorded on the backup channel. By this system, it would be possible to obtain an equivalent quality. Next, when finally the film is worn out, the system switches over to an analogue playback signal.

This system also has a digital room EQ function. This supplies 28 bands of graphic EQ with 1/3 octave characteristics and a high and low pass filter. Moreover, a simple operation to control the sound field in the theater will become possible by using a graphic user interface panel of an external personal computer.

Such control usually took hours, but it can be completed in about 30 min with this SDDS player. The stability of its features, reproducibility, and reliability of digitizing is well appreciated.

Furthermore, the SDDS player carries a backup function and a reset function for setting parameters by using memories.

43.5 Switched Predictive Coding of Audio Signals for the CD-I and CD-ROM XA Format

Masayuki Nishiguchi

43.5.1 Abstract

An audio bit rate reduction system for the CD-I and CD-ROM XA format based on switched predictive coding algorithm is described. The principal feature of the system is that the coder provides multiple prediction error filters, each of which has fixed coefficients. The prediction error filter that best matches the input signal is selected every 28 samples (1 block). A first-order and two kinds of second-order prediction error filters are used for signals in the low and middle frequencies, and the straight PCM is used for high-frequency signals. The system also uses near-instantaneous companding to expand the dynamic range. A noise-shaping filter is incorporated in the quantization stage, and its frequency response is varied to minimize the energy of the output noise. With a complexity of less than 8MIPS/channel, audio quality almost the same as CD audio can be achieved at 310 Kbps (8.2 bits/sample), near transparent audio can be achieved at 159 Kbps (4.2 bits/sample), and mid-fidelity audio can be achieved at 80 Kbps (4.2 bits/sample).

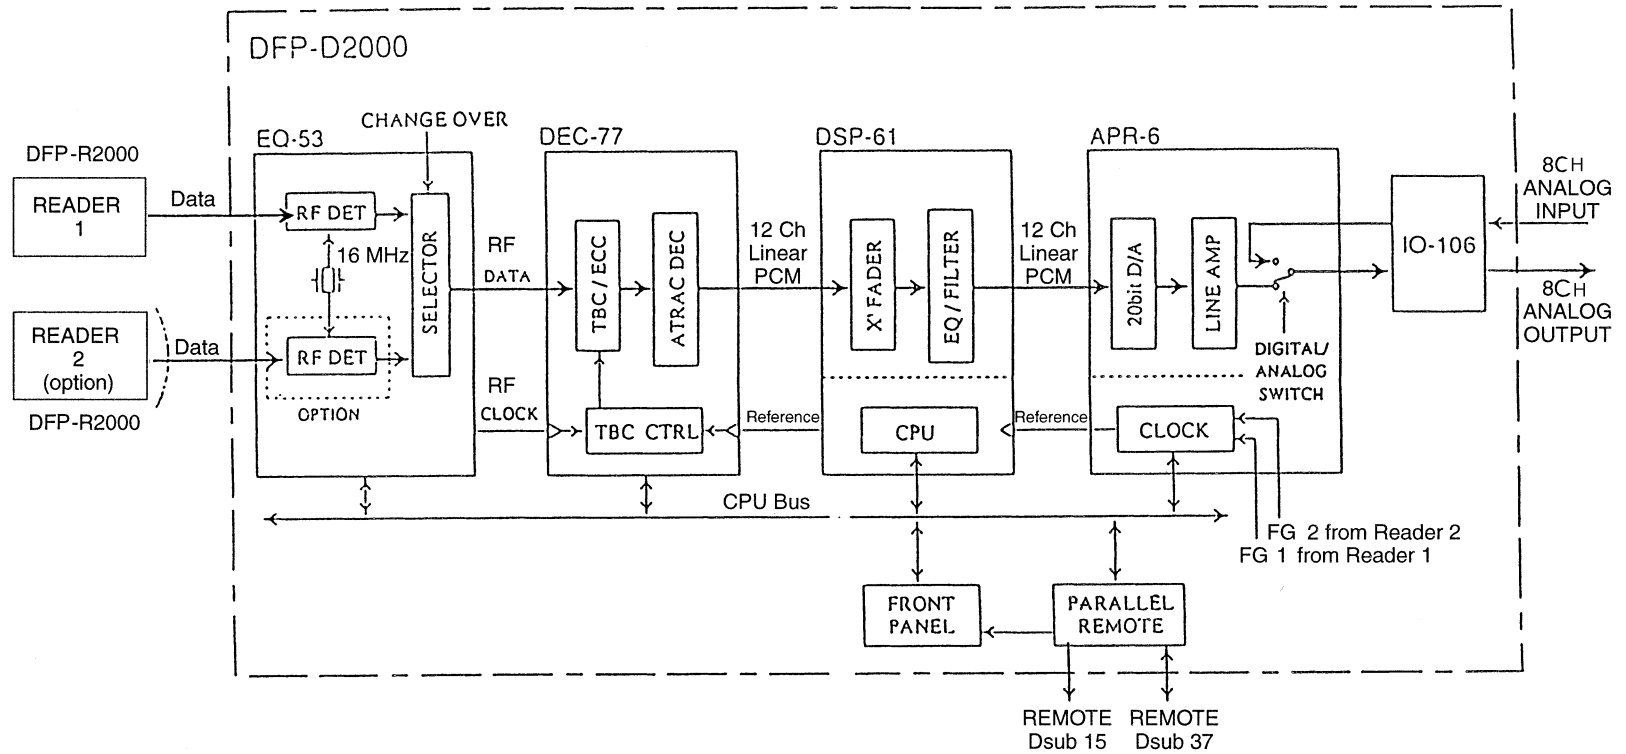

FIGURE 43.13: Overall block diagram.

TABLE 43.1 SDDS Player System
Electrical Specifications

Item	Specification
Sampling frequency	44.1 KHz
Dynamic range	Over 90 dB
Channel	Max 8 cH
Frequency band	20 Hz - 20 KHz +/- 1.0dB
K.F	< 0.7%
Crosstalk	< -80 dB
Reference output level	-10 dB / Unbalanced +4 dB / Balanced
Head room	> 20 dB / Balanced

43.5.2 Coder Scheme

Figure 43.14 is a block diagram of the encoder and decoder system. The input signal, prediction error, quantization error, encoder output, decoder input, and decoder output are respectively expressed as $x(n)$, $d(n)$, $e(n)$, $\hat{d}(n)$, $\hat{d}'(n)$, and $\hat{x}'(n)$. The z -transforms of the signals are expressed as $X(z)$, $D(z)$, $E(z)$, $\hat{D}(z)$, $\hat{D}'(z)$, and $\hat{X}'(z)$. The encoder response can then be expressed as

$$\hat{D}(z) = G \cdot X(z) \cdot \{1 - P(z)\} + E(z) \cdot \{1 - R(z)\}, \quad (43.8)$$

and the decoder response as

$$\hat{X}'(z) = \frac{G^{-1} \cdot \hat{D}'(z)}{1 - P(z)}, \quad (43.9)$$

Assuming that there is no channel error, we can write $\hat{D}'(z) = \hat{D}(z)$. Using Eq. (43.8) and (43.9), we can write the decoder output in terms of the encoder input as

$$\hat{X}'(z) = X(z) + G^{-1} \cdot E(z) \cdot \frac{1 - R(z)}{1 - P(z)}. \quad (43.10)$$

where

$$P(z) = \sum_{k=1}^P \alpha_k \cdot z^{-k} \text{ and } R(z) = \sum_{k=1}^R \beta_k \cdot z^{-k} \quad (43.11)$$

Here α_k and β_k are, respectively, the coefficients of predictor $P(z)$ and $R(z)$. Equation (43.10) shows the encoder-decoder performance characteristics of the system. It shows that the quantization error $E(z)$ is reduced by the extent of the noise-reduction effect G^{-1} . The distribution of the noise spectrum that appears at the decoder output is

$$N(z) = E(z) \cdot \frac{1 - R(z)}{1 - P(z)}. \quad (43.12)$$

$R(z)$ can be varied according to the spectral shape of the input signal in order to have a maximum masking effect, but we have set $R(z) = P(z)$ to keep from coloring the quantization noise.

G can be regarded as the normalization factor for the peak prediction error (over 28 residual words) from the chosen prediction error filter. The value of G changes according to the frequency response of the prediction gain:

$$G \propto \frac{|X(z)|}{|D(z)|}. \quad (43.13)$$

This is also proportional to the inverse of the prediction error filter, $1/|1 - P(z)|$. So, in order to maximize G , it is necessary to change the frequency response of the prediction error filter $1 - P(z)$ according to the frequency distribution of the input signals.

FIGURE 43.14: Block diagram of the bit rate reduction system.

Selection of the Optimum Filter

Several different strategies of selecting filters are possible in the CD-I/CD-ROM XA format, but the simplest way for the encoder to choose which predictor is most suitable is the following:

- The predictor adaptation section compares the peak value of the prediction errors (over 28 words) from each prediction error filter $1 - P(z)$ and selects the filter that generates the minimum peak.
- The group of prediction errors chosen is then gain controlled (normalized by its maximum value) and noise shaping is executed at the same time.

As a result, a high SNR is obtained by using a first-order and two kinds of second-order prediction error filters for signals with the low and middle frequencies and by using the straight PCM for high-frequency signals.

Coder Parameters

This system provides three bit rates for the CD-I/CD-ROM XA format, and data encoded at any bit rate can be decoded by a single decoder. The following sections explain how the parameters used in the decoder and the encoder change according to the level of sound quality. Table 43.2 lists the parameters for each level.

TABLE 43.2 The Parameters for Each Level

	Level A	Level B	Level C
Sampling frequency (KHz)	37.8	37.8	18.9
Residual word length (bits per sample)	8	4	4
Block length (Number of samples)	28	28	28
Range data (bits per block)	4	4	4
Range values	0-8	0-12	0-12
Filter data (bits per block)	1	2	2
Number of prediction error filters used	2	3	4
Average of bits used per sample (bits per sample)	8.18	4.21	4.21
Bit rate (Kbps)	$= (8 \times 28 + 4 + 1)/28$ 309	$= (4 \times 28 + 4 + 1)/28$ 159	$= (4 \times 28 + 4 + 1)/28$ 80

Level A

We can obtain the highest quality audio sound with Level A, which uses only two prediction error filters. Either the straight PCM or the first-order differential PCM is selected. The transfer functions of the prediction error filters are as follows:

$$H(z) = 1 \quad (43.14)$$

and

$$H(z) = 1 - 0.975z^{-1}, \quad (43.15)$$

where $H(z) = 1 - P(z)$.

Level B

The bit rate at Level B is half as high as that at Level A. By using this level, we can obtain high-fidelity audio sound from most high-quality sources. This level uses three filters: the straight PCM,

the first-order differential PCM, or the second-order differential PCM-1 is selected. The transfer functions of the first two filters are the same as in Level A, and that for the second-order differential PCM-1 mode is:

$$H(z) = 1 - 1.796875z^{-1} + 0.8125z^{-2} . \quad (43.16)$$

Level C

We can obtain mid-fidelity audio sound at Level C, and a monoaural audio program 16 hours long can be recorded on a single CD. Four filters are used for this level. The transfer function of the first three filters are the same as in Level B. The transfer function of the second-order differential PCM-2 mode, used only at this level, is

$$H(z) = 1 - 1.53125z^{-1} + 0.859375z^{-2} . \quad (43.17)$$

At all levels, the noise-shaping filter and the inverse-prediction-error filter in the decoder have the same coefficients as the prediction error filter in the encoder.

43.5.3 Applications

The simple structure and low complexity of this CD-I/CD-ROM XA audio compression algorithm make it suitable for applications with PCs, workstations, and video games.

43.7 ATRAC (Adaptive Transform Acoustic Coding) and ATRAC 2

K. Tsutsui

43.7.1 ATRAC

ATRAC is a coding system designed to meet the following criteria for the MiniDisc system:

- Compression of 16-bit 44.1-kHz audio (705.6 kbps) into 146 kbps with minimal reduction in sound quality.
- Simple hardware implementation suitable for portable players and recorders.

Block diagrams of the encoder and decoder structures are shown in Figs. 43.15 and 43.16, respectively. The time-frequency analysis block of the encoder decomposes the input signal into spectral coefficients grouped into 52 block floating units (BFUs). The bit allocation block divides the available bits among the BFUs adaptively based on the psychoacoustics. The spectrum quantization block normalizes spectral coefficients with the scale factor given to each Bfu, and then quantizes each

FIGURE 43.15: ATRAC encoder.

FIGURE 43.16: ATRAC decoder.

of them to the specified word length. These processes are performed in every sound unit, a block consisting of 512 samples per channel.

In order to generate the BFUs, the time-frequency analysis block first divides the input signal into three subbands. And then, each of these subbands is transformed into the frequency domain by modified discrete cosine transform (MDCT), producing a set of spectral coefficients. Finally, these spectral coefficients are nonuniformly grouped into BFUs. The subband decomposition is performed using cascaded 48-tap quadrature mirror filters (QMFs). The input signal is divided into upper and lower frequency bands by the first QMF, and then, the lower-frequency band is divided again by a second QMF. While the output samples of each filter are decimated by two, the aliasing caused by the subband decomposition is cancelled during reconstruction, due to the use of QMFs. MDCT block length is adaptively determined based on the signal characteristics in each band. There are two block-length modes: long mode (11.6 msec for $f_s = 44.1$ kHz) and short mode (1.45 ms in the high frequency band, 2.9 ms in the others). Normally, long mode is chosen, as this provides good frequency resolution. However, problems occur during attack portions of the signal since the quantization noise is spread over the entire block and the initial quantization noise is not masked by simultaneous masking. In order to prevent this degradation known as pre-echo, ATRAC switches to short mode when it detects an attack signal. In this case, as the noise before the attack exists only for a very short period of time, it is masked by backward masking. The window form is symmetric for both long and short modes, and the window form in the non-zero-non-one region of the long mode is the same as that of the short mode. Although this window form is somewhat disadvantageous to the separability of the spectrum, it brings the following merits:

- The transform mode can be determined based only on the existence of an attack signal in the current sound unit, and hence, no extra buffer is required in the encoder.
- A smaller size of buffer memory is required to store the overlapped samples for the next sound unit in the encoder and decoder.

The mapping structure of ATRAC is summarized in Fig. 43.18.

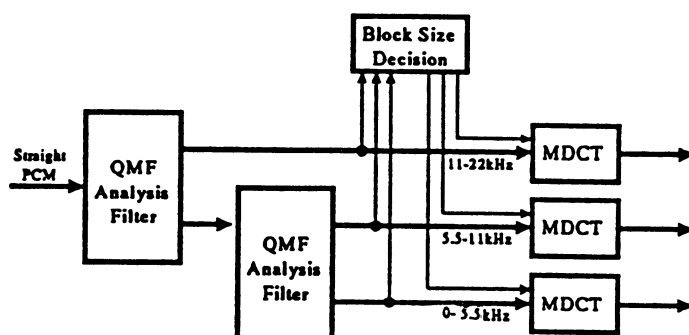

FIGURE 43.17: ATRAC time-frequency analysis.

FIGURE 43.18: ATRAC mapping structure.

43.7.2 ATRAC2

The ATRAC2 system, taking advantage of the progress in LSI technologies, allows audio signals of 16 bits per sample with a sampling frequency of 44.1 kHz (705.6 kbps) to be compressed to 64 kbps, sacrificing almost no audio quality. It was designed focusing on efficient coding of tonal signals, as the human ear is very sensitive to distortions in such signals.

Block diagrams of the encoder and decoder structures are shown in Figs. 43.19 and 43.20. The encoder extracts psychoacoustically important tone components from the input signal spectra in order to encode them separately from the other less important spectrum data in an efficient way. A tone component is a group of consecutive spectral coefficients and is defined with several parameters including its location and width data. The remaining spectral coefficients are grouped into 32 non-uniform BFUs. Both the tone components and the remaining spectral coefficients may be encoded with Huffman coding, which is shown in Table 43.3 and for which simple decoding with a look-up table is practical due to its small size. Although the quantization step number is limited to 63, high S/N ratio can be obtained by repeatedly extracting tone components from the same frequency range.

The mapping structure of ATRAC2 is shown in Fig. 43.21. The frequency resolution is twice that

FIGURE 43.19: ATRAC2 encoder.

TABLE 43.3 Huffman Code Table

ID	Quantization step number	Dimension (spectr. num.)	Maximum code length	Look-up table size
0	1	—	—	—
1	3	2	5	32
2	5	1	3	8
3	7	1	4	16
4	9	1	5	32
5	15	1	6	64
6	31	1	7	128
7	63	1	8	256

Note: Total = 536

of ATRAC, and in order to secure the frequency separability, ATRAC2 performs a signal analysis using a combination of a 96-tap polyphase quadrature filter (PQF) and a fixed-length 50%-overlap MDCT whose forward and backward window forms are different from each other. ATRAC2 prevents pre-echo by amplifying the signal preceding an attack adaptively before transforming it into spectral coefficients in the encoder and restoring it to the original level after the inverse transform in the decoder. This technique, called gain control, simplifies the spectral structure of the system.

The subband decomposition realizes frequency scalability; decoders with smaller complexity can be constructed by simply decoding only lower-band data. Use of PQF lowers the computational complexity.

WITH THE ADVENT OF CHEAP, HIGH SPEED PROCESSORS, and with the ever-decreasing cost of memory, the cost of speech processing has been driven down to the point where it can be (and has been) embedded in almost any system, from a low cost consumer product (e.g., solid-state digital answering machines, voice controlled telephones, etc.), to a desktop application (e.g., voice dictation of a first draft quality manuscript), to an application embedded in a voice or data network (e.g., voice dialing, packet telephony, voice browser for the Internet, etc.). It is the purpose of this section of the Handbook to provide discussions of several of the key technologies in speech processing and to illustrate how the technologies are implemented using special-purpose DSP processor chips or via standard software packages running on more conventional processors.

The broad area of speech processing can be broken down into several individual areas according to both applications and technology. These include:

1. **Speech Production Models and their Digital Implementations** (see Chapter 44 by Sondhi and Schroeter). In order to understand how the characteristics of a speech signal can be exploited in the different application areas, it is necessary to understand the properties and constraints of the human vocal apparatus (to understand how speech is generated by humans). It is also necessary to understand the way in which models can be built that simulate speech production as well as the ways in which they can be implemented as digital systems, since such models form the basis for almost all practical speech processing systems.
2. **Speech Coding** (see Chapter 45 by Cox). Speech coding is the process of compressing the information in a speech signal so as to either transmit it or store it economically over a channel whose bandwidth is significantly smaller than that of the uncompressed signal. Speech coding is used as the basis for most modern voice messaging and voice mail systems, for voice response systems, for digital cellular and for satellite transmission of speech, for packet telephony, for ISDN teleconferencing, and for digital answering machines and digital voice encryption machines.
3. **Text-to-Speech Synthesis** (see Chapter 46 by Sproat and Olive). Speech synthesis is the process of creating a synthetic replica of a speech signal so as to transmit a message from a machine to a person, with the purpose of conveying the information in the message. Speech synthesis is often called "text-to-speech" or TTS, to convey the idea that, in general, the input to the system is ordinary ASCII text, and the output of the system is ordinary speech. The goal of most speech synthesis systems is to provide a broad range of capability for having a machine speak information (stored in the machine) to a user. Key aspects of synthesis systems are the intelligibility and the naturalness of the resulting speech. The major applications of speech synthesis include acting as a voice server for text-based information services (e.g., stock prices, sports scores, flight information); providing a means for reading e-mail, or the text portions of FAX messages over ordinary phone lines; providing a means for previewing text stored in documents (e.g., document drafts, Internet files); and finally as a voice readout for handheld devices, (e.g., phrase book translators, dictionaries, etc.)
4. **Speech Recognition by Machine** (see Chapter 47 by Rabiner and Juang). Speech recognition is the process of extracting the message information in a speech signal so as to control the action of a machine in response to spoken commands. In a sense, speech recognition is the complementary process to speech synthesis, and together they constitute the building blocks of a voice dialogue system with a machine. There are many factors which influence the type of speech recognition system that is used for different applications, including the mode of speaking to the machine (e.g., single commands, digit sequences, fluent sentences), the size and complexity of the vocabulary which the machine understands, the task which the machine

is asked to accomplish, the environment in which the recognition system must run, and finally the cost of the system. Although there is a wide range of applications of speech recognition systems, the most generic systems are simple “command-and-control” systems (with menu-like interfaces), and the most advanced systems support full voice dialogues for dictation, forms entry, catalog ordering, reservation services, etc.

5. **Speaker Verification** (see Chapter 48 by Furui and Rosenberg). Speaker verification is the process of verifying the claimed identity of a speaker for the purpose of restricting access to information (e.g., personal or private records), networks (computer, PBX), or physical premises. The basic problem of speaker verification is to decide whether or not an unknown speech sample was spoken by the individual whose identity was claimed. A key aspect of any speaker verification system is to accept the true speaker as often as possible while rejecting the impostor as often as possible. Since these are inherently conflicting goals, all practical systems arrive at some compromise between levels of these two types of system errors. The major area of application for speaker verification is in access control to information, credit, banking, machines, computer networks, private branch exchanges (PBX's), and even premises. The concept of a “voice lock” that prevents access until the appropriate speech by the authorized individual(s) (e.g., “Open Sesame”) is “heard” by the system is made a reality using speaker verification technology.
6. **DSP Implementations of Speech Processing** (see Chapter 49 by Baudendistel). Until a few years ago, almost all speech processing systems were implemented on low-cost DSP fixed-point processors because of their high efficiency in realizing the computational aspects of the various signal processing algorithms. A key problem in the realization of any digital system in integer DSP code is how to map an algorithm efficiently (in both time and space) which is typically running in floating point C code on a workstation to integer C code that takes advantage of the unique characteristics of different DSP chips. Furthermore, because of the rate of change of technology, it is essential that the conversion to DSP code occur rapidly (e.g., on the order of 3-person months) or else by the time a given algorithm is mapped to a specific DSP processor, a new (faster, cheaper) generation of DSP chips will have evolved, obsoleting the entire process.
7. **Software Tools for Speech Research and Development** (see Chapter 50 by Shore). The field of speech processing has become a complex one, where an investigator needs a broad range of tools to record, digitize, display, manipulate, process, store, format, analyze, and listen to speech in its different file forms and manifestations. Although it is conceivable that an individual could create a suite of software tools for an individual application, that process would be highly inefficient and would undoubtedly result in tools which were significantly less powerful than those developed in the commercial sector, such as the Entropic Signal Processing System, MATLAB, Waves, Interactive Laboratory System (ILS), or the commercial packages for TTS and speech recognition such as the Hidden Markov Model Toolkit (HTK).

The material presented in this section should provide the reader with a framework for understanding the signal processing aspects of speech processing and some pointers into the literature for further investigation of this fascinating and rapidly evolving field.

44.1 Introduction

The characteristics of a speech signal that are exploited for various applications of speech signal processing to be discussed later in this section on speech processing (e.g., coding, recognition, etc.) arise from the properties and constraints of the human vocal apparatus. It is, therefore, useful in the design of such applications to have some familiarity with the process of speech generation by humans. In this chapter we will introduce the reader to (1) the basic physical phenomena involved in speech production, (2) the simplified models used to quantify these phenomena, and (3) the digital implementations of these models.

44.1.1 Speech Sounds

Speech is produced by acoustically exciting a time-varying cavity — the vocal tract, which is the region of the mouth cavity bounded by the vocal cords and the lips. The various speech sounds are produced by adjusting both the type of excitation as well as the shape of the vocal tract.

There are several ways of classifying speech sounds [1]. One way is to classify them on the basis of the type of excitation used in producing them:

- **Voiced** sounds are produced by exciting the tract by quasi-periodic puffs of air produced by the vibration of the vocal cords in the larynx. The vibrating cords modulate the air stream from the lungs at a rate which may be as low as 60 times per second for some

males to as high as 400 or 500 times per second for children. All vowels are produced in this manner. So are laterals, of which **l** is the only exemplar in English.

- **Nasal** sounds such as **m**, **n**, **ng**, and nasalized vowels (as in the French word **bon**) are also voiced. However, part or all of the airflow is diverted into the nasal tract by opening the velum.
- **Plosive** sounds are produced by exciting the tract by a sudden release of pressure. The plosives **p**, **t**, **k** are voiceless, while **b**, **d**, **g** are voiced. The vocal cords start vibrating before the release for the voiced plosives.
- **Fricatives** are produced by exciting the tract by turbulent flow created by air flow through a narrow constriction. The sounds **f**, **s**, **sh** belong to this category.
- **Voiced fricatives** are produced by exciting the tract simultaneously by turbulence and by vocal cord vibration. Examples are **v**, **z**, and **zh** (as in **pleasure**).
- **Affricates** are sounds that begin as a stop and are released as a fricative. In English, **ch** as in **check** is a voiceless affricate and **j** as in **John** is a voiced affricate.

In addition to controlling the type of excitation, the shape of the vocal tract is also adjusted by manipulating the tongue, lips, and lower jaw. The shape determines the frequency response of the vocal tract. The frequency response at any given frequency is defined to be the amplitude and phase at the lips in response to a sinusoidal excitation of unit amplitude and zero phase at the source. The frequency response, in general, shows concentration of energy in the neighborhood of certain frequencies, called **formant frequencies**.

For vowel sounds, three or four resonances can usually be distinguished clearly in the frequency range 0 to 4 kHz. (On average, over 99% of the energy in a speech signal is in this frequency range.) The configuration of these resonance frequencies is what distinguishes different vowels from each other.

For fricatives and plosives, the resonances are not as prominent. However, there are characteristic broad frequency regions where the energy is concentrated.

For nasal sounds, besides formants there are anti-resonances, or zeros in the frequency response. These zeros are the result of the coupling of the wave motion in the vocal and nasal tracts. We will discuss how they arise in a later section.

44.1.2 Speech Displays

We close this section with a description of the various ways of displaying properties of a speech signal. The three common displays are (1) the **pressure waveform**, (2) the **spectrogram**, and (3) the **power spectrum**. These are illustrated for a typical speech signal in Figs. 44.1a–c.

Figure 44.1a shows about half a second of a speech signal produced by a male speaker. What is shown is the **pressure waveform** (i.e., pressure as a function of time) as picked up by a microphone placed a few centimeters from the lips. The sharp click produced at a plosive, the noise-like character of a fricative, and the quasi-periodic waveform of a vowel are all clearly discernible.

Figure 44.1b shows another useful display of the same speech signal. Such a display is known as a **spectrogram** [2]. Here the x-axis is time. But the y-axis is frequency and the darkness indicates the intensity at a given frequency at a given time. [The intensity at a time t and frequency f is just the power in the signal averaged over a small region of the time-frequency plane centered at the point (t, f)]. The dark bands seen in the vowel region are the **formants**. Note how the energy is much more diffusely spread out in frequency during a plosive or fricative.

Finally, Fig. 44.1c shows a third representation of the same signal. It is called the **power spectrum**. Here the power is plotted as a function of frequency, for a short segment of speech surrounding a specified time instant. A logarithmic scale is used for power and a linear scale for frequency. In

FIGURE 44.1: Display of speech signal: (a) waveform, (b) spectrogram, and (c) frequency response.

this particular plot, the power is computed as the average over a window of duration 20 msec. As indicated in the figure, this spectrum was computed in a voiced portion of the speech signal. The regularly spaced peaks — the fine structure — in the spectrum are the harmonics of the fundamental frequency. The spacing is seen to be about 100 Hz, which checks with the time period of the wave seen in the pressure waveform in Fig. 44.1a. The peaks in the envelope of the harmonic peaks are the formants. These occur at about 650, 1100, 1900, and 3200 Hz, which checks with the positions of the formants seen in the spectrogram of the same signal displayed in Fig. 44.1b.

44.2 Geometry of the Vocal and Nasal Tracts

Much of our knowledge of the dimensions and shapes of the vocal tract is derived from a study of x-ray photographs and x-ray movies of the vocal tract taken while subjects utter various specific speech sounds or connected speech [3]. In order to keep x-ray dosage to a minimum, only one view is photographed, and this is invariably the side view (a view of the mid-sagittal plane). Information about the cross-dimensions is inferred from static vocal tracts using frontal X rays, dental molds, etc.

More recently, Magnetic Resonance Imaging (MRI) [4] has also been used to image the vocal and nasal tracts. The images obtained by this technique are excellent and provide three-dimensional

reconstructions of the vocal tract. However, at present MRI is not capable of providing images at a rate fast enough for studying vocal tracts in motion.

Other techniques have also been used to study vocal tract shapes. These include:

(1) ultrasound imaging [5]. This provides information concerning the shape of the tongue but not about the shape of the vocal cavity.

(2) Acoustical probing of the vocal tract [6]. In this technique, a known acoustic wave is applied at the lips. The shape of the time-varying vocal cavity can be inferred from the shape of the time-varying reflected wave. However, this technique has thus far not achieved sufficient accuracy. Also, it requires the vocal tract to be somewhat constrained while the measurements are made.

(3) Electropalatography [7]. In this technique, an artificial palate with an array of electrodes is placed against the hard palate of a subject. As the tongue makes contact with this palate during speech production, it closes an electrical connection to some of the electrodes. The pattern of closures gives an estimate of the shape of the contact between tongue and palate. This technique cannot provide details of the shape of the vocal cavity, although it yields important information on the production of consonants.

(4) Finally, the movement of the tongue and lips has also been studied by tracking the positions of tiny coils attached to them [8]. The motion of the coils is tracked by the currents induced in them as they move in externally applied electromagnetic fields. Again, this technique cannot provide a detailed shape of the vocal tract.

Figure 44.2 shows an x-ray photograph of a female vocal tract uttering the vowel sound /u/. It is seen that the vocal tract has a very complicated shape, and without some simplifications it would be very difficult to just specify the shape, let alone compute its acoustical properties. Several models have been proposed to specify the main features of the vocal tract shape. These models are based on studies of x-ray photographs of the type shown in Fig. 44.2, as well as on x-ray movies taken of subjects uttering various speech materials. Such models are called **articulatory models** because they specify the shape in terms of the positions of the **articulators** (i.e., the tongue, lips, jaw, and velum).

Figure 44.3 shows such an idealization, similar to one proposed by Coker [9], of the shape of the vocal tract in the mid-sagittal plane. In this model, a fixed shape is used for the palate, and the shape of the vocal cavity is adjusted by specifying the positions of the articulators. The coordinates used to describe the shape are labeled in the figure. They are the position of the tongue center, the radius of the tongue body, the position of the tongue tip, the jaw opening, the lip opening and protrusion, the position of the hyoid, and the opening of the velum. The cross-dimensions (i.e., perpendicular to the sagittal plane) are estimated from static vocal tracts. These dimensions are assumed fixed during speech production. In this manner, the three-dimensional shape of the vocal tract is modeled.

Whenever the velum is open, the nasal cavity is coupled to the vocal tract, and its dimensions must also be specified. The nasal cavity is assumed to have a fixed shape which is estimated from static measurements.

44.3 Acoustical Properties of the Vocal and Nasal Tracts

Exact computation of the acoustical properties of the vocal (and nasal) tract is difficult even for the idealized models described in the previous section. Fortunately, considerable further simplification can be made without affecting most of the salient properties of speech signals generated by such a model. Almost without exception, three assumptions are made to keep the problem tractable. These assumptions are justifiable for frequencies below about 4 kHz [10, 11].

FIGURE 44.2: X-ray side view of a female vocal tract. The tongue, lips, and palate have been outlined to improve visibility. (*Source:* Modified from a single frame from “Laval Film 55,” Side 2 of Munhall, K.G., Vatikiotis-Bateson, E., Tohkura, Y., X-ray film data-base for speech research, ATR Technical Report Tr-H-116, 12/28/94, ATR Human Information Processing Research Laboratories, Kyoto, Japan. With permission from Dr. Claude Rochette, Departement de Radiologie de l’Hotel-Dieu de Quebec, Quebec, Canada.)

44.3.1 Simplifying Assumptions

1. It is assumed that the vocal tract can be “**straightened out**” in such a way that a center line drawn through the tract (shown dotted in Fig. 44.3) becomes a straight line. In this way, the tract is converted to a straight tube with a variable cross-section.
2. Wave propagation in the straightened tract is assumed to be **planar**. This means that if we consider any plane perpendicular to the axis of the tract, then every quantity associated with the acoustic wave (e.g., pressure, density, etc.) is independent of position in the plane.
3. The third assumption that is invariably made is that wave propagation in the vocal tract is **linear**. Nonlinear effects appear when the ratio of particle velocity to sound velocity (the **Mach number**) becomes large. For wave propagation in the vocal tract the Mach number is usually less than .02, so that nonlinearity of the wave is negligible. There are, however, two exceptions to this. The flow in the **glottis** (i.e., the space between the vocal folds), and that in the narrow constrictions used to produce fricative sounds, is nonlinear. We will show later how these special cases are handled in current speech production models.

FIGURE 44.3: An idealized articulatory model similar to that of Coker [9].

We ought to point out that some computations have been made without the first two assumptions, and wave phenomena studied in two or three dimensions [12]. Recently there has been some interest in removing the third assumption as well [13]. This involves the solution of the so called **Navier-Stokes equation** in the complicated three-dimensional geometry of the vocal tract. Such analyses require very large amounts of high speed computations making it difficult to use them in speech production models. Computational cost and speed, however, are not the only limiting factors. An even more basic barrier is that it is difficult to specify accurately the complicated time-varying shape of the vocal tract. It is, therefore, unlikely that such computations can be used directly in a speech production model. These computations should, however, provide accurate data on the basis of which simpler, more tractable, approximations may be abstracted.

44.3.2 Wave Propagation in the Vocal Tract

In view of the assumptions discussed above, the propagation of waves in the vocal tract can be considered in the simplified setting depicted in Fig. 44.4. As shown there, the vocal tract is represented as a variable area tube of length L with its axis taken to be the x -axis. The glottis is located at $x = 0$ and the lips at $x = L$, and the tube has a cross-sectional area $A(x)$ which is a function of the distance x from the glottis. Strictly speaking, of course, the area is time-varying. However, in normal speech

FIGURE 44.4: The vocal tract as a variable area tube.

the temporal variation in the area is very slow in comparison with the propagation phenomena that we are considering. So, the cross-sectional area may be represented by a succession of stationary shapes.

We are interested in the spatial and temporal variation of two interrelated quantities in the acoustic wave: the pressure $p(x, t)$ and the volume velocity $u(x, t)$. The latter is $A(x)v(x, t)$, where v is the **particle** velocity. For the assumption of linearity to be valid, the pressure p in the acoustic wave is assumed to be small compared to the equilibrium pressure P_0 , and the particle velocity v is assumed to be small compared to the velocity of sound, c . Two equations can be written down that relate $p(x, t)$ and $u(x, t)$: the equation of motion and the equation of continuity [14]. A combination of these equations will give us the basic equation of wave propagation in the variable area tube. Let us derive these equations first for the case when the walls of the tube are rigid and there are no losses due to viscous friction, thermal conduction, etc.

44.3.3 The Lossless Case

The **equation of motion** is just a statement of Newton's second law. Consider the thin slice of air between the planes at x and $x + dx$ shown in Fig. 44.4. By equating the net force acting on it due to the pressure gradient to the rate of change of momentum one gets

$$\frac{\partial p}{\partial x} = -\frac{\rho}{A} \frac{\partial u}{\partial t} \quad (44.1)$$

(To simplify notation, we will not always explicitly show the dependence of quantities on x and t .)

The **equation of continuity** expresses conservation of mass. Consider the slice of tube between x and $x + dx$ shown in Fig. 44.4. By balancing the net flow of air out of this region with a corresponding decrease in the density of air we get

$$\frac{\partial u}{\partial x} = -\frac{A}{\rho} \frac{\partial \delta}{\partial t} \quad (44.2)$$

where $\delta(x, t)$ is the fluctuation in density superposed on the equilibrium density ρ . The density is related to pressure by the gas law. It can be shown that pressure fluctuations in an acoustic wave follow the adiabatic law, so that $p = (\gamma P/\rho)\delta$, where γ is the ratio of specific heats at constant pressure and constant volume. Also, $(\gamma P/\rho) = c^2$, where c is the velocity of sound. Substituting this into Eq. (44.2) gives

$$\frac{\partial u}{\partial x} = -\frac{A}{\rho c^2} \frac{\partial p}{\partial t} \quad (44.3)$$

Equations (44.1) and (44.3) are the two relations between p and u that we set out to derive. From these equations it is possible to eliminate u by subtracting $\frac{\partial}{\partial t}$ of Eq. (44.3) from $\frac{\partial}{\partial x}$ of Eq. (44.1). This gives

$$\frac{\partial}{\partial x} A \frac{\partial p}{\partial x} = \frac{A}{c^2} \frac{\partial^2 p}{\partial t^2} \quad (44.4)$$

Equation (44.4) is known in the literature as **Webster's horn equation** [15]. It was first derived for computations of wave propagation in horns, hence the name. By eliminating p from Eqs. (44.1) and (44.3), one can also derive a single equation in u .

It is useful to write Eqs. (44.1), (44.3), and (44.4) in the frequency domain by taking Laplace transforms. Defining $P(x, s)$ and $U(x, s)$ as the Laplace transforms of $p(x, t)$ and $u(x, t)$, respectively, and remembering that $\frac{\partial}{\partial t} \rightarrow s$, we get:

$$\frac{dP}{dx} = -\frac{\rho s}{A} U \quad (44.1a)$$

$$\frac{dU}{dx} = -\frac{sA}{\rho c^2} P\psi \quad (44.3a)$$

and

$$\frac{d}{dx} A \frac{dP}{dx} = \frac{s^2}{c^2} A P\psi \quad (44.4a)$$

It is important to note that in deriving these equations we have retained only first order terms in the fluctuating quantities p and u . Inclusion of higher order terms gives rise to nonlinear equations of propagation. By and large these terms are quite negligible for wave propagation in the vocal tract. However, there is one second order term, neglected in Eq. (44.1), which becomes important in the description of flow through the narrow constriction of the glottis. In deriving Eq. (44.1) we neglected the fact that the slice of air to which the force is applied is moving away with the velocity v . When this effect is correctly taken into account, it turns out that there is an additional term $\rho v \frac{\partial v}{\partial x}$ appearing on the left hand side of that equation. The corrected form of Eq. (44.1) is

$$\frac{\partial}{\partial x} \left[p + \frac{\rho}{2} (u/A)^2 \right] = -\rho \frac{d}{dt} \left[\frac{u}{A} \right] \cdot \psi \quad (44.5)$$

The quantity $\frac{\rho}{2} (u/A)^2$ has the dimensions of pressure, and is known as the **Bernoulli pressure**. We will have occasion to use Eq. (44.5) when we discuss the motion of the vocal cords in the section on sources of excitation.

44.3.4 Inclusion of Losses

The equations derived in the previous section can be used to approximately derive the acoustical properties of the vocal tract. However, their accuracy can be considerably increased by including terms that approximately take account of the effect of viscous friction, thermal conduction, and yielding walls [16]. It is most convenient to introduce these effects in the frequency domain.

The effect of viscous friction can be approximated by modifying the equation of motion, Eq. (44.1a) as follows:

$$\frac{dP}{dx} = -\frac{\rho s}{A} U - R(x, s) U \cdot \psi \quad (44.6)$$

Recall that Eq. (44.1a) states that the force applied per unit area equals the rate of change of momentum per unit area. The added term in Eq. (44.6) represents the viscous drag which reduces the force available to accelerate the air. The assumption that the drag is proportional to velocity can be approximately validated. The dependence of R on x and s can be modeled in various ways [16].

The effect of thermal conduction and yielding walls can be approximated by modifying the equation of continuity as follows:

$$\rho \frac{dU}{dx} = -\frac{A}{c^2} s P - Y(x, s) P\psi \quad (44.7)$$

Recall that the left hand side of Eq. (44.3a) represents net outflow of air in the longitudinal direction, which is balanced by an appropriate decrease in the density of air. The term added in Eq. (44.7) represents net outward volume velocity into the walls of the vocal tract. This velocity arises from (1) a temperature gradient perpendicular to the walls which is due to the thermal conduction by the walls, and (2) due to the yielding of the walls. Both these effects can be accounted for by appropriate choice of the function $Y(x, s)$, provided the walls can be assumed to be **locally reacting**. By that we mean that the motion of the wall at any point depends on the pressure at that point alone. Models for the function $Y(x, s)$ may be found in [16].

Finally, the lossy equivalent of Eq. (44.4a) is

$$\frac{d}{dx} \frac{A}{\rho s + AR} \frac{dP}{dx} = \left(\frac{As}{\rho c^2} + Y \right) P \cdot \psi \quad (44.8)$$

44.3.5 Chain Matrices

All properties of linear wave propagation in the vocal tract can be derived from Eqs. (44.1a), (44.3a), (44.4a) or the corresponding Eqs. (44.6), (44.7), and (44.8) for the lossy tract. The most convenient way to derive these properties is in terms of **chain matrices**, which we now introduce.

Since Eq. (44.8) is a second order linear ordinary differential equation, its general solution can be written as a linear combination of two independent solutions, say $\phi(x, s)$ and $\Psi(x, s)$. Thus

$$P(x, s) = a\phi(x, s) + b\Psi(x, s)\psi \quad (44.9)$$

where a and b are, in general, functions of s . Hence, the pressure at the input of the tube ($x = 0$) and at the output ($x = L$) are linear combinations of a and b . The volume velocity corresponding to the pressure given in Eq. (44.9) is obtained from Eq. (44.6) to be

$$U(x, s) = -\frac{A}{\rho s + AR} [a d\phi/dx + b d\Psi/dx] \cdot \psi \quad (44.10)$$

Thus, the input and output volume velocities are seen to be linear combinations of a and b . Eliminating the parameters a and b from these relationships shows that the input pressure and volume velocity are linear combinations of the corresponding output quantities. Thus, the relationship between the input and output quantities may be represented in terms of a 2×2 matrix as follows:

$$\begin{aligned} \begin{bmatrix} P_{\text{in}} \\ U_{\text{in}} \end{bmatrix} &= \begin{bmatrix} \mathbf{k}_{11} & \mathbf{k}_{12} \\ \mathbf{k}_{21} & \mathbf{k}_{22} \end{bmatrix} \begin{bmatrix} P_{\text{out}} \\ U_{\text{out}} \end{bmatrix} \\ &= \mathbf{K} \begin{bmatrix} P_{\text{out}} \\ U_{\text{out}} \end{bmatrix}. \end{aligned} \quad (44.11)$$

The matrix \mathbf{K} is called a **chain matrix** or ABCD matrix [17]. Its entries depend on the values of ϕ and Ψ at $x = 0$ and $x = L$. For an arbitrarily specified area function $A(x)$ the functions ϕ and ψ are hard to find. However, for a **uniform** tube, i.e., a tube for which the area and the losses are independent of x , the solutions are very easy. For a uniform tube, Eq. (44.8) becomes

$$\frac{d^2 P}{dx^2} = \sigma^2 P \psi \quad (44.12)$$

where σ is a function of s given by

$$\sigma^2 = (\rho s + AR) \left(\frac{s}{\rho c^2} + \frac{Y}{A} \right).$$

Two independent solutions of Eq. (44.12) are well known to be $\cosh(\sigma x)$ and $\sinh(\sigma x)$, and a bit of algebra shows that the chain matrix for this case is

$$\mathbf{K} = \begin{bmatrix} \cosh(\sigma L)\psi & (1/\beta) \sinh(\sigma L) \\ \beta \sinh(\sigma L)\psi & \cosh(\sigma L) \end{bmatrix} \quad (44.13)$$

where

$$\beta = \sqrt{\left[Y + \frac{As}{\rho c^2} \right] / \left[R + \frac{\rho s}{A} \right]}.$$

For an arbitrary tract, one can utilize the simplicity of the chain matrix of a uniform tube by approximating the tract as a concatenation of N uniform sections of length $\Delta = L/N$. Now the output quantities of the i th section become the input quantities for the $i + 1$ st section. Therefore, if \mathbf{K}_i is the chain matrix for the i th section, then the chain matrix for the variable-area tract is approximated by

$$\mathbf{K} = \mathbf{K}_1 \mathbf{K}_2 \cdots \mathbf{K}_N \cdot \psi \quad (44.14)$$

This method can, of course, be used to relate the input-output quantities for any portion of the tract, not just the entire vocal tract. Later we shall need to find the input-output relations for various sections of the tract, for example, the tract from the glottis to the velum for nasal sounds, from the narrowest constriction to the lips for fricative sounds, etc.

As stated above, all linear properties of the vocal tract can be derived in terms of the entries of the chain matrix. Let us give several examples.

Let us associate the input with the glottal end, and the output with the lip end of the tract. Suppose the tract is terminated by the radiation impedance Z_R at the lips. Then, by definition, $P_{\text{out}} = Z_R U_{\text{out}}$. Substituting this in Eq. (44.11) gives

$$\begin{bmatrix} P_{\text{in}}/U_{\text{out}} \\ U_{\text{in}}/U_{\text{out}} \end{bmatrix} = \begin{bmatrix} \mathbf{k}_{11} & \mathbf{k}_{12} \\ \mathbf{k}_{21} & \mathbf{k}_{22} \end{bmatrix} \begin{bmatrix} Z_R \\ 1 \end{bmatrix} \cdot \psi \quad (44.15)$$

From Eq. (44.15) it follows that

$$\frac{U_{\text{out}}}{U_{\text{in}}} = \frac{1}{\mathbf{k}_{21} Z_R + \mathbf{k}_{22}} \cdot \psi \quad (44.16a)$$

Equation (44.16a) gives the **transfer function** relating the output volume velocity to the input volume velocity. Multiplying this by Z_R gives the transfer function relating output pressure to the input volume velocity. Other transfer functions relating output pressure or volume velocity to input pressure may be similarly derived.

Relationships between pressure and volume velocity at a single point may also be derived. For example,

$$\frac{P_{\text{in}}}{U_{\text{in}}} = \frac{\mathbf{k}_{11} Z_R + \mathbf{k}_{12}}{\mathbf{k}_{21} Z_R + \mathbf{k}_{22}} \quad (44.16b)$$

gives the **input impedance** of the vocal tract as seen at the glottis, when the lips are terminated by the radiation impedance.

Also, **formant frequencies**, which we mentioned in the Introduction, can be computed from the transfer function of Eq. (44.16a). They are just the values of s at which the denominator on the right-hand side becomes zero. For a lossy vocal tract, the zeros are complex and have the form $s_n = -\alpha_n + j\omega_n$, $n = 1, 2, \dots$. Then ω_n is the frequency (in rad/s) of the n th formant, and α_n is its half bandwidth.

Finally, the chain matrix formulation also leads to **linear prediction coefficients** (LPC), which are the most commonly used representation of speech signals today. Strictly speaking, the representation is valid for speech signals for which the excitation source is at the glottis (i.e., voiced or aspirated speech sounds). Modifications are required when the source of excitation is at an interior point.

To derive the LPC formulation, we will assume the vocal tract to be lossless, and the radiation impedance at the lips to be zero. From Eq. (44.16a) we see that to compute the output volume velocity from the input volume velocity, we need only the \mathbf{k}_{22} element of the chain matrix for the entire vocal tract. This chain matrix is obtained by a concatenation of matrices as shown in Eq. (44.14).

The individual matrices \mathbf{K}_i are derived from Eq. (44.13), with $N = L/\Delta$. In the lossless case, R and Y are zero, so $\sigma = s/c$ and $\beta = A/\rho c$. Also, if we define $z = e^{2s\Delta/c}$, then the matrix \mathbf{K}_i becomes

$$\mathbf{K}_i = z^{N/2} \begin{bmatrix} \frac{1}{2} (1 + z^{-1}) & \frac{A_i}{2\rho c} (1 - z^{-1}) \\ \frac{\rho c}{2A_i} (1 - z^{-1}) & \frac{1}{2} (1 + z^{-1}) \end{bmatrix} \cdot \psi \quad (44.17)$$

Clearly, therefore, \mathbf{k}_{22} is $z^{N/2}$ times an N th degree polynomial in z^{-1} . Hence, Eq. (44.16a) can be written as

$$\sum_{k=0}^N a_k z^{-k} U_{\text{out}} = z^{-N/2} U_{\text{in}} \cdot \psi \quad (44.18)$$

where a_k are the coefficients of the polynomial. The frequency domain factor $z = e^{-2s\Delta/c}$ represents a delay of $2\Delta/c$ s. Thus, the time domain equivalent of Eq. (44.18) is

$$\sum_{k=0}^N a_k u_{\text{out}}(t - 2k\Delta/c) = u_{\text{in}}(t - N\Delta/c) \cdot \psi \quad (44.19)$$

Now $u_{\text{out}}(t)$ is the volume velocity in the speech signal, so we will call it $s(t)$ for brevity. Similarly, since $u_{\text{in}}(t)$ is the input signal at the glottis, we will call it $g(t)$. To get the time-sampled version of Eq. (44.19) we set $t = 2n\Delta/c$ and define $s(2n\Delta/c) = s_n$ and $g((2n - N)\Delta/c) = g_n$. Then Eq. (44.19) becomes

$$\sum_{k=0}^N a_k s_{n-k} = \varepsilon_n \cdot \psi \quad (44.20)$$

Equation (44.20) is the LPC representation of a speech signal.

44.3.6 Nasal Coupling

Nasal sounds are produced by opening the velum and thereby coupling the nasal cavity to the vocal tract. In nasal consonants, the vocal tract itself is closed at some point between the velum and the lips, and all the airflow is diverted into the nostrils. In nasal vowels the vocal tract remains open. (Nasal vowels are common in French and several other languages. They are not nominally phonemes of English. However, some nasalization of vowels commonly occurs in English speech.)

In terms of chain matrices, the nasal coupling can be handled without too much additional effort. As far as its acoustical properties are concerned, the nasal cavity can be treated exactly like the vocal tract, with the added simplification that its shape may be regarded as fixed. The common assumption is that the nostrils are symmetric, in which case the cross-sectional areas of the two nostrils can be added and the nose replaced by a single, fixed, variable-area tube.

The description of the computations is easier to follow with the aid of the block diagram shown in Fig. 44.5. From a knowledge of the area functions and losses for the vocal and nasal tracts three chain matrices \mathbf{K}_{gv} , \mathbf{K}_{vt} , and \mathbf{K}_{vn} are first computed. These represent, respectively, the matrices from glottis to velum, velum to tract closure (or velum to lips, in case of a nasal vowel), and velum to nostrils.

From \mathbf{K}_{vn} with some assumed impedance termination at the nostrils, the input impedance of the nostrils at the velum may be computed as indicated in Eq. (44.16b). Similarly, \mathbf{K}_{vt} gives the input impedance at the velum, of the vocal tract looking toward the lips. At the velum, these two impedances are combined in parallel to give a total impedance, say Z_v . With this as termination, the velocity to velocity transfer function, T_{gv} , from glottis to velum can be computed from \mathbf{K}_{gv} as shown

FIGURE 44.5: Chain matrices for synthesizing nasal sounds.

in Eq. (44.16b). For a given volume velocity at the glottis, U_g , the volume velocity at the velum is $U_v = T_{gv} U_g$, and the pressure at the velum is $P_v = Z_v U_v$. Once P_v and U_v are known, the volume velocity and/or pressure at the nostrils and lips can be computed by inverting the matrices \mathbf{K}_{vn} and \mathbf{K}_{vl} .

44.4 Sources of Excitation

As mentioned earlier, speech sounds may be classified by type of excitation: periodic, turbulent, or transient. All of these types of excitation are created by converting the potential energy stored in the lungs due to excess pressure into sound energy in the audible frequency range of 20 Hz to 20 kHz.

The lungs of a young adult male may have a maximum usable volume (“vital capacity”) of about 5 l. While reading aloud the pressure in the lungs is typically in the range of 6 to 15 cm of water (6000 to 15000 Pa). Vocal cord vibrations can be sustained with a pressure as low as .2 cm of water. At the other extreme, a pressure as high as 195 cm of water has been recorded for a trumpet player. Typical average airflow for normal speech is about 0.1 l/s. It may peak as high as 5 l/s during rapid inhales in singing.

Periodic excitation originates mainly at the vibrating vocal folds, turbulent excitation originates primarily downstream of the narrowest constriction in the vocal tract, and transient excitations occur whenever a complete closure of the vocal pathway is suddenly released. In the following, we will explore these three types of excitation in some detail. The interested reader is referred to [18] for more information.

44.4.1 Periodic Excitation

Many of the acoustic and perceptual features of an individual’s voice are believed to be due to specific characteristics of the quasi-periodic excitation signal provided by the vocal folds. These, in turn, depend on the morphology of the voice organ, the **larynx**. The anatomy of the larynx is quite complicated, and descriptions of it may be found in the literature [19]. From an engineering point of view, however, it suffices to note that the larynx is the structure that houses the **vocal folds** whose vibration provides the periodic excitation. The space between the vocal folds, called the **glottis**, varies with the motion of the vocal folds, and thus modulates the flow of air through them. As late as 1950 Husson postulated that each movement of the folds is in fact induced by individual nerve signals sent from the brain (the Neurochronaxis hypothesis) [20]. We now know that the larynx is a self-oscillating acousto-mechanical oscillator. This oscillator is controlled by several groups of tiny muscles also housed in the larynx. Some of these muscles control the rest position of the folds, others control their tension, and still others control their shape. During breathing and production of fricatives, for example, the folds are pulled apart (abducted) to allow free flow of air. To produce voiced speech, the vocal folds are brought close together (adducted). When brought close enough together, they go into a spontaneous periodic oscillation. These oscillations are driven by Bernoulli pressure (the same mechanism that keeps airplanes aloft) created by the airflow through the glottis.

If the opening of the glottis is small enough, the Bernoulli pressure due to the rapid flow of air is large enough to pull the folds toward each other, eventually closing the glottis. This, of course, stops the flow and the laryngeal muscles pull the folds apart. This sequence repeats itself until the folds are pulled far enough away, or if the lung pressure becomes too low. We will discuss this oscillation in greater detail later in this section.

Besides the laryngeal muscles, the lung pressure and the acoustic load of the vocal tract also affect the oscillation of the vocal folds.

The larynx also houses many mechanoreceptors that signal to the brain the vibrational state of the vocal folds. These signals help control pitch, loudness, and voice timbre.

Figure 44.6 shows stylized snapshots taken from the side and above the vibrating folds. The view from above can be obtained on live subjects with high speed (or stroboscopic) photography, using a laryngeal mirror or a fiber optic bundle for illumination and viewing. The view from the side is

FIGURE 44.6: One cycle of vocal fold oscillation seen from the front and from above. (After Schönhärl, E., 1960 [25]. With permission of Georg Thieme Verlag, Stuttgart, Germany.)

the result of studies on excised (mostly animal) larynges. From studies such as these, we know that, during glottal vibration, the folds carry a mechanical wave that starts at the tracheal (lower) end of the folds and moves upwards to the pharyngeal (upper) end. Consequently, the edge of the folds that faces the vocal tract usually lags behind the edge of the folds that faces the lungs. This phenomenon is called **vertical phasing**. Higher eigenmodes of these mechanical waves have been observed and have been modeled.

Figure 44.7 shows typical acoustic flow waveforms, called **flow glottograms**, and their first time derivatives. In a normal glottogram, the **closed phase** of the glottal cycle is characterized by zero flow. Often, however, the closure is not complete. Also, in some cases, although the folds close completely, there is a parallel path — a chink — which stays open all the time.

In the **open phase** the flow gradually builds up, reaches a peak, and then falls sharply. The asymmetry is due to the inertia of the airflow in the vocal tract and the sub-glottal cavities. The amplitude of the fundamental frequency is governed mainly by the peak of the flow while the amplitudes of the higher harmonics is governed mainly by the (negative) peak rate of change of flow, which occurs just before closure.

FIGURE 44.7: Example of glottal volume velocity and its time derivative.

Voice Qualities

Depending on the adjustment of the various parameters mentioned above, the glottis can produce a variety of phonations (i.e., excitations for voiced speech), resulting in different perceptual voice qualities. Some perceptual qualities vary continuously whereas others are essentially categorical (i.e., they change abruptly when some parameters cross a threshold).

Voice timbre is an important continuously variable quality which may be given various labels ranging from “mellow” to “pressed”. The spectral slope of the glottal waveform is the main physical correlate of this perceptual quality. On the other hand, nasality and aspiration may be regarded as categorical qualities.

The physical properties that distinguish a “male” voice from a “female” voice are still not well understood, although many distinguishing features are known. Besides the obvious cue of fundamental frequency, the perceptual quality of “breathiness” seems to be important for producing a female-sounding voice. It occurs when the glottis does not close completely during the glottal cycle. This results in a more sinusoidal movement of the folds which makes the amplitude of the fundamental frequency much larger compared to those of the higher harmonics. The presence of leakage in the abducted glottis also increases the damping of the lower formants, thus increasing their bandwidths. Also, the continuous airflow through the leaking glottis gives rise to increased levels of glottal noise (aspiration noise) that masks the higher harmonics of the glottal spectrum. Finally, in

glottograms of female voices, the open phase is a larger proportion of the glottal cycle (about 80%) than in glottograms of male voices (about 60%). The points of closure are also smoother for female voices, which results in lower high frequency energy relative to the fundamental.

Finally, the individuality of a voice (which allows us to recognize the speaker) appears to be dependent largely on the exact relationships between the amplitudes of the first few harmonics.

Models of the Glottis

A study of the mechanical and acoustical properties of the larynx is still an area of active interdisciplinary research. Modeling in the mechanical and acoustical domains requires making simplifying assumptions about the tissue movements and the fluid mechanics of the airflow. Depending on the degree to which the models incorporate physiological knowledge, one can distinguish three categories of glottal models:

Parametrization of glottal flow is the “black-box” approach to glottal modeling. The glottal flow wave or its first time derivative is parametrized in segments by analytical functions. It seems doubtful that any simple model of this kind can match all kinds of speakers and speaking styles. Examples of speech sounds that are difficult to parametrize in this way are nasal and mixed-excitation sounds (i.e., sounds with an added fricative component) and “simple” high-pitch female vowels.

Parametrization of glottal area is more realistic. In this model, the area of the glottal opening is parametrized in segments, but the airflow is computed from the propagation equations, and includes its interaction with the acoustic loads of the vocal tract and the subglottal structures. Such a model is capable of reproducing much more of the detail and individuality of the glottal wave than the black box approach. Problems are still to be expected for mixed glottal/fricative sounds unless the tract model includes an accurate mechanism for frication (see the section on turbulent excitation below).

In a complete, self-oscillating model of the glottis described below, the amplitude of the glottal opening as well as the instants of glottal closure are automatically derived, and depend in a complicated manner on the laryngeal parameters, lung pressure, and the past history of the flow. The area-driven model has the disadvantage that amplitude and instants of closure must be specified as side information. However, the ability to specify the points of glottal closure can, in fact, be an advantage in some applications; for example, when the model is used to mimic a given speech signal.

Self-oscillating physiological models of the glottis attempt to model the complete interaction of the airflow and the vocal folds which results in periodic excitation. The input to a model of this type is slowly varying physical parameters such as lung pressure, tension of the folds, pre-phonatory glottal shape, etc. Of the many models of this type that have been proposed, the one most often used is the 2-mass model of Ishizaka and Flanagan (I&F). In the following we will briefly review this model.

The I&F two-mass model is depicted in Fig. 44.8. As shown there, the thickness of the vocal folds that separates the trachea from the vocal tract is divided into two parts of length d_1 and d_2 , respectively, where the subscript 1 refers to the part closest to the trachea and 2 refers to the part closest to the vocal tract. These portions of the vocal folds are represented by damped spring-mass systems coupled to each other. The division into two portions is a refinement of an earlier version that represented the folds by a single spring-mass system. By using two sections the model comes closer to reality and exhibits the phenomenon of vertical phasing mentioned earlier.

In order to simulate tissue, all the springs and dampers are chosen to be nonlinear. Before discussing the choice of these nonlinear elements, let us first consider the relationship between the airflow and the pressure variations from the lungs to the vocal tract.

Airflow in the Glottis

The dimensions d_1 and d_2 are very small — about 1.5 mm each. This is a very small fraction of the wavelength even at the highest frequencies of interest. (The wavelength of a sound wave in air at 100 kHz is about 3 mm!). Therefore we may assume the flow through the glottis to be incompressible.

FIGURE 44.8: The two-mass model of Ishizaka and Flanagan [21].

With this assumption the equation of continuity, Eq. (44.2), merely states that the volume velocity is the same everywhere in the glottis. We will call this volume velocity u_g . The relationship of this velocity to the pressure is governed by the equation of motion. Since the particle velocity in the glottis can be very large, we need to consider the nonlinear version given in Eq. (44.5). Also, since the cross-section of the glottis is very small, viscous drag cannot be neglected. So we will include a term representing viscous drag proportional to the velocity. With this addition, Eq. (44.5) becomes:

$$\frac{\partial}{\partial x} \left[p + \frac{\rho}{2} (u_g/A)^2 \right] = -\rho \frac{\partial}{\partial t} \left(\frac{u_g}{A} \right) - R_v (u_g/A) . \quad (44.21)$$

The drag coefficient R_v can be estimated for simple geometries. In the present application a rectangular aperture is appropriate. If the length of the aperture is l , its width (corresponding to the opening between the folds) is w and its depth in the direction of flow is d , then $R_v = \frac{12\mu d}{lw^3}$, where μ is the coefficient of shear viscosity. The pressure distribution is obtained by repeated use of Eq. (44.21), using the appropriate value of A (and hence of R_v) in the different parts of the glottis. In this manner, the pressure at any point in the glottis may be determined in terms of the volume velocity, u_g , the lung pressure, P_s , and the pressure at the input to the vocal tract, p_1 .

The detailed derivation of the pressure distribution is given in [21]. The derivation shows that the total pressure drop across the glottis, $P_s - p_1$, is related to the glottal volume velocity, u_g , by an equation of the form

$$P_s - p_1 = Ru_g + \frac{d}{dt}(Lu_g) + \frac{\rho}{2} (u_g/\alpha)^2 . \quad (44.22)$$

With the analogy of pressure to voltage and volume velocity to current, the quantity R is analogous to resistance and L to inductance. The term in u_g^2 may be regarded as u_g times a current-dependent resistance. The quantity α has the dimensions of an area.

Models of Vocal Fold Tissue

When the pressure distribution derived above is coupled to the mechanical properties of the vocal folds, we get a self-oscillating system with properties quite similar to those of a real larynx. The mechanical properties of the vocal folds have been modeled in many ways with varying degrees of complexity ranging from a single spring-mass system to a distributed parameter flexible tube. In the following, by way of example, we will summarize only the original 1972 I&F model.

Returning to Fig. 44.8, we observe that the mechanical properties of the folds are represented by the masses m_1 and m_2 , the (nonlinear) springs s_1 and s_2 , the coupling spring k_c , and the nonlinear

dampers r_1 and r_2 . The opening in each section of the glottis is assumed to have a rectangular shape with length l_g . The widths of the two sections are $2x_j$, $j = 1, 2$. Assuming a symmetrical glottis, the cross-sectional areas of the two sections are

$$A_{gj} = A_{g0j} + 2l_g x_j, \quad j = 1, 2, \quad (44.23)$$

where A_{g01} and A_{g02} are the areas at rest. From this equation, we compute the lateral displacements $x_{j \min}$, $j = 1, 2$ at which the two folds touch each other in each section to be $x_{j \min} = -A_{g0j}/(2l_g)$. Displacements more negative than these indicate a collision of the folds. The springs s_1 and s_2 are assumed to have restoring forces of the form $ax + bx^3$, where the constants a and b take on different values for the two sections and for the colliding and non-colliding conditions.

The dampers r_1 and r_2 are assumed to be linear, but with different values in the colliding and non-colliding cases. The coupling spring k_c is assumed to be linear. With these choices, the coupled equations of motion for the two masses are:

$$m_1 \frac{d^2 x_1}{dt^2} + r_1 \frac{dx_1}{dt} + f_{s1}(x_1) + k_c(x_1 - x_2) = F_1, \quad (44.24a)$$

and

$$m_2 \frac{d^2 x_2}{dt^2} + r_2 \frac{dx_2}{dt} + f_{s2}(x_2) + k_c(x_2 - x_1) = F_2. \quad (44.24b)$$

Here f_{s1} and f_{s2} are the cubic nonlinear springs. The parameters of these springs as well as the damping constants r_1 and r_2 change when the folds go from a colliding state to a non-colliding state and vice versa. The driving forces F_1 and F_2 are proportional to the average acoustic pressures in the two sections of the glottis. Whenever a section is closed (due to the collision of its sides) the corresponding driving force is zero. Note that it is these forces that provide the feedback of the acoustic pressures to the mechanical system. This feedback is ignored in the area-driven models of the glottis.

We close this section with an example of ongoing research in glottal modeling. In the introduction to this section we had stated that breathiness of a voice is considered important for producing a natural-sounding synthetic female voice. Breathiness results from incomplete closures of the folds. We had also stated that incomplete glottal closures due to abducted folds lead to a steep spectral roll-off of the glottal excitation and a strong fundamental. However, practical experience shows that many voices show clear evidence for breathiness but do not show a steep spectral roll-off, and have relatively weak fundamentals instead. How can this mystery be solved? It has been suggested that the glottal “chink” mentioned in the discussion of Fig. 44.7 might be the answer. Many high-speed videos of the vocal folds show evidence of a separate leakage path in the “posterior commissure” (where the folds join) which stays open all the time. Analysis of such a permanently open path produces the stated effect [22].

44.4.2 Turbulent Excitation

Turbulent airflow shows highly irregular fluctuations of particle velocity and pressure. These fluctuations are audible as broadband noise. Turbulent excitation occurs mainly at two locations in the vocal tract: near the glottis and at constriction(s) between the glottis and the lips. Turbulent excitation at a constriction downstream of the glottis produces fricative sounds or voiced fricatives depending on whether or not voicing is simultaneously present. Also, stressed versions of the vowel i , and liquids l and r are usually accompanied by turbulent flow. Measurements and models for turbulent excitation

are even more difficult to establish than for the periodic excitation produced by the glottis because, usually, no vibrating surfaces are involved. Because of the lack of a comprehensive model, much confusion exists over the proper sub-classification of fricatives. The simplest model for turbulent excitation is a “nozzle” (narrow orifice) releasing air into free space. Experimental work has shown that half (or more) of the noise power generated by a jet of air originates within the so-called mixing region that starts at the nozzle outlet and extends as far as a distance four times the diameter of the orifice. The noise source is therefore distributed. Several scaling relations hold between the acoustic output and the nozzle geometry. One of these scaling properties is the so-called **Reynolds number**, Re , that characterizes the amount of turbulence generated as the air from the jet mixes with the ambient air downstream from the orifice:

$$Re = \frac{u}{A} \frac{x}{\nu} . \quad (44.25)$$

Here u is the volume velocity, A is the area of the orifice (hence, u/A is the particle velocity), x is a characteristic dimension of the orifice (the width for a rectangular orifice), and $\nu = \mu/\rho$ is the kinematic viscosity of air. Beyond a critical value of the Reynolds number, Re_{crit} (which is about 1200 for the case of a free jet), the flow becomes fully turbulent; below this value, the flow is partly turbulent and becomes fully laminar at very low velocities. Another scaling equation defines the so-called **Strouhal number**, S , that relates the frequency F_{max} of the (usually broad) peak in the power spectrum of the generated noise to the width of the orifice and the velocity:

$$S = F_{max} \frac{x}{u/A} . \quad (44.26)$$

For the case of a free jet, the Strouhal number S is 0.15. Within the jet, higher frequencies are generated closer to the orifice and lower frequencies further away.

Distributed sources of turbulence can be modeled by expanding them in terms of monopoles (i.e., pulsating spheres), dipoles (two pulsating spheres in opposite phase), quadrupoles (two dipoles in opposite phase), and higher-order representations. The total power generated by a monopole source in free space is proportional to the fourth power of the particle velocity of the flow, that of a dipole source obeys a $(u/A)^6$ power law, and that of a quadrupole source obeys a $(u/A)^8$ power law. Thus, the low order sources are more important at low flow rates, while the reverse is the case at high flow rates. In a duct, however, the exponents of the power laws decrease by 2, that is, a dipole source's noise power is proportional to $(u/A)^4$, etc.

Thus far, we have summarized noise generation in a free jet or air. A much stronger noise source is created when a jet of air hits an obstacle. Depending on the angle between the surface of the obstacle and the direction of flow, the surface roughness, and the obstacle geometry, the noise generated can be up to 20 dB higher than that generated by the same jet in free space. Because of the spatially concentrated source, modeling obstacle noise is easier than modeling the noise in a free jet. Experiments reveal that obstacle noise can be approximated by a dipole source located at the obstacle.

The above theoretical findings qualitatively explain the observed phenomenon that the fricatives *th* and *f* (and the corresponding voiced *dh* and *v*) are weak compared to the fricatives *s* and *sh*. The teeth (upper for *s* and lower for *sh*) provide the obstacle on which the jet impinges to produce the higher noise levels. A fricative of intermediate strength results from a **distributed** obstacle (the “wall” case) when the jet is forced along the roof of the mouth as for the sound *y*.

In a synthesizer, dipole noise sources can be implemented as series pressure sources. One possible implementation is to make the source pressure proportional to $Re^2 - Re_{crit}^2$ for $Re > Re_{crit}$ and zero otherwise [11]. Another option [23] is to relate the noise source power to the Bernoulli pressure $B = .5\rho(u/A)^2$. Since the power of a dipole source located at the teeth (and radiating into free space) is $(u/A)^6$, it is also proportional to B^3 , and the noise source pressure $p_n \propto B^{3/2}$. On the

other hand, for wall sources located further away from the lips, we need multiple (distributed) dipole sources with source pressures proportional either to $Re^2 - Re_{\text{crit}}^2$ or to B . In either case, the source should have a broadband spectrum with a peak at a frequency given by Eq. (44.26).

When a noise source is located at some point inside the tract, its effect on the acoustic output at the lips is computed in terms of two chain matrices — the matrix \mathbf{K}_F from the glottis to the noise source, and the matrix \mathbf{K}_L from the noise source to the lips. For fricative sounds, the glottis is wide open, so the termination impedance at the glottis end may be assumed to be zero. With this termination, the impedance at the noise source looking toward the glottis is computed from \mathbf{K}_F as explained in the section on chain matrices. Call this impedance Z_1 . Similarly, a knowledge of the radiation impedance at the lips and the matrix \mathbf{K}_L allows us to compute the input impedance Z_2 looking toward the lips. The volume velocity at the source is then just $P_n/(Z_1 + Z_2)$ where P_n is the pressure generated by the noise source. The transfer function obtained from Eq. (44.16a) for the matrix \mathbf{K}_L then gives the volume velocity at the lips.

It can be shown that the series noise source P_n excites all formants of the entire tract (i.e., the ones we would see if the source were at the glottis). However, the spectrum of fricative noise usually has a high pass character. This can be understood qualitatively by the following considerations.

When the tract has a very narrow constriction, the front and back cavities are essentially decoupled, and the formants of the tract are the formants of the back cavity plus those of the front cavity. If now the noise source is just downstream of the constriction, the formants of the back cavity are only slightly excited because the impedance Z_1 also has poles at those frequencies. Since the back cavity is usually much longer than the front cavity for fricatives, the lower formants are missing in the velocity at the lips. This gives it a high pass character.

44.4.3 Transient Excitation

Transient excitation of the vocal tract occurs whenever pressure is built up behind a total closure of the tract and suddenly released. This sudden release produces a step-function of input pressure at the point of release. The output velocity is therefore proportional to the integral of the impulse response of the tract from the point of release to the lips. In the frequency domain, this is just P_r/s times the transfer function, where P_r is the step change in pressure. Hence, the velocity at the lips may be computed in the same way as in the case of turbulent excitation, with P_n replaced by P_r/s . In practice, this step excitation is usually followed by the generation of fricative noise for a short period after release when the constriction is still narrow enough. Sometimes, if the glottis is also being constricted (e.g., to start voicing) some aspiration might also result.

44.5 Digital Implementations

The models of the various parts of the human speech production apparatus which we have described above can be assembled to produce fluent speech. Here we will consider how a digital implementation of this process may be carried out. Basically, the standard theory of sampling in the time and frequency domains is used to convert the continuous signals considered above to sampled signals, and the samples are represented digitally to the desired number of bits per sample.

44.5.1 Specification of Parameters

The parameters that drive the synthesizer need to be specified about every 20 ms. (The assumed quasi-stationarity is valid over durations of this size.)

Two sets of parameters are needed — the parameters that specify the shape of the vocal tract and those that control the glottis. The vocal tract parameters implicitly control nasality (by specifying the opening area of the velum) and also frication (by specifying the size of the narrowest constriction).

44.5.2 Synthesis

The vocal tract is approximated by a concatenation of about 20 uniform sections. The cross-sectional areas of these sections is either specified directly, or computed from a specification of articulatory parameters as shown in Fig. 44.3. The chain matrix for each section is computed at an adequate sampling rate in the frequency domain to avoid time-aliasing of the corresponding time functions. (Computation of the chain matrices requires a specification of the losses also. Several models exist which assign the losses in terms of the cross-sectional area [11, 16]).

The chain matrices for the individual sections are combined to derive the matrices for various portions of the tract, as appropriate for the particular speech sound being synthesized. For voiced sounds, the matrices for the sections from the glottis to the lips are sequentially multiplied to give the matrix from the glottis to the lips. From the \mathbf{k}_{11} , \mathbf{k}_{12} , \mathbf{k}_{21} , \mathbf{k}_{22} components of this matrix, the transfer function $\frac{U_{\text{out}}}{U_{\text{in}}}$ and the input impedance are obtained as in Eqs. (44.16a) and (44.16b). Knowing the radiation impedance Z_R at the lips we can compute the transfer function for output pressure, $H = \frac{U_{\text{out}}}{U_{\text{in}}} Z_R$. The inverse FFT of the transfer function H and the input impedance Z_{in} give the corresponding time functions $h(n)$ and $z_{\text{in}}(n)$, respectively. These functions are computed every 20 ms, and the intermediate values are obtained by linear interpolation.

For the current time sampling instant n , the current pressure $p_1(n)$ at the input to the vocal tract is then computed by convolving z_{in} with the past values of the glottal volume velocity u_g . With p_1 known, the pressure difference $P_s - p_1$ on the left hand side of Eq. (44.22) is known. Equation (44.18) is discretized by using a backward difference for the time derivative. Thus, a new value of the glottal volume velocity is derived. This, together with the current values of the displacements of the vocal folds, gives us new values for the driving forces F_1 and F_2 for the coupled oscillator Eqs. (44.24a) and (44.24b). The coupled oscillator equations are also discretized by backward differences for time derivatives. Thus, the new values of the driving forces give new values for the displacements of the vocal folds. The new value of volume velocity also gives a new value for p_1 , and the computational cycle repeats, to give successive samples of p_1 , u_g , and the vocal fold displacements.

The glottal volume velocity obtained in this way, is convolved with the impulse response $h(n)$ to produce voiced speech.

If the speech sound calls for frication, the chain matrix of the tract is derived as the product of two matrices — from the glottis to the narrowest constriction and from the constriction to the lips, as discussed in the section on turbulent excitation. This enables us to compute the volume velocity at the constriction, and thus introduce a noise source on the basis of the Reynolds number.

Finally, to produce nasal sounds, the chain matrix for the nasal tract is also computed, and the output at the nostrils computed as discussed in the section on chain matrices. If the lips are open, the output from the lips is also computed and added to the output from the nostrils to give the total speech signal. Details of the synthesis procedure may be found in [24].

45.1 Introduction

Digital speech coding is used in a wide variety of everyday applications that the ordinary person takes for granted, such as network telephony or telephone answering machines. By speech coding we mean a method for reducing the amount of information needed to represent a speech signal for transmission or storage applications. For most applications this means using a lossy compression algorithm because a small amount of perceptible degradation is acceptable. This section reviews some of the applications, the basic attributes of speech coders, methods currently used for coding, and some of the most important speech coding standards.

45.1.1 Examples of Applications

Digital speech transmission is used in network telephony. The speech coding used is just sample-by-sample quantization. The transmission rate for most calls is fixed at 64 kilobits per second (kb/s). The speech is sampled at 8000 Hz (8 kHz) and a logarithmic 8-bit quantizer is used to represent each sample as one of 256 possible output values. International calls over transoceanic cables or satellites are often reduced in bit rate to 32 kb/s in order to boost the capacity of this relatively expensive equipment. Digital wireless transmission has already begun. In North America, Europe, and Japan there are digital cellular phone systems already in operation with bit rates ranging from 6.7 to 13 kb/s for the speech coders. Secure telephony has existed since World War II, based on the first vocoder. (Vocoder is a contraction of the words voice coder.) Secure telephony involves first converting the speech to a digital form, then digitally encrypting it and then transmitting it. At the receiver, it is decrypted, decoded, and reconverted back to analog. Current videotelephony is accomplished

through digital transmission of both the speech and the video signals. An emerging use of speech coders is for simultaneous voice and data. In these applications, users exchange data (text, images, FAX, or any other form of digital information) while carrying on a conversation.

All of the above examples involve real-time conversations. Today we use speech coders for many storage applications that make our lives easier. For example, voice mail systems and telephone answering machines allow us to leave messages for others. The called party can retrieve the message when they wish, even from halfway around the world. The same storage technology can be used to broadcast announcements to many different individuals. Another emerging use of speech coding is multimedia. Most forms of multimedia involve only one-way communications, so we include them with storage applications. Multimedia documents on computers can have snippets of speech as an integral part. Capabilities currently exist to allow users to make voice annotations onto documents stored on a personal computer (PC) or workstation.

45.1.2 Speech Coder Attributes

Speech coders have attributes that can be placed in four groups: *bit rate*, *quality*, *complexity*, and *delay*. For a given application, some of these attributes are pre-determined while tradeoffs can be made among the others. For example, the communications channel may set a limit on bit rate, or cost considerations may limit complexity. Quality can usually be improved by increasing bit rate or complexity, and sometimes by increasing delay. In the following sections, we discuss these attributes.

Primarily we will be discussing *telephone bandwidth speech*. This is a slightly nebulous term. In the telephone network, speech is first bandpass filtered from roughly 200 to 3200 Hz. This is often referred to as 3 kHz speech. Speech is sampled at 8 kHz in the telephone network. The usual telephone bandwidth filter rolls off to about 35 dB by 4 kHz in order to eliminate the aliasing artifacts caused by sampling.

There is a second bandwidth of interest. It is referred to as *wideband speech*. The sampling rate is doubled to 16 kHz. The lowpass filter is assumed to begin rolling off at 7 kHz. At the low end, the speech is assumed to be uncontaminated by line noise and only the DC component needs to be filtered out. Thus, the highpass filter cutoff frequency is 50 Hz. When we refer to wideband speech, we mean speech with a bandwidth of 50 to 7000 Hz and a sampling rate of 16 kHz. This is also referred to as 7 kHz speech.

Bit Rate

Bit rate tells us the degree of compression that the coder achieves. Telephone bandwidth speech is sampled at 8 kHz and digitized with an 8-bit logarithmic quantizer, resulting in a bit rate of 64 kb/s. For telephone bandwidth speech coders, we measure the degree of compression by how much the bit rate is lowered from 64 kb/s. International telephone network standards currently exist for coders operating from 64 kb/s down to 5.3 kb/s. The speech coders for regional cellular standards span the range from 13 to 3.45 kb/s and those for secure telephony span the range from 16 kb/s to 800 b/s. Finally, there are proprietary speech coders that are in common use which span the entire range.

Speech coders need not have a constant bit rate. Considerable compression can be gained by not transmitting speech during the silence intervals of a conversation. Nor is it necessary to keep the bit rate fixed during the talkspurts of a conversation.

Delay

The communication delay of the coder is more important for transmission than for storage applications. In real-time conversations, a large communication delay can impose an awkward protocol on talkers. Large communication delays of 300 ms or greater are particularly objectionable to users even if there are no echoes.

Most low bit rate speech coders are block coders. They encode a block of speech, also known as a frame, at a time. Speech coding delay can be allocated as follows. First, there is algorithmic delay. Some coders have an amount of *look-ahead* or other inherent delays in addition to their frame size. The sum of frame size and other inherent delays constitutes algorithmic delay. The coder requires computation. The amount of time required for this is called processing delay. It is dependent on the speed of the processor used. Other delays in a complete system are the multiplexing delay and the transmission delay.

Complexity

The degree of complexity is a determining factor in both the cost and power consumption of a speech coder. Cost is almost always a factor in the selection of a speech coder for a given application. With the advent of wireless and portable communications, power consumption has also become an important factor. Simple scalar quantizers, such as linear or logarithmic PCM, are necessary in any coding system and have the lowest possible complexity.

More complex speech coders are first simulated on host processors, then implemented on DSP chips and may later be implemented on special purpose VLSI devices. Speed and random access memory (RAM) are the two most important contributing factors of complexity. The faster the chip or the greater the chip size, the greater the cost. In fact, complexity is a determining factor for both cost and power consumption. Generally 1 word of RAM takes up as much on-chip area as 4 to 6 words of read only memory (ROM). Most speech coders are implemented on fixed point DSP chips, so one way to compare the complexity of coders is to measure their speed and memory requirements when efficiently implemented on commercially available fixed point DSP chips.

DSP chips are available in both 16-bit fixed point and 32-bit floating point. 16-bit DSP chips are generally preferred for dedicated speech coder implementations because the chips are usually less expensive and consume less power than implementations based on floating point DSPs. A disadvantage of fixed-point DSP chips is that the speech coding algorithm must be implemented using 16-bit arithmetic. As part of the implementation process, a representation must be selected for each and every variable. Some can be represented in a fixed format, some in block floating point, and still others may require double precision. As VLSI technology has advanced, fixed point DSP chips contain a richer set of instructions to handle the data manipulations required to implement representations such as block floating point. The advantage of floating point DSP chips is that implementing speech coders is much quicker. Their arithmetic precision is about the same as that of a high level language simulation, so the steps of determining the representation of each and every variable and how these representations affect performance can be omitted.

Quality

The attribute of quality has many dimensions. Ultimately quality is determined by how the speech sounds to a listener. Some of the factors that affect the performance of a coder are whether the input speech is clean or noisy, whether the bit stream has been corrupted by errors, and whether multiple encodings have taken place.

Speech coder quality ratings are determined by means of subjective listening tests. The listening is done in a quiet booth and may use specified telephone handsets, headphones, or loudspeakers. The speech material is presented to the listeners at specified levels and is originally prepared to have particular frequency characteristics. The most often used test is the absolute category rating (ACR) test. Subjects hear pairs of sentences and are asked to give one of the following ratings: *excellent*, *good*, *fair*, *poor*, or *bad*. A typical test contains a variety of different talkers and a number of different coders or reference conditions. The data resulting from this test can be analyzed in many ways. The simplest way is to assign a numerical ranking to each response, giving a 5 to the best possible rating, 4 to the next best, down to a 1 for the worst rating, then computing the mean rating for each of the

conditions under test. This is referred to as a mean opinion score (MOS) and the ACR test is often referred to as a MOS test.

There are many other dimensions to quality besides those pertaining to noiseless channels. Bit error sensitivity is another aspect of quality. For some low bit rate applications such as secure telephones over 2.4 or 4.8 kb/s modems, it might be reasonable to expect the distribution of bit errors to be random and coders should be made robust for low random bit error rates up to 1 to 2%. For radio channels, such as in digital cellular telephony, provision is made for additional bits to be used for channel coding to protect the information bearing bits. Errors are more likely to occur in bursts and the speech coder requires a mechanism to recover from an entire lost frame. This is referred to as frame erasure concealment, another aspect of quality for cellular speech coders.

For the purposes of conserving bandwidth, voice activity detectors are sometimes used with speech coders. During non-speech intervals, the speech coder bit stream is discontinued. At the receiver “comfort noise” is injected to simulate the background acoustic noise at the encoder. This method is used for some cellular systems and also in digital speech interpolation (DSI) systems to increase the effective number of channels or circuits. Most international phone calls carried on undersea cables or satellites use DSI systems. There is some impact on quality when these techniques are used. Subjective testing can determine the degree of degradation.

45.2 Useful Models for Speech and Hearing

45.2.1 The LPC Speech Production Model

Human speech is produced in the vocal tract by a combination of the vocal cords in the glottis interacting with the articulators of the vocal tract. The vocal tract can be approximated as a tube of varying diameter. The shape of the tube gives rise to resonant frequencies called formants. Over the years, the most successful speech coding techniques have been based on linear prediction coding (LPC). The LPC model is derived from a mathematical approximation to the vocal tract representation as a variable diameter tube. The essential element of LPC is the linear prediction filter. This is an all pole filter which predicts the value of the next sample based on a linear combination of previous samples.

Let x_n be the speech sample value at sampling instant n . The object is to find a set of prediction coefficients $\{a_i\}$ such that the prediction error for a frame of size M is minimized:

$$\varepsilon = \sum_{m=0}^{M-1} \left(\sum_{i=1}^I a_i x_{n+m-i} + x_{n+m} \right)^2 \quad (45.1)$$

where I is the order of the linear prediction model. The prediction value for x_n is given by

$$\tilde{x}_n = - \sum_{i=1}^I a_i x_{n-i} \quad (45.2)$$

The prediction error signal $\{e_n\}$ is also referred to as the *residual* signal. In z -transform notation we can write

$$A(z) = 1 + \sum_{i=1}^I a_i z^{-i} \quad (45.3)$$

$1/A(z)$ is referred to as the *LPC synthesis* filter and (ironically) $A(z)$ is referred to as the *LPC inverse* filter.

LPC analysis is carried out as a block process on a frame of speech. The most often used techniques are referred to as the autocorrelation and the autocovariance methods [1]–[3]. Both methods involve inverting matrices containing correlation statistics of the speech signal. If the poles of the LPC filter are close to the unit circle, then these matrices become more ill-conditioned, which means that the techniques used for inversion are more sensitive to errors caused by finite numerical precision. Various techniques for dealing with this aspect of LPC analysis include windows for the data [1, 2], windows for the correlation statistics [4], and bandwidth expansion of the LPC coefficients.

For forward adaptive coders, the LPC information must also be quantized and transmitted or stored. Direct quantization of LPC coefficients is not efficient. A small quantization error in a single coefficient can render the entire LPC filter unstable. Even if the filter is stable, sufficient precision is required and too many bits will be needed. Instead, it is better to transform the LPC coefficients to another domain in which stability is more easily determined and fewer bits are required for representing the quantization levels.

The first such domain to be considered is the reflection coefficient [5]. Reflection coefficients are computed as a byproduct of LPC analysis. One of their properties is that all reflection coefficients must have magnitudes less than 1, making stability easily verified. Direct quantization of reflection coefficients is still not efficient because the sensitivity of the LPC filter to errors is much greater when reflection coefficients are nearly 1 or -1 . More efficient quantizers have been designed by transforming the individual reflection coefficients with a nonlinearity that makes the error sensitivity more uniform. Two such nonlinear functions are the inverse sine function, $\arcsin(k_i)$, and the logarithm of the area ratio, $\log \frac{1+k_i}{1-k_i}$.

A second domain that has attracted even greater interest recently is the line spectral frequency (LSF) domain [6]. The transformation is given as follows. We first use $A(z)$ to define two polynomials:

$$P(z) = A(z) + z^{-(I+1)} A(z^{-1}) \quad (45.4a)$$

$$Q(z) = A(z) - z^{-(I+1)} A(z^{-1}) \quad (45.4b)$$

These polynomials can be shown to have two useful properties: all zeroes of $P(z)$ and $Q(z)$ lie on the unit circle and they are interlaced with each other. Thus, stability is easily checked by assuring both the interlaced property and that no two zeroes are too close together. A second property is that the frequencies tend to be clustered near the formant frequencies; the closer together two LSFs are, the sharper the formant. LSFs have attracted more interest recently because they typically result in quantizers having either better representations or using fewer bits than reflection coefficient quantizers.

The simplest quantizers are scalar quantizers [8]. Each of the values (in whatever domain is being used to represent the LPC coefficients) is represented by one of the possible quantizer levels. The individual values are quantized independently of each other. There may also be additional redundancy between successive frames, especially during stationary speech. In such cases, values may be quantized differentially between frames.

A more efficient, but also more complex, method of quantization is called vector quantization [9]. In this technique, the complete set of values is quantized jointly. The actual set of values is compared against all sets in the codebook using a distance metric. The set that is nearest is selected. In practice, an exhaustive codebook search is too complex. For example, a 10-bit codebook has 1024 entries. This seems like a practical limit for most codebooks, but does not give sufficient performance for typical 10th order LPC. A 20-bit codebook would give increased performance, but would contain over 1 million vectors. This is both too much storage and too much computational complexity to be practical. Instead of using large codebooks, product codes are used. In one technique, an initial codebook is used, then the remaining error vector is quantized by a second stage codebook. In the

second technique, the vector is sub-divided and each sub-vector is quantized using its own codebook. Both of these techniques lose efficiency compared to a full-search vector quantizer, but represent a good means for reducing computational complexity and codebook size for bit rate or quality.

45.2.2 Models of Human Perception for Speech Coding

Our ears have a limited dynamic range that depends on both the level and the frequency content of the input signal. The typical bandpass telephone filter has a stopband of only about 35 dB. Also, the logarithmic quantizer characteristics specified by CCITT Rec. G.711 result in a signal-to-quantization noise ratio of about 35 dB. Is this a coincidence? Of course not! If a signal maintains an SNR of about 35 dB or greater for telephone bandwidth, then most humans will perceive little or no noise.

Conceptually, the masking property tells us that we can permit greater amounts of noise in and near the formant regions and that noise will be most audible in the spectral valleys. If we use a coder that produces a white noise characteristic, then the noise spectrum is flat. The white noise would probably be audible in all but the formant regions.

In modern speech coders, an additional linear filter is added to weight the difference between the original speech signal and the synthesized signal. The object is to minimize the error in a space whose metric is like that of the human auditory system. If the LPC filter information is available, it constitutes the best available estimate of the speech spectrum. It can be used to form the basis for this “perceptual weighting filter” [10]. The perceptual weighting filter is given by

$$W(z) = \frac{1 - A(z/\gamma_1)}{1 - A(z/\gamma_2)} \quad 0 < \gamma_2 < \gamma_1 < 1 \quad (45.5)$$

The perceptual weighting filter de-emphasizes the importance of noise in the formant region and emphasizes its importance in spectral valleys. The quantization noise will have a spectral shape that is similar to that of the LPC spectral estimate, making it easier to mask.

The adaptive postfilter is an additional linear filter that is combined with the synthesis filter to reduce noise in the spectral valleys [11]. Once again the LPC synthesis filter is available as the estimate of the speech spectrum. As in the perceptual weighting filter, the synthesis filter is modified. This idea was later further extended to include a long-term (pitch) filter. A tilt-compensation filter was added to correct for the low pass characteristic that causes a muffled sound. A gain control strategy helped prevent any segments from being either too loud or too soft. Adaptive postfilters are now included as a part of many standards.

45.3 Types of Speech Coders

This part of the section describes a variety of speech coders that are widely used. They are divided into two categories: waveform-following coders and model-based coders. Waveform-following coders have the property that if there were no quantization error, the original speech signal would be exactly reproduced. Model-based coders are based on parametric models of speech production. Only the values of the parameters are quantized. If there were no quantization error, the reproduced signal would not be the original speech.

45.3.1 Model-Based Speech Coders

LPC Vocoders

A block diagram of the LPC vocoder is shown in Fig. 45.1. LPC analysis is performed on a frame of speech and the LPC information is quantized and transmitted. A voiced/unvoiced determination is made. The decision may be based on either the original speech or the LPC residual signal, but it

will always be based on the degree of periodicity of the signal. If the frame is classified as unvoiced, the excitation signal is white noise. If the frame is voiced, the pitch period is transmitted and the excitation signal is a periodic pulse train. In either case, the amplitude of the output signal is selected such that its power matches that of the original speech. For more information on the LPC vocoder, the reader is referred to [12].

FIGURE 45.1: Block diagram of LPC vocoder.

Multiband Excitation (MBE) Coders

Figure 45.2 is a block diagram of a multiband sinusoidal excitation coder. The basic premise of these coders is that the speech waveform can be modeled as a combination of harmonically related sinusoidal waveforms and narrowband noise. Within a given bandwidth, the speech is classified as periodic or aperiodic. Harmonically related sinusoids are used to generate the periodic components and white noise is used to generate the aperiodic components. Rather than transmitting a single voiced/unvoiced decision, a frame consists of a number of voiced/unvoiced decisions corresponding to the different bands. In addition, the spectral shape and gain must be transmitted to the receiver. LPC may or may not be used to quantize the spectral shape. Most often the analysis of the encoder is performed via fast Fourier transform (FFT). Synthesis at the decoder is usually performed by a number of parallel sinusoid and white noise generators. MBE coders are model-based because they do not transmit the phase of the sinusoids, nor do they attempt to capture anything more than the energy of the aperiodic components. For more information the reader is referred to [13]–[16].

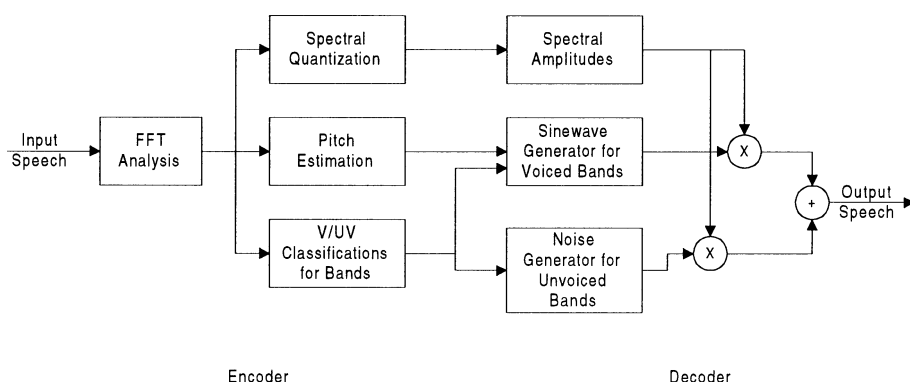

FIGURE 45.2: Block diagram of multiband excitation coder.

Waveform Interpolation Coders

Figure 45.3 is a block diagram of a waveform interpolation coder. In this coder, the speech is assumed to be composed of a slowly evolving periodic waveform (SEW) and a rapidly evolving noise-like waveform (REW). A frame is analyzed first to extract a “characteristic waveform”. The evolution of these waveforms is filtered to separate the REW from the SEW. REW updates are made several times more often than SEW updates. The LPC, the pitch, the spectra of the SEW and REW, and the overall energy are all transmitted independently. At the receiver a parametric representation of the SEW and REW information is constructed, summed, and passed through the LPC synthesis filter to produce output speech. For more information the reader is referred to [17, 18].

FIGURE 45.3: Block diagram of waveform interpolation coder.

45.3.2 Time Domain Waveform-Following Speech Coders

All of the time domain waveform coders described in this section include a prediction filter. We begin with the simplest.

Adaptive Differential Pulse Code Modulation (ADPCM)

Adaptive differential pulse code modulation (ADPCM) [19] is based on sample-by-sample quantization of the prediction error. A simple block diagram is shown in Fig. 45.4. Two parts of the coder may be adaptive: the quantizer step-size and/or the prediction filter. ITU Recommendations G.726 and G.727 adapt both. The adaptation may be either forward or backward adaptive. In a backward adaptive system, the adaptation is based only on the previously quantized sample values and the quantizer codewords. At the receiver, the backward adaptive parameter values must be recomputed. An important feature of such adaptation schemes is that they must use predictors that include a *leakage factor* that allows the effects of erroneous values caused by channel errors to die out over time. In a forward adaptive system, the adapted values are quantized and transmitted. This additional “side information” uses bit rate, but can improve quality. Additionally, it does not require recomputation at the decoder.

Delta Modulation Coders

In delta modulation coders [20], the quantizer is just the sign bit. The quantization step size is adaptive. Not all the adaptation schemes used for ADPCM will work for delta modulation because the quantization is so coarse. The quality of delta modulation coders tends to be proportional to their sampling clock: the greater the sampling clock, the greater the correlation between successive samples, and the finer the quantization step size that can be used. The block diagram for delta modulation is the same as that of ADPCM.

FIGURE 45.4: ADPCM encoder and decoder block diagrams.

Adaptive Predictive Coding

The better the performance of the prediction filter, the lower the bit rate needed to encode a speech signal. This is the basis of the adaptive predictive coder [21] shown in Fig. 45.5. A forward adaptive higher order linear prediction filter is used. The speech is quantized on a frame-by-frame basis. In this way the bit rate for the excitation can be reduced compared to an equivalent quality ADPCM coder.

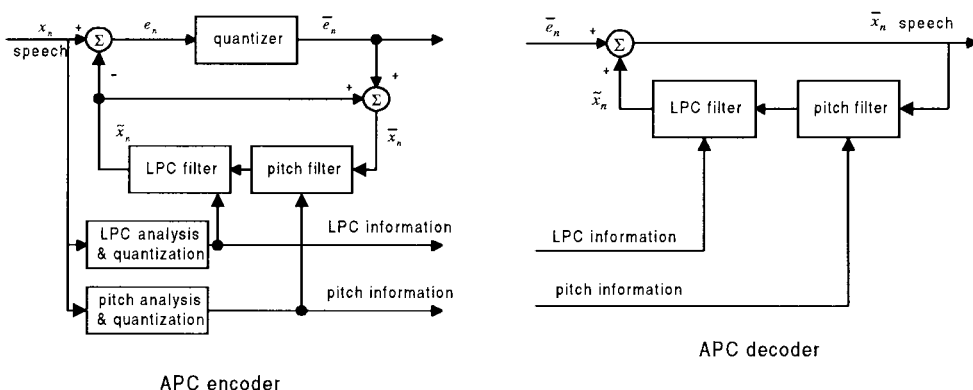

FIGURE 45.5: Adaptive predictive coding encoder and decoder.

Linear Prediction Analysis-by-Synthesis Speech Coders

Figure 45.6 shows a typical linear prediction analysis-by-synthesis speech coder [22]. Like APC, these are frame-by-frame coders. They begin with an LPC analysis. Typically the LPC information is forward adaptive, but there are exceptions. LPAS coders borrow the concept from ADPCM of having a locally available decoder. The difference between the quantized output signal and the original signal is passed through a perceptual weighting filter. Possible excitation signals are considered and the best (minimum mean square error in the perceptual domain) is selected. The long-term prediction filter removes long-term correlation (the pitch structure) in the signal. If pitch structure is present in the coder, the parameters for the long-term predictor are determined first. The most commonly used system is the adaptive codebook, where samples from previous excitation sequences are stored. The pitch period and gain that result in the greatest reduction of perceptual error are selected, quantized, and transmitted. The fixed codebook excitation is next considered and, again, the excitation vector

that most reduces the perceptual error energy is selected and its index and gain are transmitted. A variety of different possible fixed excitation codebooks and their corresponding names have been created for coders that fall into this class. Our enumeration touches only the highlights.

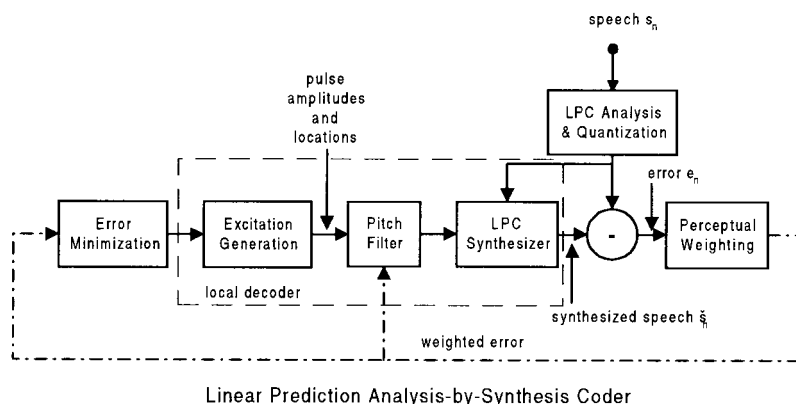

FIGURE 45.6: Linear prediction analysis-by-synthesis coder.

Multipulse Linear Predictive Coding (MPLPC) assumes that the speech frame is sub-divided into smaller sub-frames. After determining the adaptive codebook contribution, the fixed codebook consists of a number of pulses. Typically the number of pulses is about one-tenth the number of samples in a sub-frame. The pulse that makes the greatest contribution to reducing the error is selected first, then the pulse making the next largest contribution, etc. Once the requisite number of pulses have been selected, determination of the pulses is complete. For each pulse, its location and amplitude must be transmitted.

Codebook Excited Linear Predictive Coding (CELP) assumes that the fixed codebook is composed of vectors. This is similar in nature to the *Vector Excitation Coder* (VXC). In the first CELP coder, the codebooks were composed of Gaussian random numbers. It was subsequently discovered that center-clipping these random number codebooks resulted in better quality speech. This had the effect of making the codebook look more like a collection of multipulse LPC excitation vectors. One means for reducing the fixed codebook search is if the codebook consists of overlapping vectors.

Vector Sum Excitation Linear Predictive Coding (VSELP) assumes that the fixed codebook is composed of a weighted sum of a set of basis vectors. The basis vectors are orthogonal to each other. The weights on any basis vector are always either -1 or $+1$. A fast search technique is possible based on using a pseudo-Gray code method of exploration. VSELP was used for several first or second generation digital cellular phone standards [23].

45.3.3 Frequency Domain Waveform-Following Speech Coders

Sub-Band Coders

Figure 45.7 shows the structures of a typical sub-band encoder and decoder [19, 24]. The concept behind sub-band coding is quite simple: divide the speech signal into a number of frequency bands and quantize each band separately. In this way the quantization noise is kept within the band. Typically quadrature mirror or wavelet filterbanks are used. These have the properties that (1) in the absence of quantization error all aliasing caused by decimation in the analysis filterbank is canceled in the synthesis filterbank and (2) the bands can be critically sampled, i.e., the number of frequency

domain samples is the same as the number of time domain samples. The effectiveness of these coders depends largely on the sophistication of the quantization algorithm. Generally, algorithms that dynamically allocate the bits according to the current spectral characteristics of the speech give the best performance.

FIGURE 45.7: Sub-band coder.

Adaptive Transform Coders

Adaptive transform coding (ATC) can be viewed as a further extension to sub-band coding [19, 24]. The filterbank structure of SBC is replaced with a transform such as the FFT, the discrete cosine transform (DCT), wavelet transform or other transform-filterbank. They provide a higher resolution analysis than the sub-band filterbanks. This allows the coder to exploit the pitch harmonic structure of the spectrum. As in the case of SBC, the ATC coders that use sophisticated quantization techniques that dynamically allocate the bits usually give the best performance. Most recently, work has combined transform coding with LPC and time-domain pitch analysis [25]. The residual signal is coded using ATC.

45.4 Current Standards

This part of the section is divided into descriptions of current speech coder standards and activities. The subsections contain information on speech coders that have been or will soon be standardized. We begin first by briefly describing the standards organizations who formulate speech coding standards and the processes they follow in making these standards.

The International Telecommunications Union (ITU) is an agency of the United Nations Economic, Scientific and Cultural Organization (UNESCO) charged with all aspects of standardization in telecommunications and radio networks. Its headquarters are in Geneva, Switzerland. The ITU Telecommunications Standardization Sector (ITU-T) formulates standards related to both wireline and wireless telecommunications. The ITU Radio Standardization Sector (ITU-R) handles standardization related to radio issues. There is also a third branch, the ITU – Telecommunications Standards Bureau (ITU-B) is the bureaucracy handling all of the paperwork. Speech coding standards are handled jointly by Study Groups 16 and 12 within the ITU-T. Other Study Groups may originate requests for speech coders for specific applications. The speech coding experts are found in SG16. The experts on speech performance are found in SG12. When a new standard is being formulated, SG16 draws up a list of requirements based on the intended applications. SG12 and other interested bodies may review the requirements before they are finalized. SG12 then creates a test plan and enlists the help of subjective testing laboratories to measure the quality of the speech coders under the various test conditions. The process of standardization can be time consuming and take between 2 to 6 years.

Three different standards bodies make regional cellular standards, including those for the speech

coders. In Europe, the parent body is the European Telecommunications Standards Institute (ETSI). ETSI is an organization that is composed mainly of telecommunications equipment manufacturers. In North America, the parent body is the American National Standards Institute (ANSI). The body charged with making digital cellular standards is the Telecommunications Industry Association (TIA). In Japan, the body charged with making digital cellular standards is the Research and Development Center for Radio Systems (RCR).

There are also speech coding standards for satellite, emergencies, and secure telephony. Some of these standards were promulgated by government bodies, while others were promulgated by private organizations.

Each of these standards organizations works according to its own rules and regulations. However, there is a set of common threads among all of the organizations. These are the standards making process. Creating a standard is a long process, not to be undertaken lightly. First, a consensus must be reached that a standard is needed. In most cases this is obvious. Second, the terms of reference need to be created. This becomes the governing document for the entire effort. It defines the intended applications. Based on these applications, requirements can be set on the attributes of the speech coder: quality, complexity, bit rate, and delay. The requirements will later determine the test program that is needed to ascertain whether any candidates are suitable.

Finally, the members of the group need to define a schedule for doing the work. There needs to be an initial period to allow proponents to design coders that are likely to meet the requirements. A deadline is set for submissions. The services of one or more subjective test labs need to be secured and a test plan needs to be defined. A host lab is also needed to process all of the data that will be used in the Selection Test. Some criteria are needed for determining how to make the selection. Based on the selection, a draft standard needs to be written. Only after the standard is fully specified can manufacturers begin to produce implementations of the standard.

45.4.1 Current ITU Waveform Signal Coders

Table 45.1 describes current ITU speech coding recommendations that are based on sample-by-sample scalar quantization. Three of these coders operate in the time domain on the original sampled signal while the fourth is based on a two-band sub-band coder for wideband speech.

TABLE 45.1 ITU Waveform Speech Coders

Standard body	ITU	ITU	ITU	ITU
Number	G.711	G.726	G.727	G.722
Year	1972	1990	1990	1988
Type of coder	Companded PCM	ADPCM	ADPCM	SBC/ADPCM
Bit rate	64 kb/s	16–40 kb/s	16–40 kb/s	48, 56 64 kb/s
Quality	Toll	≤ Toll	≤ Toll	Commentary
Complexity				
MIPS	≪ 1	1	1	10
RAM	1 byte	< 50 bytes	< bytes	1 K words
Delay				
Frame size	0.125 ms	0.125 ms	0.125 ms	1.5 ms
Specification type				
Fixed point	Bit exact	Bit exact	Bit exact	Bit exact

The CCITT standardized two 64 kb/s companded PCM coders in 1972. North America and Japan use μ -law PCM. The rest of the world uses A-law PCM. Both coders use 8 bits to represent the signal. Their effective signal-to-noise ratio is about 35 dB. The tables for both of the G.711 quantizer

characteristics are contained in [19]. Both coders are considered equivalent in overall quality. A tandem encoding with either coder is considered equivalent to dropping the least significant bit (which is equivalent to reducing the bit rate to 56 kb/s). Both coders are extremely sensitive to bit errors in the most significant bits. Their complexity is very low.

32 kb/s ADPCM was first standardized by the ITU in 1984 [26]–[28]. Its primary application was intended to be digital circuit multiplication equipment (DCME). In combination with digital speech interpolation, a 5:1 increase in the capacity of undersea cables and satellite links was realized for voice conversations. An additional reason for its creation was that such links often encountered the problem of having μ -law PCM at one end and A-law at the other. G.726 can accept either μ -law or A-law PCM as inputs or outputs. Perhaps its most unique feature is a property called synchronous tandeming. If a circuit involves two ADPCM codings with a μ -law or A-law encoding in-between, no additional degradation occurs because of the second encoding. The second bit stream will be identical to the first! In 1986 the Recommendation was revised to eliminate the all-zeroes codeword and so that certain low rate modem signals would be passed satisfactorily. In 1988 extensions for 24 and 40 kb/s were added and in 1990 the 16 kb/s rate was added. All of these additional rates were added for use in digital circuit multiplication equipment applications.

G.727 includes the same rates as G.726, but all of the quantizers have an even number of levels. The 2-bit quantizer is embedded in the 3-bit quantizer, which is embedded in the 4-bit quantizer, which is embedded in the 5-bit quantizer. The is needed for Packet Circuit Multiplex Equipment (PCME) where the least significant bits in the packet can be discarded when there is an overload condition.

Recommendation G.722 is a wideband speech coding standard. Its principal applications are teleconferences and videoteleconferences [29]. The wider bandwidth (50 – 7000 Hz) is more natural sounding and less fatiguing than telephone bandwidth (200 – 3200 Hz). The wider bandwidth increases the intelligibility of the speech, especially for fricative sounds such as /f/ and /s/, which are difficult to distinguish for telephone bandwidth. The G.722 coder is a two-band sub-band coder with ADPCM coding in both bands. The ADPCM is similar in structure to that of the G.727 recommendation. The upper band uses an ADPCM coder with a 2-bit adaptive quantizer. The lower band uses an ADPCM coder with an embedded 4-5-6 bit adaptive quantizer. This makes the rates of 48, 56, and 64 kb/s all possible. A 24-tap quadrature mirror filter is used to efficiently split the signal.

45.4.2 ITU Linear Prediction Analysis-by-Synthesis Speech Coders

Table 45.2 describes three current analysis-by-synthesis speech coder recommendations of the ITU. All three are block coders based on extensions of the original multipulse LPC speech coder.

TABLE 45.2 ITU Linear Prediction Analysis-By-Synthesis Speech Coders

Standard body	ITU	ITU	ITU
Number	G.728	G.729	G.723.1
Year	1992 and 1994	1995	1995
Type of coder	LD-CELP	CS-ACELP	MPC-MLQ and ACELP
Bit rate	16 kb/s	8 kb/s	6.3 & 5.3 kb/s
Quality	Toll	Toll	≤ Toll
Complexity			
MIPS	30	≤ 22	≤ 16

Frame size	0.625 ms	10 ms	30 ms
Look ahead	0	5 ms	7.5 ms
Specification type			
Floating point	Algorithm exact	None	None
Fixed point	Bit exact	Bit exact C	Bit exact C

G.728 Low-Delay CELP (LD-CELP) [30] is a backward adaptive CELP coder whose quality is equivalent to that of 32 kb/s ADPCM. It was initially specified as a floating point CELP coder that required implementers to follow exactly the algorithm specified in the recommendation. A set of test vectors for verifying correct implementation was created. Subsequently, a bit exact fixed point specification was requested and completed in 1994. The performance of G.728 has been extensively tested by SG12. It gives robust performance for signals with background noise or music. It is very robust to random bit errors, more so than previous ITU standards G.711, G.726, G.727, and the newer standards described below. In addition to passing low bit rate modem signals as high as 2400 bps, it passes all network signaling tones.

In response to a request from CCIR Task Group 8/1 for a speech coder for wireless networks as envisioned in the Future Public Land Mobile Telecommunication Service (FPLMTS), the ITU initiated a work program for a toll quality 8 kb/s speech coder which resulted in G.729. It is a forward adaptive CELP coder with a 10-ms frame size that uses algebraic CELP (ACELP) excitation.

The work program for G.723.1 was initiated in 1993 by the ITU as part of a group of standards to specify a low bit rate videophone for use on the public switched toll networks (PSTN) carried over a high speed modem. Other standards in this group include the video coder, modem, and data multiplexing scheme. A dual rate coder was selected. The two rates differ primarily by their excitation scheme. The higher rate used Multipulse LPC with Maximum Likelihood Quantization (MPC-MLQ) while the lower rate used ACELP. G.723.1 and G.729 are the first ITU coders to be specified by a bit exact fixed point ANSI C code simulation of the encoder and decoder.

45.4.3 Digital Cellular Speech Coding Standards

Table 45.3 describes the first and second generation of speech coders to be standardized for digital cellular telephony. The first generation coders provided adequate quality. Two of the second generation coders are so-called half-rate coders that have been introduced in order to double the capacity of the rapidly growing digital cellular industry. Another generation of coders will soon follow them in order to bring the voice quality of digital cellular service up to that of current wireline network telephony.

TABLE 45.3 Digital Cellular Telephony Speech Coders

Standard body	CEPT	ETSI	TIA	TIA	RCR	RCR
Standard name	GSM	GSM 1/2 Rate	IS-54	IS-96	PDC	PDC 1/2 Rate
Type of coder	RPE-LTP	VSELP	VSELP	CELP	VSELP	PSI-CELP

The RPE-LTP coder [33] was standardized by the Group Special Mobile (GSM) of CEPT in 1987 for pan-European digital cellular telephony. RPE-LTP stands for Regular Pulse Excitation with Long-Term Predictor. The GSM full-rate channel supports 22.8 kb/s. The additional 9.8 kb/s is used for

channel coding to protect the coder from bit errors in the radio channel. Voice activity detection and discontinuous transmission are included as part of this standard. In addition to digital cellular telephony, this coder has since been used for other applications, such as messaging, because of its low complexity.

The GSM half-rate coder was standardized by ETSI (an off-shoot of CEPT) in order to double the capacity of the GSM cellular system. The coder is a 5.6 kb/s VSELP coder [23]. A greater percentage of the channel bits are used for error protection because the half-rate channel has less frequency diversity than the full-rate system. The overall performance was measured to be similar to that of RPE-LTP, except for certain signals with background noise.

Vector Sum Excitation Liner Prediction Coding (VSELP) was standardized by the Telecommunications Industry Association (TIA) for time division multiple access (TDMA) digital cellular telephony in North America as a part of Interim Standard 54 (IS-54). It was selected on the basis of subjective listening tests in 1989. The quality of this coder and RPE-LTP are somewhat different in the character of their distortion, but they usually receive about the same MOS in subjective listening tests. IS-54 does not have a bit exact specification. Implementations need only conform to the bit stream specification. The TIA does have a qualification procedure, IS-85, to verify whether the performance of an implementation is good enough to be used for digital cellular [34]. In addition, Motorola provided a floating point C program for their version of the coder, which implementers may use as a guideline.

The IS-96 coder [35] was standardized by the TIA for code division multiple access (CDMA) digital cellular telephony in North America. It is a part of IS-96 and is used in the system specified by IS-95. CDMA system capacity is its most attractive feature. When there is no speech, the rate of the channels is reduced. IS-96 is a variable rate CELP coder which uses digital speech interpolation to achieve this rate reduction. It runs at 8.5 kb/s during most of a talk spurt. When there is no speech on the channel, it drops down to just 0.8 kb/s. At this rate, it is just supplying statistics about the background noise. These two rates are the ones most often used during operation of IS96, although the coder does transition through the two intermediate rates of 2 and 4 kb/s. The validation procedure for this coder is similar to that of IS-85.

The Personal Digital Cellular (PDC) full-rate speech coder was standardized by the Research and Development Center for Radio Systems (RCR) for TDMA digital cellular telephone service in Japan as RCR STD-27B. The coder is very similar to IS-54 VSELP. The principal difference is that instead of two vector sum excitation codebooks, there is only one.

The PDC half-rate coder [37] was standardized by RCR to double the capacity of the Japanese TDMA PDC system. Pitch synchronous innovation CELP (PSI-CELP) uses fixed codebooks that are modified as a function of the pitch in order to improve the speech quality for such a low rate coder. If the pitch period is less than the frame size, then all vectors in the fixed codebook for that frame are made periodic. It has a background noise pre-processor as part of the standard. When it senses that the background noise exceeds a certain threshold, the pre-processor attempts to improve the quality of the speech. To date, this coder appears to be the most complex yet standardized.

45.4.4 Secure Voice Standards

Table 45.4 presents information about three secure voice standards. Two are existing standards, while the third describes a standard that the U.S. government hopes to promulgate in 1996.

FS1015 [12] is a U.S. Federal Standard 2.4 kb/s LPC vocoder that was created over a long period of time beginning in the late 1970s. It was standardized by the U.S. Department of Defense (DoD) and later the North Atlantic Treaty Organization (NATO) before becoming a U.S. Federal Standard in 1984. It was always intended for secure voice terminals. It does not produce natural sounding speech, but over the years its intelligibility has been greatly improved through a series of changes to both its encoder and decoder. Remarkably, these changes never required changes to the bit stream. Presently the intelligibility of FS1015 for clean input speech having telephone bandwidth is almost equivalent

TABLE 45.4 Secure Telephony Speech Coding Standards

Standard body	U.S. Dept. of Defense	U.S. Dept. of Defense	U.S. Dept. of Defense
Standard number	FS-1015	FS-1016	?
Type of coder	LPC vocoder	CELP	Model-based
Year	1984	1991	1996
Bit rate	2.4 kb/s	4.8 kb/s	2.4 kb/s
Quality	high DRT	< IS-54	= FS-1016
Complexity			
MIPS	20	19	41 ^a
RAM	2K	1.5K	Unknown
Delay			
Frame size	22.5 ms	30 ms	22.5
Look ahead	90 ms	7.5 ms	23
Specification type	Bit stream	Bit stream	Bit stream

^a Actual goal is 40 MIPS floating point or 80 MIPS fixed point.

to that of the source material as measured by the diagnostic rhyme test (DRT). Most recently an 800 bps vector quantized version of FS1015 has been standardized by NATO [39].

FS1016 [40] is the result of a project undertaken by DoD to increase the naturalness of the secure telephone unit III (STU-3) by the introduction of 4.8 kb/s modem technology. DoD surveyed available 4.8 kb/s speech coder technology in 1988 and 1989. It selected a CELP-based coder having a so-called ternary codebook, meaning that all excitation amplitudes are +1, -1, or 0 before scaling by the gain for that sub-frame. This allows an easier codebook search. FS1016 definitely preserves far more of the naturalness of the original speech than FS1015, but the speech still contains many artifacts and the quality is substantially below that of the cellular coders such as GSM of IS54. Both FS-1015 and FS-1016 have bit stream specifications, but there are C code simulations of them available from the government.

The next coder to be standardized by DoD is a new 2.4 kb/s coder to replace both FS1015 and FS1016. A 3-year project was initiated in 1993 which should culminate in a new standard in 1997. Subjective testing was done in 1993 and 1994 on software versions of potential coders and a realtime hardware evaluation took place in 1995 and 1996 to select a best candidate. The Mixed Excitation Linear Prediction (MELP) coder was selected [41]–[43]. The need for this coder is due to the lack of a sufficient number of satellite channels at 4.8 kb/s. The quality target for this coder is to match or exceed the quality and intelligibility of FS1016 for most scenarios. Many of the scenarios include severe background noise and noisy channel conditions. At 2.4 kb/s, there is not enough bit rate available for explicit channel coding, so the speech coder itself must be designed to be robust for the channel conditions. The noisy background conditions have proven to be difficult for vocoders making voiced/unvoiced classification decisions, whether the decisions are made for all bands or for individual bands.

45.4.5 Performance

Figure 45.8 is included to give an impression of the relative performance for clean speech of most of the standard coders that were included above. There has never been a single subjective test which included all of the above coders. Figure 45.8 is based on the relative performances of these coders across a number of tests that have been reported. In the case of coders that are not yet standards, their performance is projected and shown as a circle. The vertical axis of Fig. 45.8 gives the approximate single encoding quality for clean input speech. The horizontal axis is a logarithmic scale of bit rate. Figure 45.8 only includes telephone bandwidth speech coders. The 7-kHz speech coders have been omitted. Figure 45.9 compares the complexity as measured in MIPS and RAM for a fixed point DSP

Quality vs Bit Rate for Standard Coders

FIGURE 45.8: Approximate speech quality of speech coding standards.

Complexity of Standard Coders

FIGURE 45.9: Approximate complexity of speech coding standards.

implementation for most of the same standard coders. The horizontal axis is in RAM and the vertical axis is in MIPS.

46.1 Introduction

Text-to-speech synthesis has had a long history, one that can be traced back at least to Dudley's "Voder", developed at Bell Laboratories and demonstrated at the 1939 World's Fair [1]. Practical systems for automatically generating speech parameters from a linguistic representation (such as a phoneme string) were not available until the 1960s, and systems for converting from ordinary text into speech were first completed in the 1970s, with MITalk being the best-known such system [2]. Many projects in text-to-speech conversion have been initiated in the intervening years, and papers on many of these systems have been published.¹

It is tempting to think of the problem of converting written text into speech as "speech recognition in reverse": current speech recognition systems are generally deemed successful if they can convert speech input into the sequence of words that was uttered by the speaker, so one might imagine that a text-to-speech (TTS) synthesizer would start with the words in the text, convert each word one-by-one into speech (being careful to pronounce each word correctly), and concatenate the result together. However, when one considers what literate native speakers of a language must do when they read a text aloud, it quickly becomes clear that things are much more complicated than this simplistic view suggests. Pronouncing words correctly is only part of the problem faced by human readers: in order to sound natural and to sound as if they understand what they are reading, they must also appropriately emphasize (accent) some words, and deemphasize others; they must "chunk" the sentence into meaningful (intonational) phrases; they must pick an appropriate F0 (fundamental frequency) contour; they must control certain aspects of their voice quality; they must know that a word should be pronounced longer if it appears in some positions in the sentence than if it appears in others because *segmental durations* are affected by various factors, including phrasal position.

¹For example, [3] gives an overview of recent Dutch efforts in this area. Audio examples of several current projects on TTS can be found at the WWW URL <http://www.cs.bham.ac.uk/~jpi/synth/museum.html>.

What makes reading such a difficult task is that *all* writing systems systematically fail to specify many kinds of information that are important in speech. While the written form of a sentence (usually) completely specifies the words that are present, it will only partly specify the intonational phrases (typically with some form of punctuation), will usually not indicate which words to accent or deaccent, and hardly ever give information on segmental duration, voice quality, or intonation. (One might think that a question mark “?” indicates that a sentence should be pronounced with a rising intonation: generally, though, a question mark merely indicates that a sentence is a question, leaving it up to the reader to judge whether this question should be rendered with a rising intonation.) The orthographies of some languages — e.g., Chinese, Japanese, and Thai — fail to give information on where word boundaries are, so that even this needs to be figured out by the reader.² Humans are able to perform these tasks because, in addition to being knowledgeable about the grammar of their language, they also (usually) understand the content of the text that they are reading, and can thus appropriately manipulate various extragrammatical “affective” factors, such as appropriate use of intonation and voice quality.

The task of a TTS system is thus a complex one that involves mimicking what human readers do. But a machine is hobbled by the fact that it generally “knows” the grammatical facts of the language only imperfectly, and generally can be said to “understand” nothing of what it is reading. TTS algorithms thus have to do the best they can making use, where possible, of purely grammatical information to decide on such things as accentuation, phrasing, and intonation — and coming up with a reasonable “middle ground” analysis for aspects of the output that are more dependent on actual understanding.

It is natural to divide the TTS problem into two broad subproblems. The first of these is the conversion of text — an imperfect representation of language, as we have seen — into some form of linguistic representation that includes information on the phonemes (sounds) to be produced, their duration, the locations of any pauses, and the F0 contour to be used. The second — the actual synthesis of speech — takes this information and converts it into a speech waveform. Each of these main tasks naturally breaks down into further subtasks, some of which have been alluded to. The first part, text and linguistic analysis, may be broken down as follows:

- *Text preprocessing*: including end-of-sentence detection, “text normalization” (expansion of numerals and abbreviations), and limited grammatical analysis, such as grammatical part-of-speech assignment.
- *Accent assignment*: the assignment of levels of prominence to various words in the sentence.
- *Word pronunciation*: including the pronunciation of names and the disambiguation of homographs.³
- *Intonational phrasing*: the breaking of (usually long) stretches of text into one or more intonational units.
- *Segmental durations*: the determination, on the basis of linguistic information computed thus far, of appropriate durations for phonemes in the input.
- *F0 contour computation*.

²Even in English, single *orthographic* words, e.g., *AT&T*, can actually represent multiple words — *A T and T*.

³A *homograph* is a single written word that represents two or more different lexical entries, often having different pronunciations: an example would be *bass*, which could be the word for a musical range — with pronunciation /beɪs/ — or a fish — with pronunciation /baɪs/. We transcribe pronunciations using the International Phonetic Association’s (IPA) symbol set. Symbols used in this chapter are defined in Table 46.1.

Speech synthesis breaks down into two parts:

- The selection and concatenation of appropriate concatenative units given the phoneme string.
- The synthesis of a speech waveform given the units, plus a model of the glottal source.

46.2 Text Analysis and Linguistic Analysis

46.2.1 Text Preprocessing

The input to TTS systems is text encoded using an electronic coding scheme appropriate for the language, such as ASCII, JIS (Japanese), or Big-5 (Chinese). One of the first tasks facing a TTS system is that of dividing the input into reasonable chunks, the most obvious chunk being the sentence. In some writing systems there is a designated symbol used for marking the end of a declarative sentence and for nothing else — in Chinese, for example, a small circle is used — and in such languages end-of-sentence detection is generally not a problem. For English and other languages we are not so fortunate because a period, in addition to its use as a sentence delimiter, is also used, for example, to mark abbreviations: if one sees the period in *Mr.*, one would not (normally) want to analyze this as an end-of-sentence marker. Thus, before one concludes that a period does in fact mark the end of a sentence, one needs to eliminate some other possible analyses. In a typical TTS system, text analysis would include an abbreviation-expansion module; this module is invoked to check for common abbreviations which might allow one to eliminate one or more possible periods from further consideration. For example, if a preprocessor for English encounters the string *Mr.* in an appropriate context (e.g., followed by a capitalized word), it will expand it as *mister* and remove the period.

Of course, abbreviation expansion itself is not trivial, since many abbreviations are ambiguous. For example, is *St.* to be expanded as *Street* or *Saint*? Is *Dr.*, *Doctor* or *Drive*? Such cases can be disambiguated via a series of heuristics. For *St.*, for example, the system might first check to see if the abbreviation is followed by a capitalized word (i.e., a potential name), in which case it would be expanded as *Saint*; otherwise, if it is preceded by a capitalized word, a number, or an alphanumeric (*49th*), it would be expanded as *Street*. Another problem that must be dealt with is the conversion of numbers into words: *232* should usually be expanded as *two hundred thirty two*, whereas if the same sequence occurs as part of *232-3142* — a likely telephone number — it would normally be read *two three two*.

In languages like English, tokenization into words can to a large extent be done on the basis of white space. In contrast, in many Asian languages, including Chinese, the situation is not so simple because spaces are never used to delimit words. For the purposes of text analysis it is therefore generally necessary to “reconstruct” word boundary information. A minimal requirement for word segmentation is an on-line dictionary that enumerates the wordforms of the language. This is not enough on its own, however, since there are many words that will not be found in the dictionary; among these are personal names, foreign names in transliteration, and morphological derivatives of words that do not occur in the dictionary. It is therefore necessary to build models of these non-dictionary words; see [4] for further discussion.

In addition to lexical analysis, the text-analysis portion of a TTS system will typically perform syntactic analysis of various kinds. One commonly performed analysis is grammatical part-of-speech assignment, as information on the part of speech of words can be useful for accentuation and phrasing, among other things. Thus, in a sentence like *they can can cans*, it is useful for accentuation purposes to know that the first *can* is a *function word* — an auxiliary verb, whereas the second and third are *content words* — respectively a verb and a noun. There are a number of part-of-speech algorithms available, perhaps the best known being the stochastic method of [5], which computes the

most likely analysis of a sequence of words, maximizing the product of the *lexical probabilities* of the parts-of-speech in the sentence (i.e., the possible parts of speech of each word and their probabilities), and the *n-gram probabilities* (probabilities of n-grams of parts of speech), which provide a model of the context.

46.2.2 Accentuation

In languages like English, various words in a sentence are associated with *accents*, which are usually manifested as upward or downward movements of fundamental frequency. Usually, not every word in the sentence bears an accent, however, and the decision on which words should be accented and which should be unaccented is one of the problems that must be addressed as part of text analysis. It is common in prosodic analysis to distinguish three levels of *prominence*. Two are accented and unaccented, as just described, and the third is *cliticized*. Cliticized words are unaccented but in addition have lost their word stress, so that they tend to be durationally short: in effect, they behave like unstressed affixes, even though they are written as separate words.

A good first step in assigning accents is to make the accentual determination on the basis of broad lexical categories or parts of speech. Content words — nouns, verbs, adjectives, and perhaps adverbs, tend in general to be accented; function words, including auxiliary verbs and prepositions tend to be deaccented; short function words tend to be cliticized. But accenting has a wider function than merely communicating lexical category distinctions between words. In English, one important set of constructions where accenting is more complicated than what might be inferred from the above discussion are complex noun phrases — basically, a noun preceded by one or more adjectival or nominal modifiers. In a “discourse-neutral” context, some constructions are accented on the final word (*Madison Avenue*), some on the penultimate (*Wall Street, kitchen towel rack*), and some on an even earlier word (*sump pump factory*). The assignment of accent to complex noun phrases depends on complex lexical and semantic factors; see [6].

Accenting is not only sensitive to syntactic structure and semantics, but also to properties of the discourse. One straightforward effect is *contrast*, as in the example *I didn't ask for **cherry** pie, I asked for **apple** pie*. For most speakers, the “discourse neutral” accent would be on *pie*, but in this example there is a clear intention to contrast the ingredients in the pies, and *pie* is thus deaccented to effect the contrast between *cherry* and *apple*. See [7] for a discussion of how these kind of effects are handled in a TTS system for English. Note, while humanlike accenting capabilities are possible in many cases, there are still some intractable problems. For example, just as one would often deaccent a word that had been previously mentioned, so would one often deaccent a word if a supercategory of that word had been mentioned: *My son wants a Labrador, but I'm **allergic** to dogs*. Handling such cases in any general way is beyond the capabilities of current TTS systems.

46.2.3 Word Pronunciation

The next stage of analysis involves computing pronunciations for the words in the input, given the orthographic representation of those words. The simplest approach is to have a set of “letter-to-sound” rules that simply map sequences of graphemes into sequences of phonemes, along with possible diacritic information, such as stress placement. This approach is naturally best suited to languages where there is a relatively simple relation between orthography and phonology: languages such as Spanish or Finnish fall into this category. However, languages like English manifestly do not, so it has generally been recognized that a highly accurate word pronunciation module must contain

a pronouncing dictionary that, at the very least, records words whose pronunciation could not be predicted on the basis of general rules. However, having a dictionary that is merely a list of words presents us with familiar problems of coverage: many text words occur that are not to be found in the dictionary, including morphological derivatives from known words, or previously unseen personal names.

For morphological derivatives, standard techniques for morphological analysis [2, 8] can be applied to achieve a morphological decomposition for a word. The pronunciation of the whole can then, in general, be computed from the (presumably known) pronunciation of the morphological parts, applying appropriate phonological rules of the language. For novel personal names, additional mechanisms may be necessary since novel names cannot always be related *morphologically* to previously seen ones. One such additional method involves computing the pronunciation of a new name by analogy with the pronunciation of a similar name [9, 10]. For example, imagine that we have the name *Califano* in our dictionary and that we know its pronunciation: then we could compute the pronunciation of a hypothetical name *Balifano* by noting that both names share the “suffix” *alifano*. The pronunciation of *Balifano* can then be computed by removing the phoneme /k/, corresponding to the letter *C* in *Califano*, and replacing it with the phoneme /b/.

There are some word forms that are inherently ambiguous in pronunciation, and for which a word pronunciation module as just described can only return a set of possible pronunciations, from which one must then be chosen. A straightforward example is the word *Chevy*, which is most commonly pronounced /ʃ'ɛvi/, but is /tʃ'ɛvi/ in the name *Chevy Chase*, so in this case one could succeed by simply storing the bigram *Chevy Chase*. But n-gram models do not solve all cases of homograph

TABLE 46.1 IPA Symbols Used in this Chapter

IPA Symbol	Phonetic value
æ	a as in <i>cat</i>
b	b as in <i>bass</i>
e ^j	a as in <i>bake</i>
ɛ	e as in <i>bet</i>
ə	a as in <i>data</i>
i	i as in <i>linguini</i>
ɪ	i as in <i>in</i>
s	s as in <i>soggy</i>
ʃ	sh as in <i>ship</i>
t	t as in <i>test</i>
tʃ	ch as in <i>chase</i>
ð	th as in <i>the</i>
r	r as in <i>are</i>
v	v as in <i>voodoo</i>
w	w as in <i>we</i>
ˈ	primary stress

disambiguation. So, the word *bass*, is most likely to be pronounced /bæs/ in a “fishy” context like *he was fishing for bass*, but /be^js/ in a musical context like *he plays bass*. What defines the context as being musical or “fishy” is not characterizable in terms of n-grams, but rather relates to the occurrence of certain words (e.g., *fish, lake, boat* vs. *play, sing, orchestra*) in a wider context. A method proposed by

Yarowsky [11, 12] allows for both local (n-gram) context and wide context to be used in homograph disambiguation, and excellent results have been achieved using this approach.⁴

46.2.4 Intonational Phrasing

In reading a long sentence, speakers will typically break the sentence up into several phrases, each of which can be said to “stand alone” as an intonational unit. If punctuation is used liberally so that there are relatively few words between the commas, semicolons, or periods, then a reasonable guess at an appropriate phrasing would be simply to break the sentence at the punctuation marks (though this is not always appropriate [13]). The real problem comes when long stretches occur without punctuation; in such cases, human readers would normally break the string of words into phrases, and the problem then arises of where to place these breaks.

The simplest approach is to have a list of words, typically function words, that are likely indicators of good places to break [1]. One has to use some caution, however, because while a particular function word such as *and* may coincide with a plausible phrase break in some cases (*He got out of the car and walked towards the house*), in other examples it might coincide with a particularly *poor* place to break as in *I was forced to sit through a dog and pony show that lasted most of Wednesday afternoon*. Other approaches to intonational phrasing have been proposed in the literature, including methods that depend on syntactic parsers of various degrees of sophistication [13, 14]. An alternative approach, described in [15], uses a decision tree model [16, 17] that is trained on a corpus of text annotated with prosodic phrase-boundary information.

46.2.5 Segmental Durations

Having computed which phonemes are to be produced by the synthesizer, it is necessary to decide how long to make each one. In this section we briefly describe the methods used for computing segmental durations: the reader is referred to [18] for an extended discussion of this topic.

What duration to assign to a phonemic segment depends on many factors, including:

- The identity of the segment in question. For example, in many dialects of English, the vowel /æ/ has a longer *intrinsic duration* than the vowel /ɪ/.
- The stress of the syllable of which the segment is a member. For example, vowels in stressed syllables tend to be longer than vowels in unstressed syllables.
- Whether the syllable of which the segment is a member bears an accent. Accented syllables tend to be longer than otherwise identical unaccented syllables.
- The quality of the surrounding segments. For example, a vowel preceding a voiced consonant in the same syllable tends to be longer than the same vowel preceding a voiceless consonant.
- The position of the segment in the phrase: elements close to the ends of phrases tend to be longer than elements more internal to the phrase.

Various approaches have been taken to modeling segmental durations in TTS systems. One method involves *duration rules*, which are rules of the form “if the segment is *X* and it is in phrase-final position, then lengthen *X* by *n* milliseconds” [19, 20]. In rule-based systems of this kind, it is not unusual for the duration of a given segment to be rewritten several times as the conditions for the application of

⁴Clearly the above-described method for homograph disambiguation can also be applied to other formally similar problems in TTS, such as whether *St.* to be expanded as *Saint* or *Street*, or *747* is to be read as a number *seven hundred and forty seven* or the name of an aircraft *seven forty seven*.

the various rules are considered. The rule-based approach can be formalized explicitly in terms of the second approach — *duration models* — which are mathematical expressions that prescribe how the various conditioning factors are to be used in computing the duration of a segment [19]; the successive application of the rules can, in effect, be “compiled” into a single mathematical expression that implements the combined effect of the rules. As argued in [18], all extant duration models can be viewed as instances of a more general *sum-of-products* model, where the duration of a segment is predicted by a formula of the general form:

$$DUR(\mathbf{f}) = \sum_{i \in T} \prod_{j \in I_i} S_{i,j}(f_j) \quad (46.1)$$

Here the duration assigned to a feature vector — $DUR(\mathbf{f})$ — is computed by scaling each factor f_j in the i th product term by a factor scale $S_{i,j}$; computing the product of all scaled factors within each product term; and then summing over all i product terms. Rather than deciding *a priori* on a particular sums-of-products model (or set of such models) within the space of all possible models, one approach taken to segmental duration is to use exploratory data analysis to arrive at models whose predictions show a good fit to durations from a corpus of labeled speech [18].

More specifically, we start with a text corpus that (ideally) has a good coverage both of various phonemes and of the factors (and their combinations) that are deemed likely to be relevant for duration. A native speaker of the language reads this text and the speech is segmented and labeled. Using the text-analysis modules of TTS, with some possible hand correction, we automatically compute the sequence of phonemes, and the feature vectors (including features on stress, accent, phrasal position, etc.) associated with each phoneme. Given the feature vectors, various sums-of-products models are compared and their predictions of the values of the observed segmental durations are evaluated. In general, different specific duration models may be better suited to different sets of conditions than others: for example, in the English duration system, intervocalic consonants are associated with a different sums-of-products model than consonants that occur in clusters. In the actual implementation of segmental duration predictions, a decision tree is used to determine, on the basis of contextual factors appropriate to the segment at hand, what particular sums-of-products model to use; this model is then used to compute the duration of the segment.

Designing a corpus with good coverage of relevant factors is a non-trivial task in itself: the basic problem is to provide a set that has maximal coverage with the minimal amount of text to be read by a speaker, and analyzed. The method that we use involves starting with a large corpus of text in a language and automatically predicting the phonemic segments along with their features (again, using text analysis components for the language). A *greedy* algorithm is then applied to arrive at a minimal set of sentences that have good (ideally total) coverage of the desired feature vectors.

46.2.6 Intonation

Having computed linguistic information such as the sequence of segments to be produced, their duration, the prominence of the various words, and the locations of prosodic boundaries, the next thing that a TTS system needs to compute is an intonation contour. There are almost as many models of intonation implemented in TTS systems as there are TTS systems, and we do not have the space to review these different approaches here. Suffice it to say that most intonation models that have actually been incorporated into working TTS systems can be classified into one of three “schools”:

- The *Fujisaki* school [21, 22, inter alia]. An intonation contour for a phrase is computed from a phrase impulse and some number of accent impulses. These impulses are convolved with a smoothing function to produce phrase and accent curves, which are then summed to produce the final contour.

- The *Dutch* school [23]. Intonation contours are represented as sequences of connected line segments which are chosen so as to perceptually closely approximate real (smooth) intonation contours.
- The *autosegmental/metrical* school [24, 25, inter alia]. Intonation contours are represented abstractly as sequences of high and low targets.

The computation of an intonation contour from a phonological representation can be illustrated by considering the Bell Labs English TTS system, which currently uses a version of the Pierrehumbert autosegmental model [26, 27, 28]. As the first stage in the computation of an intonation contour, a tone-timing function sets up nominal times for each accent in the sentence. Separate routines are called for initial boundary tones, final boundary tones, pitch accents and phrase accents. Roughly, initial boundary tones are aligned with the silence that is placed at the beginning of each minor phrase, whereas final boundary tones are aligned with the final vowel of each minor phrase. Phrase accents are aligned after the final word accent of the minor phrase, if there is one; otherwise at the end of the first vowel of the first word, or else at the end of the first phoneme. Finally, accents on words are aligned with their associated syllables using a complex set of contextual factors. These nominal accent times are then converted into actual F_0 /time pairs, by another function. F_0 values are computed dependent on the prominence of the accent (either determined automatically, or else definable by the user), and various phrasal parameters from the intonation model, as well as the particular type of accent involved. Finally, an *F_0 contour* is produced by interpolating the computed pitch/time pairs, and smoothing via convolution with a rectangular window.

46.3 Speech Synthesis

Once the text has been transformed into phonemes, and their associated durations and a fundamental frequency contour have been computed, the system is ready to compute the speech parameters for synthesis.

There are two independent variables in the choice of parametric computation in a TTS system. One variable is the choice between a *rule-based* scheme for the computation of the parameters on the one hand, and a *concatenative scheme* involving concatenation of short segments of previously uttered speech on the other. The second variable is the actual parametric representation chosen: possible choices include articulatory parameters, formants, LPC (linear predictive coding), spectral parameters, or time domain parameters. In a concatenative scheme, any parametric representation that permits independent control of loudness, F_0 , voicing, timing, and possibly spectral manipulations is appropriate. Rule-based systems are more restrictive of the choice of parameters since such schemes rely both on our understanding of the relation between the parameters and the acoustic signals they represent, and on our ability to compute the dynamics of the parameters as they move from one sound to another. Thus far only articulatory parameters and formants have been used in rule-based systems. The best-known examples of a formant-based synthesizer are the Klatt synthesizer and its commercial offshoot DECtalk.

Rule-based systems are space-efficient because they eliminate the need to store speech segments. Rule-based approaches also make it easier, in principle, to implement new speaker characteristics for different voices, as well as different phone inventories for new dialects and languages. However, since the dynamics of the parameters are very difficult to model it requires a great deal more effort to produce a rule-based system than it does to produce a concatenative system of comparable quality. Given the right choice of units, a concatenative scheme is able to store the dynamics of the speech signal and thus produce high quality synthetic sound. The choice of the exact parameters depends on what the designer values in such a system. Waveform representations — such as PSOLA [29] — have a high sound quality, but they are limiting in terms of the ability to alter the sound, and thus

FIGURE 46.1: Source-filter model for speech synthesis.

far, no one has been able to change the spectral parameters in a time domain system. Articulatory parameters or formants, on the other hand, can be successfully manipulated. However, the speech quality produced by using these parameters is somewhat degraded because there are no reliable methods to extract these parameters and even in a plain coding application (analysis and resynthesis without manipulations) these methods produce degradation of the speech signal.

Other systems use a concatenative approach. In this approach, parametrized short speech segments of natural speech are connected to form a representation of the synthetic speech. The majority of the natural speech segments are merely transitions between pairs of phonemes. However, due to the large contextual variation of some phonemes, some segments consisting of three or more phoneme elements are often necessary; such elements consist of the transition from the first phoneme to the second, and a transition from the penultimate phoneme to the last, but the intermediate phonemes are stored completely. For the Bell Labs English system, there are approximately 2900 different speech elements — also called *dyads* — in the acoustic inventory, and these elements are sufficient to make up all the legal phoneme combinations for English.

The concatenative approach to speech synthesis requires that speech samples be stored in some parametric representation that will be suitable for connecting the segments and changing the signal's characteristics of loudness, F0, and spectrum. One method for changing the characteristics of natural speech is to analyze the speech in terms of a source/filter model, as diagrammed in Fig. 46.1.

This model of speech synthesis has a variety of independent input controls. Starting at the left side of the figure, we show two possible source generators: a noise generator and a simple pulse generator. The noise generator has no controlling input whereas the pulse generator is controlled by the F0 parameter; the F0 parameter specifies the distance between any two pulses thus controlling the F0 of the periodic source. These inputs are selected by a switch which is controlled by a voicing flag. It is also possible to have a mixer to control the relative contribution of the noise and pulse source, and to insert a glottal pulse with additional controls for the shape of the glottal source in place of the simple pulse generator. To the right of the switch, we have a multiplier that multiplies the source by an amplitude parameter. This serves as the loudness control for the system. The signal from the multiplier is fed into a filter controlled by the filter coefficients which are varied slowly to shape the speech spectrum.

The source/filter model can be used to replicate naturally spoken speech when the parameters are obtained by analysis of natural speech. Speech can be parametrized by an amplitude control, voiced/voiceless flag, F0, and filter coefficients at a small interval (on the order of 5 msec. to 15 msec.) The loudness control is determined from the power of the speech at the time frame of the analysis. F0 extraction algorithms determine the voicing of the speech as well as the fundamental frequency. The filter parameters can be determined by various analysis techniques. The parameters obtained from the analysis can be used to drive the source filter model to reproduce the analyzed speech. However, these parameters can also be varied independently to change the speech. The ability to alter the analysis parameters is crucial to a concatenative approach, where the spectral parameters have to be smoothed and interpolated whenever two elements from different utterances are connected, or when

the duration of the speech has to be altered. Of course, the fundamental frequency of the original speech is completely discarded and replaced during synthesis by a rule-generated F0, as described earlier.

46.4 The Future of TTS

Using current methods such as those outlined in this chapter, it is possible to produce speech output that is of high intelligibility and reasonable naturalness, given unrestricted input text. (See [30] for a discussion of methods for evaluating TTS systems.) However, there is still much work to be done in all areas of the problem, including: improving voice quality, and allowing for greater user control over aspects of voice quality; producing better models of intonation to allow for more natural-sounding F0 contours; and improving linguistic analysis so that more accurate information on contextually appropriate word pronunciation, accenting, and phrasing can be computed automatically. This latter area — linguistic analysis — is particularly crucial: most high-quality TTS systems allow for user control of the output speech by means of various “escape sequences”, which can be inserted into the input text. By use of such escape sequences, it is possible to produce highly appropriate and natural-sounding output. What is still lacking in many cases are natural-language analysis techniques that can mimic what a human annotator is able to do.

47.1 Introduction

Over the past several decades a need has arisen to enable humans to communicate with machines in order to control their actions or to obtain information. Initial attempts at providing human-machine communications led to the development of the keyboard, the mouse, the trackball, the touch screen, and the joy stick. However, none of these communication devices provides the richness or the ease of use of speech which has been the most natural form of communication between humans for tens of centuries. Hence, a need has arisen to provide a voice interface between humans and machines. This need has been met, to a limited extent, by speech processing systems which enable a machine to speak (speech synthesis systems) and which enable a machine to understand (speech recognition systems) human speech. We concentrate on speech recognition systems in this section.

Speech recognition by machine refers to the capability of a machine to convert human speech to a textual form, providing a transcription or interpretation of everything the human speaks while the machine is listening. This capability is required for tasks in which the human is controlling the actions of the machine using only limited speaking capability, e.g., while speaking simple commands or sequences of words from a limited vocabulary (e.g., digit sequences for a telephone number). In

the more general case, usually referred to as speech understanding, the machine need only recognize a limited subset of the user input speech, namely the speech that specifies enough about the action requested so that the machine can either respond appropriately, or initiate some action in response to what was understood.

Speech recognition systems have been deployed in applications ranging from control of desktop computers, to telecommunication services, to business services, and have achieved varying degrees of success and commercialization.

In this section we discuss a range of issues involved in the design and implementation of speech recognition systems.

47.2 Characterization of Speech Recognition Systems

A number of issues define the technology of speech recognition systems. These include:

1. The manner in which a user speaks to the machine. There are generally three modes of speaking, including:
 - isolated word (or phrase) mode in which the user speaks individual words (or phrases) drawn from a specified vocabulary;
 - connected word mode in which the user speaks fluent speech consisting entirely of words from a specified vocabulary (e.g., telephone numbers);
 - continuous speech mode in which the user can speak fluently from a large (often unlimited) vocabulary.
2. The size of the recognition vocabulary, including:
 - small vocabulary systems which provide recognition capability for up to 100 words;
 - medium vocabulary systems which provide recognition capability for from 100 to 1000 words;
 - large vocabulary systems which provide recognition capability for over 1000 words.
3. The knowledge of the user's speech patterns, including:
 - speaker dependent systems which have been custom tailored to each individual talker;
 - speaker independent systems which work on broad populations of talkers, most of which the system has never encountered or adapted to;
 - speaker adaptive systems which customize their knowledge to each individual user over time while the system is in use.
4. The amount of acoustic and lexical knowledge used in the system, including:
 - simple acoustic systems which have no linguistic knowledge;
 - systems which integrate acoustic and linguistic knowledge, where the linguistic knowledge is generally represented via syntactical and semantic constraints on the output of the recognition system.
5. The degree of dialogue between the human and the machine, including:
 - one-way (passive) communication in which each user spoken input is acted upon;
 - system-driven dialog systems in which the system is the sole initiator of a dialog, requesting information from the user via verbal input;

- natural dialogue systems in which the machine conducts a conversation with the speaker, solicits inputs, acts in response to user inputs, or even tries to clarify ambiguity in the conversation.

47.3 Sources of Variability of Speech

Speech recognition by machine is inherently difficult because of the variability in the signal. Sources of this variability include:

1. Within-speaker variability in maintaining consistent pronunciation and use of words and phrases.
2. Across-speaker variability due to physiological differences (e.g., different vocal tract lengths) regional accents, foreign languages, etc.
3. Transducer variability while speaking over different microphones/telephone handsets.
4. Variability introduced by the transmission system (the media through which speech is transmitted, telecommunication networks, cellular phones, etc.).
5. Variability in the speaking environment, including extraneous conversations and acoustic background events (e.g., noise, door slams).

47.4 Approaches to ASR by Machine

47.4.1 The Acoustic-Phonetic Approach [1]

The earliest approaches to speech recognition were based on finding speech sounds and providing appropriate labels to these sounds. This is the basis of the acoustic-phonetic approach which postulates that there exist finite, distinctive phonetic units (phonemes) in spoken language, and that these units are broadly characterized by a set of acoustic properties that are manifest in the speech signal over time. Even though the acoustic properties of phonetic units are highly variable, both with speakers and with neighboring sounds (the so-called coarticulation), it is assumed in the “acoustic-phonetic approach” that the rules governing the variability are straightforward and can be readily learned (by a machine). The first step in the acoustic-phonetic approach is a segmentation and labeling phase in which the speech signal is segmented into stable acoustic regions, followed by attaching one or more phonetic labels to each segmented region, resulting in a phoneme lattice characterization of the speech (see Fig. 47.1). The second step attempts to determine a valid word (or string of words) from the phonetic label sequences produced in the first step. In the validation process, linguistic constraints of the task (i.e., the vocabulary, the syntax, and other semantic rules) are invoked in order to access the lexicon for word decoding based on the phoneme lattice. The acoustic-phonetic approach has not been widely used in most commercial applications.

47.4.2 “Pattern-Matching” Approach [2]

The “pattern-matching approach” involves two essential steps, namely, pattern training and pattern comparison. The essential feature of this approach is that it uses a well- formulated mathematical framework, and establishes consistent speech pattern representations for reliable pattern comparison from a set of labeled training samples via a formal training algorithm. A speech pattern representation can be in the form of a speech template or a statistical model, and can be applied to a sound (smaller than a word), a word, or a phrase. In the pattern-comparison stage of the approach, a direct comparison is made between the unknown speech (the speech to be recognized) with each possible

FIGURE 47.1: Segmentation and labeling for word sequence “seven-six”.

pattern learned in the training stage, in order to determine the identity of the unknown according to the goodness of match of the patterns. The pattern matching approach has become the predominant method of speech recognition in the last decade and we shall elaborate on it in subsequent sections.

47.4.3 Artificial Intelligence Approach [3, 4]

The “artificial intelligence approach” attempts to mechanize the recognition procedure according to the way a person applies intelligence in visualizing, analyzing, and characterizing speech based on a set of measured acoustic features. Among the techniques used within this class of methods are use of an expert system (e.g., a neural network) which integrates phonemic, lexical, syntactic, semantic, and even pragmatic knowledge for segmentation and labeling, and uses tools such as artificial neural networks for learning the relationships among phonetic events. The focus in this approach has been mostly in the representation of knowledge and integration of knowledge sources. This method has not been used widely in commercial systems.

47.5 Speech Recognition by Pattern Matching

Figure 47.2 is a block diagram that depicts the pattern matching framework. The speech signal is first analyzed and a feature representation is obtained for comparison with either stored reference templates or statistical models in the pattern matching block. A decision scheme determines the word or phonetic class of the unknown speech based on the matching scores with respect to the stored reference patterns.

There are two types of reference patterns that can be used with the model of Fig. 47.2. The first type, called a nonparametric reference pattern [5] (or often a template), is a pattern created from one or more spoken tokens (exemplars) of the sound associated with the pattern. The second type, called a statistical reference model, is created as a statistical characterization (via a fixed type of model) of the behavior of a collection of tokens of the sound associated with the pattern. The hidden Markov model [6] is an example of the statistical model.

FIGURE 47.2: Block diagram of pattern-recognition speech recognizer.

The model of Fig. 47.2 has been used (either explicitly or implicitly) for almost all commercial and industrial speech recognition systems for the following reasons:

1. It is invariant to different speech vocabularies, user sets, feature sets, pattern matching algorithms, and decision rules.
2. It is easy to implement in software (and hardware).
3. It works well in practice.

We now discuss the elements of the pattern recognition model and show how it has been used in isolated word, connected word, and continuous speech recognition systems.

47.5.1 Speech Analysis

The purpose of the speech analysis block is to transform the speech waveform into a parsimonious representation which characterizes the time varying properties of the speech. The transformation is normally done on successive and possibly overlapped short intervals 10 to 30 msec in duration (i.e., short-time analysis) due to the time-varying nature of speech. The representation [7] could be spectral parameters, such as the output from a filter bank, a discrete Fourier transform (DFT), or a linear predictive coding (LPC) analysis, or they could be temporal parameters, such as the locations of various zero or level crossing times in the speech signal.

Empirical knowledge gained over decades of psychoacoustic studies suggests that the power spectrum has the necessary acoustic information for high accuracy sound identity. Studies in psychoacoustics also suggest that our auditory perception of sound power and loudness involves compression, leading to the use of the logarithmic power spectrum and the cepstrum [8], which is the Fourier transform of the log-spectrum. The low order cepstral coefficients (up to 10 to 20) provide a parsimonious representation of the short-time speech segment which is usually sufficient for phonetic identification.

The cepstral parameters are often augmented by the so-called delta cepstrum [9] which characterizes dynamic aspects of the time-varying speech process.

47.5.2 Pattern Training

Pattern training is the method by which representative sound patterns (for the unit being trained) are converted into reference patterns for use by the pattern matching algorithm. There are several ways in which pattern training can be performed, including:

1. Casual training in which a single sound pattern is used directly to create either a template or a crude statistical model (due to the paucity of data).
2. Robust training in which several (typically 2 to 4) versions of the sound pattern (usually extracted from the speech of a single talker) are used to create a single merged template or statistical model.

3. Clustering training in which a large number of versions of the sound pattern (extracted from a wide range of talkers) is used to create one or more templates or a reliable statistical model of the sound pattern.

In order to better understand how and why statistical models are so broadly used in speech recognition, we now formally define an important class of statistical models, namely the hidden Markov model (HMM) [6].

The HMM

The HMM is a statistical characterization of both the dynamics (time varying nature) and statics (the spectral characterization of sounds) of speech during speaking of a sub-word unit, a word, or even a phrase. The basic premise of the HMM is that a Markov chain can be used to describe the probabilistic nature of the temporal sequence of sounds in speech, i.e., the phonemes in the speech, via a probabilistic state sequence. The states in the sequence are not observed with certainty because the correspondence between linguistic sounds and the speech waveform is probabilistic in nature; hence the concept of a hidden model. Instead, the states manifest themselves through the second component of the HMM which is a set of output distributions governing the production of the speech features in each state (the spectral characterization of the sounds). In other words, the output distributions (which are observed) represent the local statistical knowledge of the speech pattern within the state, and the Markov chain characterizes, through a set of state transition probabilities, how these sound processes evolve from one sound to another. Integrated together, the HMM is particularly well suited for modeling speech processes.

MH1G688F.11

FIGURE 47.3: Characterization of a word (or phrase, or subword) using a N(5) state, left-to-right, HMM, with continuous observation densities in each state of the model.

An example of an HMM of a speech pattern is shown in Fig. 47.3. The model has five states (corresponding to five distinct “sounds” or “phonemes” within the speech), and the state (corresponding to the sound being spoken) proceeds from left-to-right (as time progresses). Within each state (assumed to represent a stable acoustical distribution) the spectral features of the speech signal

are characterized by a mixture Gaussian density of spectral features (called the observation density), along with an energy distribution, and a state duration probability. The states represent the changing temporal nature of the speech signal; hence indirectly they represent the speech sounds within the pattern.

The training problem for HMMs consists of estimating the parameters of the statistical distributions within each state (e.g., means, variances, mixture gains, etc.), along with the state transition probabilities for the composite HMM. Well-established techniques (e.g., the Baum-Welch method [10] or the segmental K -means method [11]) have been defined for doing this pattern training efficiently.

47.5.3 Pattern Matching

Pattern matching refers to the process of assessing the similarity between two speech patterns, one of which represents the unknown speech and one of which represents the reference pattern (derived from the training process) of each element that can be recognized. When the reference pattern is a “typical” utterance template, pattern matching produces a gross similarity (or dissimilarity) score. When the reference pattern consists of a probabilistic model, such as an HMM, the process of pattern matching is equivalent to using the statistical knowledge contained in the probabilistic model to assess the likelihood of the speech (which led to the model) being realized as the unknown pattern.

FIGURE 47.4: Results of time aligning two versions of the word “seven”, showing linear alignment of the two utterances (top panel); optimal time-alignment path (middle panel); and nonlinearly aligned patterns (lower panel).

A major problem in comparing speech patterns is due to speaking rate variations. HMMs provide an implicit time normalization as part of the process for measuring likelihood. However, for template

approaches, explicit time normalization is required. Figure 47.4 demonstrates the effect of explicit time normalization between two patterns representing isolated word utterances. The top panel of the figure shows the log energy contour of the two patterns (for the spoken word “seven”) — one called the reference (known) pattern and the other called the test (or unknown input) pattern. It can be seen that the inherent duration of the two patterns, 30 and 35 frames (where each frame is a 15-ms segment of speech), is different and that linear alignment is grossly inadequate for internally aligning events within the two patterns (compare the locations of the vowel peaks in the two patterns). A basic principle of time alignment is to nonuniformly warp the time scale so as to achieve the best possible matching score between the two patterns (regardless of whether the two patterns are of the same word identity or not). This can be accomplished by a dynamic programming procedure, often called dynamic time warping (DTW) [12] when applied to speech template matching. The “optimal” nonlinear alignment result of dynamic time warping is shown at the bottom of Fig. 47.4 in contrast to the linear alignment of the patterns at the top. It is clear that the nonlinear alignment provides a more realistic measure of similarity between the patterns.

47.5.4 Decision Strategy

The decision strategy takes all the matching scores (from the unknown pattern to each of the stored reference patterns) into account, finds the “closest” match, and decides if the quality of the match is good enough to make a recognition decision. If not, the user is asked to provide another token of the speech (e.g., the word or phrase) for another recognition attempt. This is necessary because often the user may speak words that are incorrect in some sense (e.g., hesitation, incorrectly spoken word, etc.) or simply outside of the vocabulary of the recognition system.

47.5.5 Results of Isolated Word Recognition

Using the pattern recognition model of Fig. 47.2, and using either the non-parametric template approach or the statistical HMM method to derive reference patterns, a wide variety of tests of the recognizer have been performed on telephone speech with isolated word inputs in both speaker-dependent (SD) and speaker-independent (SI) modes. Vocabulary sizes have ranged from as few as 10 words (i.e., the digits zero–nine) to as many as 1109 words. Table 47.1 gives a summary of recognizer performance under the conditions described above.

TABLE 47.1 Performance of Isolated Word Recognizers

Vocabulary		Mode	Word error rate (%)
10	Digits	SI	0.1
		SD	0.0
39	Alphadigits	SI	7.0
		SD	4.5
129	Airline terms	SI	2.9
		SD	1.0
1109	Basic English	SD	4.3

47.6 Connected Word Recognition

The systems we have been describing in previous sections have all been isolated word recognition systems. In this section we consider extensions of the basic processing methods described in pre-

vious sections in order to handle recognition of sequences of words, the so-called connected word recognition system.

The basic approach to connected word recognition is shown in Fig. 47.5. Assume we are given a fluently spoken sequence of words, represented by the (unknown) test pattern T , and we are also given a set of V reference patterns, $\{R_1, R_2, \dots, R_V\}$ each representing one of the words in the vocabulary. The connected word recognition problem consists of finding the concatenated reference pattern, R^S , which best matches the test pattern, in the sense that the overall similarity between T and R^S is maximum over all sequence lengths and over all combinations of vocabulary words.

FIGURE 47.5: Illustration of the problem of matching a connected word string, spoken fluently, using whole word patterns concatenated together to provide the best match.

There are several problems associated with solving the connected word recognition problem, as formulated above. First of all, we do not know how many words were spoken; hence, we have to consider solutions with a range on the number of words in the utterance. Second, we do not know nor can we reliably find word boundaries within the test pattern. Hence, we cannot use word boundary information to segment the problem into simple “word-matching” recognition problems. Finally, since the combinatorics of trying to solve the problem exhaustively (by trying to match every possible string) are exponential in nature, we need to devise efficient algorithms to solve this problem. Such efficient algorithms have been developed and they solve the connected word recognition problem by iteratively building up time-aligned matches between sequences of reference patterns and the unknown test pattern, one frame at a time [13, 14, 15].

47.6.1 Performance of Connected Word Recognizers

Typical recognition performance for connected word recognizers is given in Table 47.2 for a range of vocabularies, and for a range of associated tasks. In the next section we will see how we exploit linguistic constraints of the task to improve recognition accuracy for word strings beyond the level one would expect on the basis of word error rates of the system.

TABLE 47.2 Performance of Connected Word Recognizers

Vocabulary	Mode	Word error rate (%)	Task	String error rate (%)
10 Digits	SD	0.1	Variable length digit strings (1–7 digits)	0.4
	SI	0.2		0.8
26 Letters of the alphabet	SD	10.0	Name retrieval from directory of 1700 names	4.0
	SI	10.0		10.0
129 Airline terms	SD	0.1	Sentences in a grammar	1.0

47.7 Continuous Speech Recognition

The techniques used in connected word recognition systems cannot be extended to the problem of continuous speech recognition for several reasons. First of all, as the size of the vocabulary of the recognizer grows, it becomes impractical to train patterns for each individual word in the vocabulary. Hence, continuous speech recognizers generally use sub-word speech units as the basic patterns to be trained, and use a lexicon to define the structure of word patterns in terms of the sub-word units. Second, the words spoken during continuous speech generally have a syntax associated with the word order, i.e., they are spoken according to a grammar. In order to achieve good recognition performance, account must be taken of the word grammar so as to constrain the set of possible recognized sentences. Finally, the spoken sentence often must make sense according to a semantic model of the task which the recognizer is asked to perform. Again, by explicitly including these semantic constraints on the spoken sentence, as part of the recognition process, performance of the system improves.

Based on the discussion above, there are three distinct new problems associated with continuous speech recognition [16], namely:

1. Choice of sub-word unit used to represent the sounds of speech, and methods of creating appropriate acoustic models for these sub-word units;
2. Choice of a representation of words in the recognition vocabulary, in terms of the sub-word units;
3. Choice of a method for integrating syntactic (and possibly semantic) information into the recognition process so as to properly constrain the sentences that are allowed by the system.

47.7.1 Sub-Word Speech Units and Acoustic Modeling

For the basic sub-word speech recognition unit, one could consider a range of linguistic units, including syllables, half syllables, dyads, dyphones, or phonemes. The most common choice is a simple phoneme set, which for English comprises about 40 to 50 units, depending on fine choices as to what constitutes a unique phoneme. Since the number of phonemes is limited, it is usually straightforward to collect sufficient speech training data for reliable estimation of statistical models of the phonemes. The resulting set of sub-word speech models are usually referred to as “context independent” phone-like units (CI-PLU) since each unit is trained independently of the context of neighboring units. The problem with using such CI-PLU models is that phonemes are highly variable according to different contexts, and therefore using models which cannot represent this variability properly leads to inferior speech recognition performance.

A straightforward way to improve the modeling of phonemes is to augment the CI-PLU set with phoneme models that are context dependent. In this manner, a target phoneme is modeled differently depending on the phonemes that precede and follow it. By using such context dependent PLUs (in

addition to the CI-PLUs) the “resolution” of the acoustic models is increased, and the performance of the recognition system improves.

47.7.2 Word Modeling From Sub-Word Units

Once the base set of sub-word units is chosen, one can use standard lexical modeling techniques to represent words in terms of these units. The key problem here is variability of word pronunciation across talkers with different regional accents. Hence, for each word in the recognition vocabulary, the lexicon contains a baseform (or standard) pronunciation of the word, as well as alternative pronunciations, as appropriate.

The lexicon used in most recognition systems is extracted from a standard pronouncing dictionary, and each word pronunciation is represented as a linear sequence of phonemes. This lexical definition is basically data independent because no speech or text data are used to derive the pronunciation. Hence the lexical variability of a word in speech is characterized only indirectly through the sub-word unit models. To improve lexical modeling capability, the use of (multiple) pronunciation networks has been proposed [17].

47.7.3 Language Modeling Within the Recognizer

In order to determine the best match to a spoken sentence, a continuous speech recognition system has to evaluate both an acoustic match score (corresponding to the “local” acoustic matches of the words in the sentence) and a language match score (corresponding to the match of the words to the grammar and syntax of the task). The acoustic matching score is readily determined using dynamic programming methods much like those used in connected word recognition systems. The language match scores are computed according to a production model of the syntax and the semantics. Most often the language model is represented as a finite state network (FSN) for which the language score is computed according to arc scores along the best decoded path (according to an integrated model where acoustic and language modeling are combined) in the network. Other models of language include word pair models as well as N -gram word probabilities.

47.7.4 Performance of Continuous Speech Recognizers

Table 47.3 illustrates current capabilities in continuous speech recognition, for three distinct tasks, namely database access (Resource Management), natural language queries (ATIS) for air travel reservations, and read text from a set of business publications (NAB).

TABLE 47.3 Performance of Continuous Speech Recognition Systems

Task	Syntax	Mode	Vocabulary	Word error rate (%)
Resource management (DARPA)	Finite state grammar (perplexity = 60)	SI fluent input	1,000 Words	4.4
Air travel information system (DARPA)	Backoff trigram (perplexity = 18)	SI natural language	2,500 Words	3.6
North American business (DARPA)	Backoff 5-gram (perplexity = 173)	SI fluent input	60,000 Words	10.8

47.8 Speech Recognition System Issues

This section discusses some key issues in building “real world” speech recognition systems.

47.8.1 Robust Speech Recognition [18]

Robust speech recognition refers to the problem of designing an ASR system that works equally well in various unknown or adverse operating environments. Robustness is important because the performance of existing ASR systems, whose designs are predicated on known or clean environments, often degrades rapidly under field conditions.

There are basically four types of sound degradation, namely, noise, distortion, articulation effects, and pronunciation variations. Noise is an inevitable component of the acoustic environment and is normally considered additive with the speech. Distortion refers to modification to the spectral characteristics of the signal by the room, the transducer (microphone), the channel (e.g., transmission), etc. Articulation effects result from the factors that affect a talker's speaking manner when responding to a machine rather than a human. One well-known phenomenon is the Lombard effect which is related to the changes in articulation when the talker speaks in a noisy environment. Finally, different speakers will pronounce a word differently depending on the regional accent. These conditions are often not known *a priori* when the recognizer is trained in the laboratory and are often detrimental to the recognizer performance.

There are essentially two broad categories of techniques that have been proposed for dealing with adverse conditions. These are invariant methods and adaptive methods, respectively.

Invariant methods use speech features (or the associated similarity measures) that are invariant under a wide range of conditions, e.g., liftering and RASTA [19] (which suppress speech features that are more susceptible to signal variabilities), the short-time modified coherence (SMC) [20] (which has a built-in noise averaging advantage), and the Ensemble Interval Histogram (EIH) [21] (which mimics the human auditory mechanism). Robust distortion measures include the group-delay measure [22] and a family of distortion measures based on the projection operator [23] which were shown to be effective in conditions involving additive noise.

Adaptive methods differ from invariant methods in the way the characteristics of the operating environment are taken into account. Invariant methods assume no explicit knowledge of the signal environment, while adaptive methods attempt to estimate the adverse condition and adjust the signal (or the reference models) accordingly in order to achieve reliable matching results.

When channel or transducer distortions are the major factor, it is convenient to assume that the linear distortion effect appears as an additive signal bias in the cepstral domain. This distortion model leads to the method of cepstral mean subtraction and, more generally, signal bias removal [24] which makes a maximum likelihood estimate of the bias due to distortion and subtracts the estimated bias from the cepstral features before pattern matching is performed.

47.8.2 Speaker Adaptation [25]

Given sufficient training data, a SD recognition system usually performs better than a SI system for the same task. Many systems are designed for SI applications, however, due to the fact that it is often difficult to collect speaker-specific training data that would be adequate for reliable performance. One way to bridge the performance gap is to apply the method of speaker adaptation which uses a very limited amount of speaker-specific data to modify the model parameters of a SI recognition system in order to achieve a recognition accuracy, approaching that of a well-trained SD system.

47.8.3 Keyword Spotting [26] and Utterance Verification [27]

An automatic speech recognition system needs to have both high accuracy and a user-friendly interface in order to be acceptable to the users. One major component in a friendly user-interface is to allow the user to speak naturally and spontaneously without imposing a rigid speaking format. In a typical spontaneously spoken utterance, however, we usually observe various kinds of disfluency, such as hesitation and extraneous sounds such as um and ah and false starts, and unanticipated ambient noise, such as mouth clicks and lip smacks, etc. In the conventional paradigm, which formulates speech recognition as decoding of an unknown utterance into a contiguous sequence of phonetic units, the task is equivalent to designing an unlimited vocabulary continuous speech recognition and understanding system which is, unfortunately, beyond reach with today's technology.

One alternative to the above approach, particularly when implementing domain-specific services, is to focus on a finite set of vocabulary words most relevant to the intended task and design the system using the technology of keyword spotting and, more generally, utterance verification (UV). With UV incorporated into the speech recognition system, the user is allowed to speak spontaneously so long as the keywords appear somewhere in the spoken utterance. The system then detects and identifies the in-vocabulary words (i.e., keywords), while rejecting all other superfluous acoustic events in the utterance (which include out-of-vocabulary words, invalid inputs — any form of disfluency as well as lack of keywords — and ambient sounds). In such cases, no critical constraints are imposed on the users' speaking format, making the user interface natural and effective.

47.8.4 Barge-In

In human-human conversation, talkers often interrupt each other during speaking. This is called “barge-in”. For human-machine interactions, in which machine prompts are often routine messages or instructions, the capability of allowing talkers to “barge in” becomes an important enabling technology for a natural human-machine interface.

Two key technologies are integrated in the implementation of “barge-in”, namely, an echo canceler (to remove the spoken message from the machine to the recognizer) and a partial rejection mechanism.

With “barge-in”, the recognizer needs to be activated and listen starting from the beginning of the system prompt. An echo canceler, with a proper double talk detector, is used to cancel the system prompt while attempting to detect if the near-end signal from the talker (i.e., speech to be recognized) is present. The tentatively detected signal is then passed through the recognizer with rejection thresholds to produce the partial recognition results. The rejection technique is critical because extraneous input is very likely to be present, both from the ambient background and from the talker (breathing, lip smacks, etc.), during the long period when the recognizer is activated.

47.9 Practical Issues in Speech Recognition

As progress is made in fundamental recognition technologies, we need to examine carefully the key attributes that a recognition machine must possess in order for it to be useful. These include: high recognition performance in terms of speed and accuracy, ease of use, and low cost. A recognizer must be able to deliver high recognition accuracy without excessive delay. A system that does not provide high performance often adds to users' frustration and may even be considered counterproductive. A recognition system must also be easy to use. The more naturally a system interacts with the user (e.g., does not require words in a sentence to be spoken in isolation), the higher the perceived effectiveness. Finally, the recognition system must be low cost to be competitive with alternative technologies such as keyboard or mouse devices in computer interface applications.

47.10 ASR Applications

Speech recognition has been successfully applied in a range of systems. We categorize these applications into five broad classes.

1. Office or business system. Typical applications include data entry onto forms, database management and control, keyboard enhancement, and dictation. Examples of voice-activated dictation machines include the Tangora system [28] and the Dragon Dictate system [29].
2. Manufacturing. ASR is used to provide “eyes-free, hands-free” monitoring of manufacturing processes (e.g., parts inspection) for quality control.
3. Telephone or telecommunications. Applications include automation of operator assisted services (the Voice Recognition Call Processing system by AT&T to automate operator service routing according to call types), inbound and outbound telemarketing, information services (the ANSER system by NTT for limited home banking services, the stock price quotation system by Bell Northern Research, Universal Card services by Conversant/AT&T for account information retrieval), voice dialing by name/number (AT&T VoiceLine, 800 Voice Calling services, Conversant FlexWord, etc.), directory assistance call completion, catalog ordering, and telephone calling feature enhancements (AT&T VIP — Voice Interactive Phone for easy activation of advanced calling features such as call waiting, call forwarding, etc. by voice rather than by keying in the code sequences).
4. Medical. The application is primarily in voice creation and editing of specialized medical reports (e.g., Kurzweil’s system).
5. Other. This category includes voice controlled and operated toys and games, aids for the handicapped and voice control of non-essential functions in moving vehicles (such as climate control and the audio system).

48.1 Introduction

Speaker recognition is the process of automatically extracting personal identity information by analysis of spoken utterances. In this section, speaker recognition is taken to be a general process whereas speaker identification and speaker verification refer to specific tasks or decision modes associated with this process. Speaker identification refers to the task of determining who is speaking and speaker verification is the task of validating a speaker's claimed identity.

Many applications have been considered for automatic speaker recognition. These include secure access control by voice, customizing services or information to individuals by voice, indexing or labeling speakers in recorded conversations or dialogues, surveillance, and criminal and forensic investigations involving recorded voice samples. Currently, the most frequently mentioned application

is access control. Access control applications include voice dialing, banking transactions over a telephone network, telephone shopping, database access services, information and reservation services, voice mail, and remote access to computers. Speaker recognition technology, as such, is expected to create new services and make our daily lives more convenient. Another potentially important application of speaker recognition technology is its use for forensic purposes [24].

For access control and other important applications, speaker recognition operates in a speaker verification task decision mode. For this reason the section is entitled speaker verification. However, the term speaker recognition is used frequently in this section when referring to general processes.

This section is not intended to be a comprehensive review of speaker recognition technology. Rather, it is intended to give an overview of recent advances and the problems that must be solved in the future. The reader is referred to papers by Doddington [4], Furui [10, 11, 12, 13], O'Shaughnessy [39], and Rosenberg and Soong [48] for more general reviews.

48.2 Personal Identity Characteristics

A universal human faculty is the ability to distinguish one person from another by personal identity characteristics. The most prominent of these characteristics are facial and vocal features. Organized, scientific efforts to make use of personal identifying characteristics for security and forensic purposes began about 100 years ago. The most successful such effort was fingerprint classification which has gained widespread use in forensic investigations.

Today, there is a rapidly growing technology based on biometrics, the measurement of human physiological or behavioral characteristics, for the purpose of identifying individuals or verifying the claimed or asserted identity of an individual [34]. The goal of these technological efforts is to produce completely automated systems for personal identity identification or verification that are convenient to use and offer high performance and reliability. Some of the personal identity characteristics which have received serious attention are blood typing, DNA analysis, hand shape, retinal and iris patterns, and signatures, in addition to fingerprints, facial features, and voice characteristics. In general, characteristics that are subject to the least amount of contamination or distortion and variability provide the greatest accuracy and reliability. Difficulties arise, for example, with smudged fingerprints, inconsistent signature handwriting, recording and channel distortions, and inconsistent speaking behavior for voice characteristics. Indeed, behavioral characteristics, intrinsic to signature and voice features, although potentially an important source of identifying information, are also subject to large amounts of variability from one sample to another.

The demand for effective biometric techniques for personal identity verification comes from forensic and security applications. For security applications, especially, there is a great need for techniques that are not intrusive, that are convenient and efficient, and are fully automated. For these reasons, techniques such as signature verification or speaker verification are attractive even if they are subject to more sources of variability than other techniques. Speaker verification, in addition, is particularly useful for remote access, since voice characteristics are easily recorded and transmitted over telephone lines.

48.3 Vocal Personal Identity Characteristics

Both physiology and behavior underly personal identity characteristics of the voice. Physiological correlates are associated with the size and configuration of the components of the vocal tract (see Fig. 48.1).

For example, variations in the size of vocal tract cavities are associated with characteristic variations in the spectral distributions in the speech signal for different speech sounds. The most prominent of these spectral features are the characteristic resonances associated with voiced speech sounds known as formants [6]. Vocal cord variations are associated with the average pitch or fundamental

FIGURE 48.1: Simplified diagram of the human vocal tract showing how speech sounds are generated. The size and shape of the articulators differ from person to person.

frequency of voiced speech sounds. Variations in the velum and nasal cavities are associated with characteristic variations in the spectrum of nasalized speech sounds. Atypical anatomical variations, in the configuration of the teeth or the structure of the palate are associated with atypical speech sounds such as lisps or abnormal nasality.

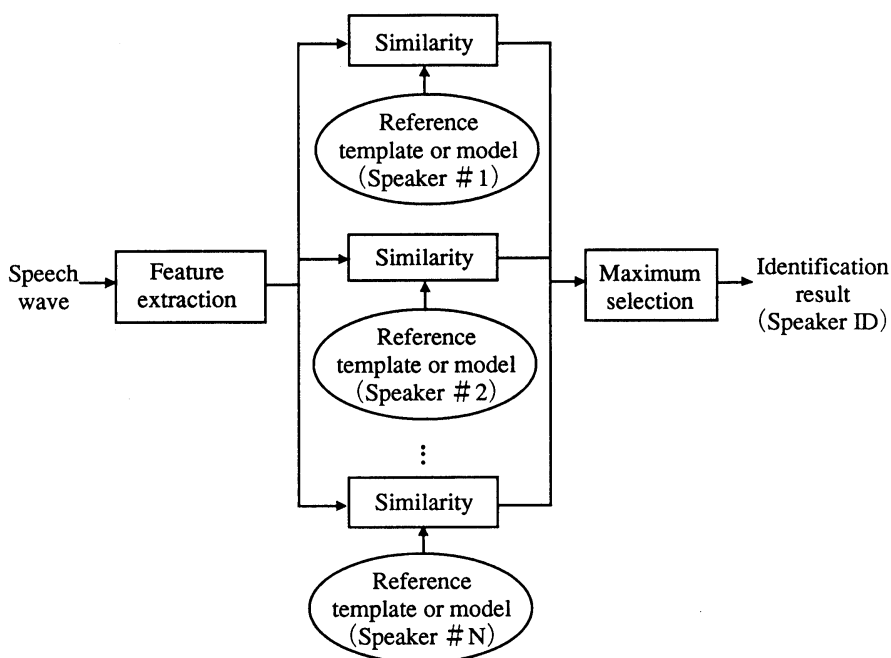

Behavioral correlates of speaker identity in the speech signal are more difficult to specify. “Low level” behavioral characteristics are associated with individuality in articulating speech sounds, characteristic pitch contours, rhythm, timing, etc. Characteristics of speech that have to do with individual speech sounds, or phones, are referred to as “segmental”, while those that pertain to speech phenomena over a sequence of phones are referred to as “suprasegmental”. Phonetic or articulatory suprasegmental “settings” distinguishing speakers have been identified which are associated with characteristic “breathy”, nasal, and other voice qualities [38]. “High-level” speaker behavioral characteristics refer to individual choice of words and phrases and other aspects of speaking styles.

48.4 Basic Elements of a Speaker Recognition System

The basic elements of a speaker recognition system are shown in Fig. 48.2. An input utterance from an unknown speaker is analyzed to extract speaker characteristic features. The measured features are compared with prototype features obtained from known speaker models.

Speaker recognition systems can operate in either an identification decision mode (Fig. 48.2(a)) or verification decision mode (Fig. 48.2(b)). The fundamental difference between these two modes is the number of decision alternatives.

In the identification mode, a speech sample from an unknown speaker is analyzed and compared

(a) Speaker identification

(b) Speaker verification

FIGURE 48.2: Basic structures of speaker recognition systems.

with models of known speakers. The unknown speaker is identified as the speaker whose model best matches the input speech sample. In the “closed set” identification mode, the number of decision alternatives is equal to the size of the population. In the “open set” identification mode, a reference model for the unknown speaker may not exist. In this case, an additional alternative, “the unknown does not match any of the models”, is required.

In the verification decision mode, an identity claim is made by or asserted for the unknown speaker. The unknown speaker’s speech sample is compared with the model for the speaker whose identity is claimed. If the match is good enough, as indicated by passing a threshold test, the identity claim is verified. In the verification mode there are two decision alternatives, accept or reject the identity claim, regardless of the size of the population. Verification can be considered as a special case of the “open set” identification mode in which the known population size is one.

Crucial to the operation of a speaker recognition system is the establishment and maintenance of speaker models. One or more enrollment sessions are required in which training utterances are obtained from known speakers. Features are extracted from the training utterances and compiled

into models. In addition, if the system operates in the “open set” or verification decision mode, decision thresholds must also be set. Many speaker recognition systems include an updating facility in which test utterances are used to adapt speaker models and decision thresholds.

A list of terms commonly found in the speaker recognition literature can be found at the end of this chapter. In the remaining sections of the chapter, the following subjects are treated: how speaker characteristic features are extracted from speech signals, how these features are used to represent speakers, how speaker models are constructed and maintained, how speech utterances from unknown speakers are compared with speaker models and scored to make speaker recognition decisions, and how speaker verification performance is measured. The chapter concludes with a discussion of outstanding issues in speaker recognition.

48.5 Extracting Speaker Information from the Speech Signal

Explicit measurements of speaker characteristics in the speech signal are often difficult to carry out. Segmenting, labeling, and measuring specific segmental speech events that characterize speakers, such as nasalized speech sounds, is difficult because of variable speech behavior and variable and distorted recording and transmission conditions. Overall qualities, such as breathiness, are difficult to correlate with specific speech signal measurements and are subject to variability in the same way as segmental speech events.

Even though voice characteristics are difficult to specify and measure explicitly, most characteristics are captured implicitly in the kinds of speech measurements that can be performed relatively easily. Such measurements as short-time and long-time spectral energy, overall energy, and fundamental frequency are relatively easy to obtain. They can often resolve differences in speaker characteristics surpassing human discriminability. Although subject to distortion and variability, features based on these analysis tools form the basis for most automatic speaker recognition systems.

The most important analysis tool is short-time spectral analysis. It is no coincidence that short-time spectral analysis also forms the basis for most speech recognition systems [42]. Short-time spectral analysis not only resolves the characteristics that differentiate one speech sound from another, but also many of the characteristics already mentioned that differentiate one speaker from another. There are two principal modes of short-time spectral analysis: filter bank analysis and linear predictive coding (LPC) analysis.

In filter bank analysis, the speech signal is passed through a bank of bandpass filters covering the available range of frequencies associated with the signal. Typically, this range is 200 to 3,000 Hz for telephone band speech and 50 to 8,000 Hz for wide band speech. A typical filter bank for wide band speech contains 16 bandpass filters spaced uniformly 500 Hz apart. The output of each filter is usually implemented as a windowed, short-time Fourier transform [using fast Fourier transform (FFT) techniques] at the center frequency of the filter. The speech is typically windowed using a 10 to 30 ms Hamming window. Instead of uniformly spacing the bandpass filters, a nonuniform spacing is often carried out reflecting perceptual criteria that allot approximately equal perceptual contributions for each such filter. Such mel scale or bark scale filters [42] provide a spacing linear in frequency below 1000 Hz and logarithmic above.

LPC-based spectral analysis is widely used for speech and speaker recognition. The LPC model of the speech signal specifies that a speech sample at time t , $s(t)$, can be represented as a linear sum of the p previous samples plus an excitation term, as follows:

$$s(t) = a_1s(t-1) + a_2s(t-2) + \cdots + a_ps(t-p) + Gu(t) \quad (48.1)$$

The LPC coefficients, a_i , are computed by solving a set of linear equations resulting from the minimization of the mean-squared error between the signal at time t and the linearly predicted estimate

of the signal. Two generally used methods for solving the equations, the autocorrelation method and the covariance method, are described in Rabiner and Juang [42].

The LPC representation is computationally efficient and easily convertible to other types of spectral representations. While the computational advantage is less important today than it was for early digital implementations of speech and speaker recognition systems, LPC analysis competes well with other spectral analysis techniques and continues to be widely used.

An important spectral representation for speech and speaker recognition is the cepstrum. The cepstrum is the (inverse) Fourier transform of the log of the signal spectrum. Thus, the log spectrum can be represented as a Fourier series expansion in terms of a set of cepstral coefficients c_n

$$\log S(\omega) = \sum_{n=-\infty}^{\infty} c_n e^{-nj\omega} \quad (48.2)$$

The cepstrum can be calculated from the filter-bank spectrum or from LPC coefficients by a recursion formula [42]. In the latter case it is known as the LPC cepstrum indicating that it is based on an all-pole representation of the speech signal. The cepstrum has many interesting properties. Since the cepstrum represents the log of the signal spectrum, signals that can be represented as the cascade of two effects which are products in the spectral domain are additive in the cepstral domain. Also, pitch harmonics, which produce prominent ripples in the spectral envelope, are associated with high order cepstral coefficients. Thus, the set of cepstral coefficients truncated, for example, at order 12 to 24 can be used to reconstruct a relatively smooth version of the speech spectrum. The spectral envelope obtained is associated with vocal tract resonances and does not have the variable, oscillatory effects of the pitch excitation. It is considered that one of the reasons that cepstral representation has been found to be more effective than other representations for speech and speaker recognition is this property of separability of source and tract. Since the excitation function is considered to have speaker dependent characteristics, it may seem contradictory that a representation which largely removes these effects works well for speaker recognition. However, in short-time spectral analysis the effects of the source spectrum are highly variable so that they are not especially effective in providing consistent representations of the source spectrum.

Other spectral features such as PARCOR coefficients, log area ratio coefficients, LSP (line spectral pair coefficients), have been used for both speech and speaker recognition [42]. Generally speaking, however, the cepstral representation is most widely used and is usually associated with better speaker recognition performance than other representations.

Cruder measures of spectral energy, such as waveform zero-crossing or level-crossing measurements have also been used for speech and speaker recognition in the interest of saving computation with some success.

Additional features have been proposed for speaker recognition which are not used often or considered to be marginally useful for speech recognition. For example, pitch and energy features, particularly when measured as a function of time over a sufficiently long utterance, have been shown to be useful for speaker recognition [27]. Such time sequences or “contours” are thought to represent characteristic speaking inflections and rhythms associated with individual speaking behavior. Pitch and energy measurements have an advantage over short-time spectral measurements in that they are more robust to many different kinds of transmission and recording variations and distortions since they are not sensitive to spectral amplitude variability. However, since speaking behavior can be highly variable due to both voluntary and involuntary activity, pitch and energy can acquire more variability than short-time spectral features and are more susceptible to imitation.

The time course of feature measurements, as represented by so-called feature contours, provides valuable speaker characterizing information. This is because such contours provide overall, suprasegmental information characterizing speaking behavior and also because they contain information on a more local, segmental time scale describing transitions from one speech sound to another. This

latter kind of information can be obtained explicitly by measuring the local trajectory in time of a measured feature at each analysis frame. Such measurements can be obtained by averaging successive differences of the feature in a window around each analysis frame, or by fitting a polynomial in time to the successive feature measurements in the window. The window size is typically 5 to 9 analysis frames. The polynomial fit provides a less noisy estimate of the trajectory than averaging successive differences. The order of the polynomial is typically 1 or 2, and the polynomial coefficients are called delta- and delta-delta-feature coefficients. It has been shown in experiments that such dynamic feature measurements are fairly uncorrelated with the original static feature measurements and provide improved speech and speaker recognition performance [9].

48.6 Feature Similarity Measurements

Much of the originality and distinctiveness in the design of a speaker recognition system is found in how features are combined and compared with reference models. Underlying this design is the basic representation of features in some space and the formation of a distance or distortion measurement to use when one set of features is compared with another. The distortion measure can be used to partition the feature vectors representing a speaker's utterances into regions representative of the most prominent speech sounds for that speaker, as in the vector quantization (VQ) codebook representation (Section 48.9.2). It can be used to segment utterances into speech sound units. And it can be used to score an unknown speaker's utterances against a known speaker's utterance models.

A general approach for calculating a distance between two feature vectors is to make use of a distance metric from the family of L_p norm distances d_p , such as the absolute value of the difference between the feature vectors

$$d_1 = \sum_{i=1}^D |f_i - f'_i| \quad (48.3)$$

or the Euclidean distance

$$d_2 = \sum_{i=1}^D (f_i - f'_i)^2 \quad (48.4)$$

where f_i , f'_i , $i = 1, 2, \dots, D$ are the coefficients of two feature vectors f and f' . The feature vectors, for example, could comprise filter-bank outputs or cepstral coefficients described in the previous section. (It is not common, however, to use filter bank outputs directly, as previously mentioned, because of the variability associated with these features due to harmonics from the pitch excitation.)

For example, a weighted Euclidean distance distortion measure for cepstral features of the form

$$d_{cw}^2 = \sum_{i=1}^D (w_i (c_i - c'_i))^2 \quad (48.5)$$

where

$$w_i = 1/\sigma_i \quad (48.6)$$

and σ_i^2 is an estimate of the variance of the i th coefficient has been shown to provide good performance for both speech and speaker recognition. A still more general formulation is the Mahalanobis distance formulation which accounts for interactions between coefficients with a full covariance matrix.

An alternate approach to comparing vectors in a feature space with a distortion measurement is to establish a probabilistic formulation of the feature space. It is assumed that the feature vectors in a subspace associated with, for example, a particular speech sound for a particular speaker, can

be specified by some probability distribution. A common assumption is that the feature vector is a random variable x whose probability distribution is Gaussian

$$p(x|\lambda) = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp \left[-\frac{1}{2} (x - \mu)^T \Sigma^{-1} (x - \mu) \right] \quad (48.7)$$

where λ represents the parameters of the distribution, which are the mean vector μ and covariance matrix Σ .

When x is a feature vector sample, $p(x|\lambda)$ is referred to as the likelihood of x with respect to λ . Suppose there is a population of n speakers each modeled by a Gaussian distribution of feature vectors, $\lambda_i, i = 1, 2, \dots, n$. In the maximum likelihood formulation, a sample x is associated with speaker I if

$$p(x|\lambda_I) > p(x|\lambda_i), \text{ for all } i \neq I \quad (48.8)$$

where $p(x|\lambda_i)$ is the likelihood of the test vector x for speaker model λ_i . It is common to use log likelihoods to evaluate Gaussian models. From Eq. (48.7)

$$L(x|\lambda_i) = \log p(x|\lambda_i) = -\frac{D}{2} \log 2\pi - \frac{1}{2} \log |\Sigma_i| - \frac{1}{2} (x - \mu_i)^T \Sigma_i^{-1} (x - \mu_i) \quad (48.9)$$

It can be seen from Eq. (48.9) that, using log likelihoods, the maximum likelihood classifier is equivalent to the minimum distance classifier using a Mahalanobis distance formulation.

A more general probabilistic formulation is the Gaussian mixture distribution of a feature vector x

$$p(x|\lambda) = \sum_{i=1}^M w_i b_i(x) \quad (48.10)$$

where $b_i(x)$ is the Gaussian probability density function with mean μ_i and covariance Σ_i , w_i is the weight associated with the i th component, and M is the number of Gaussian components in the mixture. The weights w_i are constrained so that $\sum_{i=1}^M w_i = 1$. The model parameters λ are

$$\lambda = \{\mu_i, \Sigma_i, w_i, i = 1, 2, \dots, M\} \quad (48.11)$$

The Gaussian mixture probability function is capable of approximating a wide variety of smooth, continuous, probability functions.

48.7 Units of Speech for Representing Speakers

An important consideration in the design of a speaker recognition system is the choice of a speech unit to model a speaker's utterances. The choice of units includes phonetic or linguistic units such as whole sentences or phrases, words, syllables, and phone-like units. It also includes acoustic units such as subword segments, segmented from utterances and labeled on the basis of acoustic rather than phonetic criteria. Some speaker recognition systems model speakers directly from single feature vectors rather than through an intermediate speech unit representation. Such systems usually operate in a text independent mode (see Sections 48.8 and 48.9) and seek to obtain a general model of a speaker's utterances from a usually large number of training feature vectors. Direct models might include long-time averages, VQ codebooks, segment and matrix quantization codebooks, or Gaussian mixture models of the feature vectors.

Most speech recognizers of moderate to large vocabulary are based on subword units such as phones so that large numbers of utterances transcribed as sequences of phones can be represented as concatenations of phone models. For speaker recognition, there is no absolute need to represent

utterances in terms of phones or other phonetically based units because there is no absolute need to account for the linguistic or phonetic content of utterances in order to build speaker recognition models. Generally speaking, systems in which phonetic representations are used are more complex than other representations because they require phonetic transcriptions for both training and testing utterances and because they require accurate and reliable segmentations of utterances in terms of these units. The case in which phonetic representations are required for speaker recognition is the same as for speech recognition: where there is a need to represent utterances as concatenations of smaller units. Speaker recognition systems based on subword units have been described by Rosenberg et al. [46] and Matsui and Furui [31].

48.8 Input Modes

Speaker recognition systems typically operate in one of two input modes: text dependent or text independent. In the text-dependent mode, speakers must provide utterances of the same text for both training and recognition trials. In the text-independent mode, speakers are not constrained to provide specific texts in recognition trials. Since the text-dependent mode can directly exploit the voice individuality associated with each phoneme or syllable, it generally achieves higher recognition performance than the text-independent mode.

48.8.1 Text-Dependent (Fixed Passwords)

The structure of a system using fixed passwords is rather simple; input speech is time aligned with reference templates or models created by using training utterances for the passwords. If the fixed passwords are different from speaker to speaker, the difference can also be used as additional individual information. This helps to increase performance.

48.8.2 Text Independent (No Specified Passwords)

There are several applications in which predetermined passwords cannot be used. In addition, human beings can recognize speakers irrespective of the content of the utterance. Therefore, text-independent methods have recently been actively investigated. Another advantage of text-independent recognition is that it can be done sequentially, until a desired significance level is reached, without the annoyance of having to repeat passwords again and again.

48.8.3 Text Dependent (Randomly Prompted Passwords)

Both text-dependent and independent methods have a potentially serious problem. Namely, these systems can be defeated because someone who plays back the recorded voice of a registered speaker uttering key words or sentences into the microphone could be accepted as the registered speaker. To cope with this problem, there are methods in which a small set of words, such as digits, are used as key words and each user is prompted to utter a given sequence of key words that is randomly chosen every time the system is used [20, 47].

Recently, a text-prompted speaker recognition method was proposed in which password sentences are completely changed every time [31, 33]. The system accepts the input utterance only when it judges that the registered speaker uttered the prompted sentence. Because the vocabulary is unlimited, prospective impostors cannot know in advance the sentence they will be prompted to say. This method cannot only accurately recognize speakers, but can also reject utterances whose text differs from the prompted text, even if it is uttered by a registered speaker. Thus, a recorded and played-back voice can be correctly rejected.

48.9 Representations

48.9.1 Representations That Preserve Temporal Characteristics

The most common approach to automatic speaker recognition in the text-dependent mode uses representations that preserve temporal characteristics. Each speaker is represented by a sequence of feature vectors (generally, short-term spectral feature vectors), analyzed for each test word or phrase. This approach is usually based on template matching techniques in which the time axes of an input speech sample and each reference template of registered speakers are aligned, and the similarity between them accumulated from the beginning to the end of the utterance is calculated.

Trial-to-trial timing variations of utterances of the same talker, both local and overall, can be normalized by aligning the analyzed feature vector sequence of a test utterance to the template feature vector sequence using a dynamic programming (DP) time warping algorithm or DTW [11, 42]. Since the sequence of phonetic events is the same for training and testing, there is an overall similarity among these sequences of feature vectors. Ideally the intra-speaker differences are significantly smaller than the inter-speaker differences.

Figure 48.3 shows an example of a typical structure of the DTW-based system [9]. Initially, 10 LPC cepstral coefficients are extracted every 10 ms from a short sentence of speech. The spectral equalization technique, which is described in Section 48.12.1, is applied to each cepstral coefficient to compensate for transmission distortion and intraspeaker variability. In addition to the normalized cepstral coefficients, delta-cepstral and delta-delta-cepstral coefficients (polynomial expansion coefficients) are extracted every 10 ms. The time function of the set of parameters is brought into time registration with the reference template in order to calculate the distance between them. The overall distance is then compared with a threshold for the verification decision.

Another approach using representations that preserve temporal characteristics is based on the HMM (hidden Markov model) technique [42]. In this approach, a reference model for each speaker is represented by an HMM instead of directly using a time series of feature vectors. An HMM can efficiently model statistical variation in spectral features. Therefore, HMM-based methods have achieved significantly better recognition accuracies than the DTW-based methods [36, 47, 53].

48.9.2 Representations That do not Preserve Temporal Characteristics

In a text-independent system, the words or phrases used in recognition trials generally cannot be predicted. Therefore, it is impossible to model or match speech events at the level of words or phrases. Classical text-independent speaker recognition techniques are based on measurements for which the time dimension is collapsed. Recently text-independent speaker verification techniques based on short duration speech events have been studied. The new approaches extract and measure salient acoustic and phonetic events. The bases for these approaches lie in statistical techniques for extracting and modeling reduced sets of optimally representative feature vectors or feature vector sequences or segments. These techniques fall under the related categories of vector quantization (VQ), matrix and segment quantization, probabilistic mixture models, and HMM.

A set of short-term training feature vectors of a speaker can be used directly to represent the essential characteristics of that speaker. However, such a direct representation is impractical when the number of training vectors is large, since the memory and amount of computation required become prohibitively large. Therefore, efficient ways of compressing the training data have been tried using VQ techniques.

In this method, VQ codebooks consisting of a small number of representative feature vectors are used as an efficient means of characterizing speaker-specific features [25, 29, 45, 52]. A speaker-specific codebook is generated by clustering the training feature vectors of each speaker. In the recognition stage, an input utterance is vector-quantized using the codebook of each reference speaker,

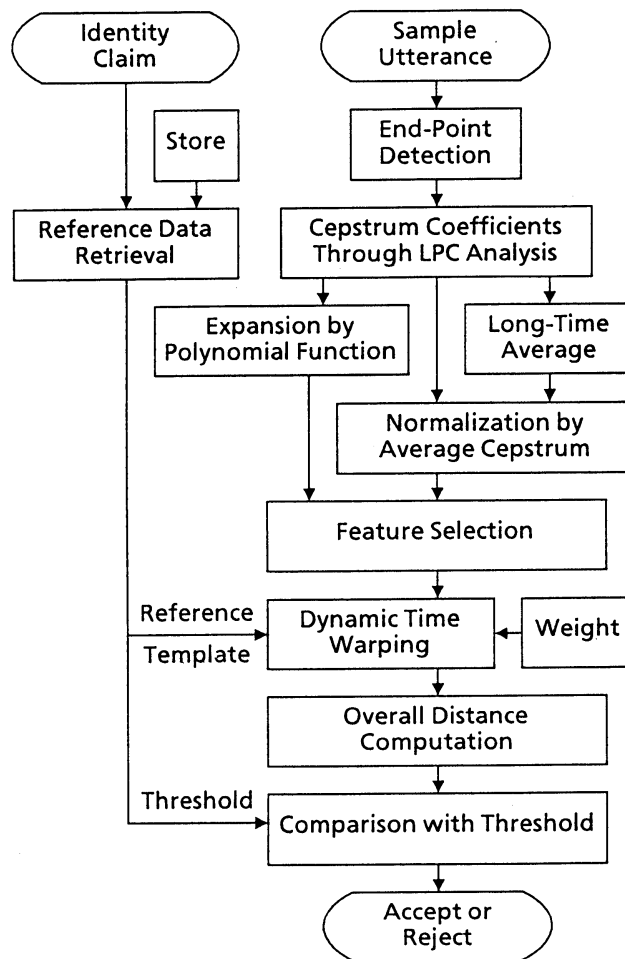

FIGURE 48.3: Typical structure of the DTW-based text-dependent speaker verification system.

and the VQ distortion accumulated over the entire input utterance is used in making the recognition decision.

In contrast with the memoryless VQ-based method, source coding algorithms with memory have also been studied using a segment (matrix) quantization technique [22]. The advantage of a segment quantization codebook over a VQ codebook representation is its characterization of the sequential nature of speech events. Higgins and Wohlford [19] proposed a segment modeling procedure for constructing a set of representative time normalized segments, which they called “filler templates”. The procedure, a combination of K -means clustering and dynamic programming time alignment, provides a way to handle temporal variation.

On a longer time scale, temporal variation in speech signal parameters can be represented by stochastic Markovian transitions between states. Poritz [41] proposed using a five-state ergodic HMM (i.e., all possible transitions between states are allowed) to classify speech segments into one of the broad phonetic categories corresponding to the HMM states. A linear predictive HMM was used to characterize the output probability function. Poritz characterized the automatically obtained categories as strong voicing, silence, nasal/liquid, stop burst/post silence, and frication.

Savic and Gupta [50] also used a five-state ergodic linear predictive HMM for broad phonetic

categorization. After identifying frames belonging to particular phonetic categories, feature selection was performed. In the training phase, reference templates are generated and verification thresholds are computed for each phonetic category. In the verification phase, after the phonetic categorization, a comparison with the reference template for each particular category provides a verification score for that category. The final verification score is a weighted linear combination of the scores for each category. The weights are chosen to reflect the effectiveness of particular categories of phonemes in discriminating between speakers and are adjusted to maximize the verification performance.

The performances of speaker recognition based on a VQ-based method and that using discrete/continuous ergodic HMM-based methods have been compared, in particular from the viewpoint of robustness against utterance variations [30]. It was shown that a continuous ergodic HMM method is far superior to a discrete ergodic HMM method, and that a continuous ergodic HMM method is as robust as a VQ-based method when enough training data is available. However, when little data is available, the VQ-based method is more robust than a continuous HMM method. It was also shown that the information on transitions between different states is ineffective for text-independent speaker recognition, so the speaker recognition rates using a continuous ergodic HMM are strongly correlated with the total number of mixtures, irrespective of the number of states.

Rose and Reynolds [44] investigated a technique based on maximum likelihood estimation of a Gaussian mixture model representation of speaker identity. This method corresponds to the single-state continuous ergodic HMM. Gaussian mixtures are noted for their robustness as a parametric model and for their ability to form smooth estimates of rather arbitrary underlying densities.

Traditionally, long-term sample statistics of various spectral features, e.g., the mean and variance of spectral components averaged over a series of utterances have been used for speaker recognition [7, 28]. However, long-term spectral averages are extreme condensations of the spectral characteristics of a speaker's utterances and, as such, lack the discriminating power obtained in the sequence of short-term spectral features used as models in text-dependent systems. Moreover, recognition based on long-term spectral averages tends to be less tolerant of recording and transmission variations since many of these variations are themselves associated with long-term spectral averages.

Studies on the use of statistical dynamic features have also been reported. Montacie et al. [35] used a multivariate auto-regression (MAR) model to characterize speakers, and reported good speaker recognition results. Griffin et al. [18] studied distance measures for the MAR-based method, and reported that the identification and verification rates were almost the same as those obtained by an HMM-based method. In these experiments, the MAR model was applied to the time series of cepstral vectors. It was also reported that the optimum order of the MAR model was 2 or 3, and that distance normalization was essential to obtain good results in speaker verification.

Speaker recognition based on feed-forward neural net models has been investigated [40]. Each registered speaker has a personalized neural net that is trained to be activated only by that speaker's utterances. It is assumed that including speech from many people in the training data of each net enables direct modeling of the differences between the registered person's speech and an impostor's speech. It has been found that while the net architecture and the amount of training utterances strongly affect the recognition performance, it is comparable to the performance of the VQ approach based on personalized codebooks.

As an expansion of the VQ-based method, a connectionist approach has also been developed based on the learning vector quantization (LVQ) algorithm [2].

48.10 Optimizing Criteria for Model Construction

The establishment of effective speaker models is fundamental for good performing speaker recognition. In the previous section, we described different kinds of representations for speaker models. In this section, we describe some of the techniques for optimizing model representations.

Statistical and discriminative training techniques are based on optimizing criteria for constructing models. Typical criteria for optimizing the model parameters include likelihood maximization, *a posteriori* probability maximization, linear discriminant analysis (LDA), and discriminative error minimization.

The maximum likelihood (ML) approach is widely used in statistical model parameter estimation, such as for HMM parameter training [42]. Although ML estimation has good asymptotic properties, it often requires a large amount of training data to achieve reliable results.

Linear discriminant analysis techniques have been used in a speaker verification system reported by Netsch and Doddington [37]. A set of LDA weights applied to word-level feature vectors is found by maximizing the ratio of between-speaker to within speaker covariances obtained from pooled customer and impostor training data.

In contrast to conventional ML training, which estimates a model based only on training utterances from the same speaker, discriminative training takes into account the models of other competing speakers and formulates the optimization criterion so that speaker separation is enhanced. In the minimum classification error/generalized probabilistic descent (MCE/GPD) method [23], the optimum solution is obtained with a steepest descent algorithm minimizing recognition error rate for the training data. Unlike the statistical framework, this method does not require estimating the probability distributions, which usually cannot be reliably obtained. However, discriminative training methods require a sufficient amount of representative reference speaker training data, which is often difficult to obtain, to be effective. This method has been applied to speaker recognition with good results [26].

Neural nets are capable of discriminative training. Various investigations have been conducted to cope with training problems, such as overtuning to training data. A typical implementation is the neural tree network (NTN) classifier [5]. In this system each speaker is represented by a VQ codebook and an NTN classifier. The NTN classifier is trained on both customer and impostor training data.

48.11 Model Training and Updating

Trial-to-trial variations have a major impact on the performance of speaker recognition systems. Variations arise from the speaker himself/herself, from differences in recording and transmission conditions, and from noise. Speakers cannot repeat an utterance precisely the same way from trial to trial. It has been found that tokens of the same utterance recorded in one session are much more highly correlated than tokens recorded in separate sessions. There are also long-term trends in voices [7, 8].

There are two approaches for dealing with variability. One, discussed in this section, is to construct and update models to accommodate variability. Another, discussed in the next section, is to condition or normalize the acoustic features or the recognition scores to manage some sources of variability.

Training difficulties are closely related to training conditions. The key training conditions include the number of training sessions, the number of tokens, and transmission channel and recording conditions. Tokens of the same utterance recorded in one session are much more highly correlated than tokens recorded in separate sessions. Therefore, wherever it is practicable, it is desirable to collect training utterances for each speaker in multiple sessions to accommodate trial-to-trial variability. For example, Gish and Schmidt [17] report a text-independent speaker identification system in which multiple models of a speaker are constructed from multiple session training utterances.

It is inconvenient to request speakers to utter training tokens at many sessions before being allowed to use a speaker recognition system. It is possible, however, to compensate for small amounts of training data collected in a small number of enrollment sessions, often only one, by updating models with utterances collected in recognition sessions. Updating is especially important for speaker verification systems used for access control, where it can be expected that user trials will take place

periodically over long periods of time in which trial-to-trial variations are likely. Updating models in this way incorporates into the models the effects of trial-to-trial variations we have mentioned. Rosenberg and Soong [45] reported significant improvements in performance in a text independent speaker verification system based on VQ speaker models in which the VQ codebooks were updated with test utterance data. A hazard associated with updating models using test session data is the possibility of adapting a customer model with impostor data.

48.12 Signal Feature and Score Normalization Techniques

Some sources of variability can be managed by normalization techniques applied to signal features or the scores. For example, as noted in Section 48.9.1, it is possible to adjust for trial-to-trial timing variations by aligning test utterances with model parameters using DTW or Viterbi alignment techniques.

48.12.1 Signal Feature Normalization

A typical normalization technique in the parameter domain, spectral equalization, also called “blind equalization” or “blind deconvolution”, has been shown to be effective in reducing linear channel effects and long-term spectral variation [1, 9]. This method is especially effective for text-dependent speaker recognition applications using sufficiently long utterances. In this method, cepstral coefficients are averaged over the duration of an entire utterance, and the averaged values are subtracted from the cepstral coefficients of each frame. This method can compensate fairly well for additive variation in the log spectral domain. However, it unavoidably removes some text-dependent and speaker specific features, and is therefore inappropriate for short utterances in speaker recognition applications.

Gish [15] demonstrated that by simply prefiltering the speech transmitted over different telephone lines with a fixed filter, text-independent speaker recognition performance can be significantly improved. Gish et al. [14, 16] have also proposed using multi-variate Gaussian probability density functions to model channels statistically. This can be achieved if enough training samples of channels to be modeled are available. It was shown that time derivatives (short-time spectral dynamic features) of cepstral coefficients (delta-cepstral coefficients) are resistant to linear channel mismatch between training and testing [51].

48.12.2 Likelihood and Normalized Scores

Likelihood measures (see Section 48.6) are commonly used in speaker recognition systems based on statistical models, such as HMMs, to compare test utterances with models. Since likelihood values are highly subject to inter-session variability, it is essential to normalize these variations.

Higgins et al. [20] proposed a normalization method that uses a likelihood ratio. The likelihood ratio is defined as the ratio of the conditional probability of the observed measurements of the utterance given the claimed identity to the conditional probability of the observed measurements given the speaker is an impostor. A mathematical expression in terms of log likelihoods is given as

$$\log l(x) = \log p(x|S = S_c) - \log p(x|S \neq S_c) \quad (48.12)$$

Generally, a positive value of $\log l$ indicates a valid claim, whereas a negative value indicates an impostor. The second term of the right hand side of Eq. (48.12) is called the normalization term. Some proposals for calculating the normalization term are described.

The density at point x for all speakers other than the true speaker S can be dominated by the density for the nearest reference speaker, if we assume that the set of reference speakers is representative of

all speakers. We can, therefore, arrive at the decision criterion

$$\log l(x) = \log p(x|S = S_c) - \max_{S \in Ref, S \neq S_c} \log p(x|S) \quad (48.13)$$

This shows that likelihood ratio normalization is approximately equal to optimal scoring in Bayes' sense. However, this decision criterion is unrealistic for two reasons. First, in order to choose the nearest reference speaker, conditional probabilities must be calculated for all the reference speakers, which involves a high computational cost. Second, the maximum conditional probability value is rather variable from speaker to speaker, depending on how close the nearest speaker is in the reference set.

48.12.3 Cohort or Speaker Background Models

A set of speakers, “cohort speakers”, has been chosen for calculating the normalization term of Eq. (48.12). Higgins et al. proposed the use of speakers that are representative of the population near the claimed speaker:

$$\log l(x) = \log p(x|S = S_c) - \log \sum_{S \in Cohort, S \neq S_c} p(x|S) \quad (48.14)$$

Experimental results show that this normalization method improves speaker separability and reduces the need for speaker-dependent or text-dependent thresholding, compared with scoring using only the model of the claimed speaker. Another experiment in which the size of the cohort speaker set was varied from 1 to 5 showed that speaker verification performance increases as a function of the cohort size, and that the use of normalization significantly compensates for the degradation obtained by comparing verification utterances recorded using an electret microphone with models constructed from training utterances recorded with a carbon button microphone [49].

This method using speakers that are representative of the population near the claimed speaker is expected to increase the selectivity of the algorithm against voices similar to the claimed speaker. However, this method has a serious problem in that it is vulnerable to attack by impostors of the opposite gender. Since the cohorts generally model only same-gender speakers, the probability of opposite-gender impostor speech is not well modeled, and the likelihood ratio is based on the tails of distributions giving rise to unreliable values. Another way of choosing the cohort speaker set is to use speakers who are typical of the general population. Reynolds [43] reported that a randomly selected, gender-balanced background speaker population outperformed a population near the claimed speaker.

Matsui and Furui [31] proposed a normalization method based on a *a posteriori* probability:

$$\log l(x) = \log p(x|S = S_c) - \log \sum_{S \in Ref} p(x|S) \quad (48.15)$$

The difference between the normalization method based on the likelihood ratio and that based on a *a posteriori* probability is in whether or not the claimed speaker is included in the speaker set for normalization; the cohort speaker set in the likelihood-ratio-based method does not include the claimed speaker, whereas the normalization term for the *a posteriori*-probability-based method is calculated using all the reference speakers, including the claimed speaker. Matsui and Furui approximated the summation in Eq. (48.15) by the summation over a small set of speakers having relatively high likelihood values. Experimental results indicate that the two normalization methods are almost equally effective.

Carey and Parris [3] proposed a method in which the normalization term is approximated by the likelihood for a world model representing the population in general. This method has the advantage

that the computational cost for calculating the normalization term is much smaller than in the original method since it does not need to sum the likelihood values for cohort speakers. Matsui and Furui [32] recently proposed a new method based on tied-mixture HMMs in which the world model is made as a pooled mixture model representing the parameter distribution for all the registered speakers. This model is created by averaging the mixture-weighting factors of each registered speaker calculated using speaker-independent mixture distributions. Therefore, the pooled model can be easily updated when a new speaker is added as a registered speaker. In addition, this method has been shown to give much better results than either of the original normalization methods.

Since these normalization methods neglect the absolute deviation between the claimed speaker's model and the input speech, they cannot differentiate highly dissimilar speakers. Higgins et al. [20] reported that a multilayer network decision algorithm makes effective use of the relative and absolute scores obtained from the matching algorithm.

48.13 Decision Process

48.13.1 Specifying Decision Thresholds and Measuring Performance

A “tight” decision threshold makes it difficult for impostors to be falsely accepted by the system. However, it increases the possibility of rejecting legitimate users (customers). Conversely, a “loose” threshold enables customers to be consistently accepted, while also falsely accepting impostors. To set the threshold at a desired level of customer acceptance and impostor rejection, the distribution of customer and impostor scores must be known. In practice, samples of impostor and customer scores of a reasonable size that will provide adequate estimates of distributions are not readily available. A satisfactory empirical procedure for setting the threshold is to assign a relatively loose initial threshold and then allow it to adapt by setting it to the average, or some other statistic, of recent trial scores, plus some margin that allows a reasonable rate of customer acceptance. For the first few verification trials, the threshold may be so loose that it does not adequately protect against impostor attempts. To prevent impostor acceptance during initial trials, they may be carried out as part of an extended enrollment.

48.13.2 ROC Curves

Measuring the false rejection and false acceptance rates for a given threshold condition is an incomplete description of system performance. A general description can be obtained by varying the threshold over a sufficiently large range and tabulating the resulting false rejection and false acceptance rates. A tabulation of this kind can be summarized in a receiver operating characteristic (ROC) curve, first used in psychophysics. An ROC curve, shown as the probability of correct acceptance vs. the probability of incorrect (false) acceptance is shown in Figure 48.4 [11].

The figure exemplifies the curves for three systems: A, B, and C. Clearly, the performance of curve B is consistently superior to that of curve A, and C corresponds to the limiting case of purely chance performance. Position a in the figure corresponds to the case in which a strict decision criterion is employed, and position b corresponds to a case involving a lax criterion.

The point-by-point knowledge of the ROC curve provides a threshold-independent description of all possible functioning conditions of the system. For example, if a false rejection rate is specified, the corresponding false acceptance rate is obtained as the intersection of the ROC curve with the vertical straight line indicating the false rejection.

Equal-error rate is a commonly accepted summary of system performance. It corresponds to a threshold at which the rate of false acceptance is equal to the rate of false rejection. The equal-error rate point corresponds to the intersection of the ROC curve with the straight line of 45 degrees, indicated in the figure.

FIGURE 48.4: Receiver operating characteristic (ROC) curves; performance examples of three speaker recognition systems: A, B, and C.

48.13.3 Adaptive Thresholds

An issue related to model updating is the selection of a strategy for updating thresholds. A threshold updating strategy must be specified that tolerates trial-to-trial variations while, at the same time, ensures the desired level of performance.

48.13.4 Sequential Decisions (Multi-Attempt Trials)

In either the verification or identification mode, an additional threshold test can be applied to determine whether the match is good enough to accept the decision or whether the decision should be deferred to a new trial.

48.14 Outstanding Issues

There are many outstanding issues and problems in the area of speaker recognition. The most pressing issues, providing challenges for implementing practical and uniformly reliable systems for speaker verification, are rooted in problems associated with variability and insufficient data. As described earlier, variability is associated with trial-to-trial variations in recording and transmission conditions and speaking behavior. The most serious variations occur between enrollment sessions and subsequent test sessions resulting in models that are mismatched to test conditions. Most applications require reliable system operation under a variety of environmental and channel conditions and require that variations in speaking behavior will be tolerated. Insufficient data refers to the unavailability of sufficient amounts of data to provide representative models and accurate decision thresholds. Insufficient data is a serious and common problem because most applications require

systems that operate with the smallest practicable amounts of training data recorded in the fewest number of enrollment sessions, preferably one. The challenge is to find techniques that compensate for these deficiencies. A number of techniques have been mentioned which provide partial solutions, such as cepstral subtraction techniques for channel normalization and spectral subtraction for noise removal. An especially effective technique for combating both variability and insufficient data is updating models with data extracted from test utterances. Studies have shown that model adaptation, properly implemented, can improve verification performance significantly with a small number of updates. It is difficult, however, for model adaptation to respond to large, precipitous changes. Moreover, adaptation provides for the possibility that customer models might be updated and possibly captured by impostors. Another effective tool for making speaker verification more robust is the use of likelihood ratio scoring. An utterance recorded in conditions mismatched to the conditions of enrollment will experience degraded scores for both the customer reference model and the cohort or background model so that the ratio of these two scores remains relatively stable. Ongoing research is directed towards constructing efficient and effective background models for which likelihood ratio scores that behave in this manner can be reliably obtained.

A desirable feature for a practical speaker verification system is reasonably uniform performance across a population of speakers. Unfortunately, it is typical to observe in a speaker verification experiment a substantial discrepancy between the best performing individuals, the “sheep”, and the worst, the “goats”. This additional problem in variability has been widely observed, but there are virtually no studies focusing on its origin. Speakers with no observable speech pathologies, and for whom apparently good reference models have been obtained, are often observed to be “goats”. It is possible that such speakers exhibit large amounts of trial-to-trial variability, beyond the ability of the system to provide adequate compensation.

Finally, there are fundamental research issues which require additional study to promote further advances in speaker recognition technology. First, and most important, is the selection of effective features for speaker discrimination and the specification of robust, efficient acoustic measurements for representing these features. Currently, as we have described, the most effective speaker recognition features are short-time spectral features, the same features used for speech recognition. These features are mainly correlated with segmental speech phenomena and have been shown to be capable of resolving very fine spectral differences, possibly exceeding human perceptual resolving ability. Suprasegmental features, such as pitch and energy, are generally acknowledged to be less effective for speaker recognition. However, it may be that suprasegmental features are not being measured or used effectively since human listeners make effective use of such features in their speaker recognition judgments.

Perhaps the single most fundamental speaker recognition research issue is the intrinsic discriminability of speakers. A related issue is whether intrinsic discriminability should be calibrated by the ability of listeners to discriminate speakers. It is not at all clear that the intrinsic discriminability of speakers is the same order as the discriminability that can be obtained using other personal identification characteristics, such as fingerprints and facial features. Speakers' voices differ on the basis of physiological and behavioral characteristics. But it is not clear precisely which characteristics are significant, what acoustic measurements are correlated with specific features, and how close features of different speakers must be to be acoustically and perceptually indistinguishable. Fundamental research on these questions will provide answers for developing better speaker recognition technology.

Defining Terms

Registered speaker: A speaker who belongs to the list of known (registered) users for a given speaker recognition system. Alternative terms: reference speaker, customer.

- Genuine speaker:** A speaker whose real identity is in accordance with the claimed identity.
Alternative terms: true speaker, correct speaker.
- Impostor:** In the context of speaker identification, a speaker who does not belong to the set of registered speakers. In the context of speaker verification, a speaker whose real identity is different from his/her claimed identity.
- Acceptance:** A decision outcome which involves a positive response to a speaker (or speaker class) verification task.
- Rejection:** A decision outcome which involves refusal to assign a registered identity (or class) in the context of open-set speaker identification or speaker verification.
- Misclassification:** Erroneous identity assignment to a registered speaker in speaker identification.
- False rejection:** Erroneous rejection of a genuine speaker in open-set speaker identification or speaker verification.
- False acceptance:** Erroneous acceptance of an impostor in open-set identification or speaker verification.
- A posteriori equal error threshold:** A decision threshold which is set *a posteriori* on the test data so that the false rejection rate and false acceptance rate become equal. Although this method cannot be put into actual practice, it is the most common constraint because it is a simple way to summarize the overall performance of the system into a single figure.
- A priori threshold:** A decision threshold which is set beforehand usually based on estimates from a set of training data.

49.3 Assembly Language Basics
49.4 Arithmetic
49.5 Algorithmic Constructs
References

Implementations of digital speech processing algorithms in software can be distinguished from those resulting from general-purpose algorithms basically in the *type of arithmetic* and the *algorithmic constructs* used in their realization. In addition, many speech processing algorithms are realized with Programmable Digital Signal Processors (PDSPs) as the software development target—this leads to important considerations in the languages and paradigms used to realize the algorithms.

Although they are important topics in their own right, this section does not discuss the historical development of PDSPs to explain why these devices provide the architectural features that they do, and it does not provide a primer on PDSP architectures, either in general or in specific. Brief synopses of these topics are presented in the text, however, where they are appropriate.

49.1 Software Development Targets

PDSPs were developed as specialized microprocessors in the late 1970s in response to the needs of speech processing algorithms, and the vast majority of these devices have remained to this day basically audio-rate and, hence, speech processing devices [1]–[5]. These processors present a unique venue in which to both examine and implement speech processing algorithms since even a cursory examination of the device architectures quickly reveals the strong synergy between PDSP features and speech processing algorithms. As a result, specialized but restricted software development skills are necessary to realize speech processing algorithms on these devices.

Within the context of speech processing application realization, PDSPs which provide *fixed-point* data processing capabilities in hardware rather than floating-point capabilities are significantly more important. The simple reason for this is that fixed-point PDSPs are significantly less expensive than floating-point PDSPs but still provide the required computational capabilities for this class of applications. The fixed-point hardware capabilities are used to realize various *types of arithmetic* or *data abstractions* for the infinite-precision mathematical constructs used in algorithms. These abstractions include the well-known *integer arithmetic*, as well as various forms of *fixed-point arithmetic* that

use fixed shifts to control the scale of values within a computation and *block floating-point arithmetic* which performs run-time scale manipulations under programmer control.

General-purpose microprocessors also present an implementation medium that is well suited to many speech processing operations, although not one so well tailored to the task as that provided by PDSPs. All of the algorithmic structures presented here can be realized via microprocessors, and in fact many software libraries have been specifically designed to allow such realization [6]–[7].

49.2 Software Development Paradigms

As with general-purpose algorithms, a single software development paradigm cannot be described under which speech processing algorithms are always implemented. A small set of such paradigms do exist, however, and they are distinguished by just a few salient features.

Imperative vs. Applicative Language

Imperative programming languages specify a program as a sequence of commands to be performed in the order given. All of the familiar high-level programming languages, such as C, C++, or FORTRAN, as well as the assembly languages of most PDSPs, are imperative.

Applicative programming languages, on the other hand, describe a program via a collection of relationships that must be maintained between variables. Applicative languages intended to be programmed directly by the user such as Silage, SIGNAL, LUCID/Lustre, and Esterel, as well as the assembly language of data-flow PDSPs, can all be used to specify speech processing algorithms in a non-imperative manner, but their use to date in real applications is quite limited. And, although usually described as a hardware-description language and used as an intermediate language generated by other tools rather than directly by programmers, from the point of view of this discussion VHDL is an applicative language that can be used to describe speech processing algorithms directly.

Graphical programming environments such as Ptolemy, GOSPL, COSSAP, and SPW also provide an applicative “language” in which speech processing algorithms can be described. However, these environments universally rely on atomic elements that are programmed with a separate paradigm, usually an imperative one.

Most speech processing applications are implemented using imperative languages, and this programming model will be used here. Note, however, that the important distinguishing features of speech processing algorithms, arithmetic and algorithmic constructs, are applicable within any programming paradigm.

High Level Language vs. Assembly Language

Given that an imperative programming paradigm is to be used, the choice of a High Level Language (HLL) or assembly language as an implementation vehicle seems very straightforward [8]–[9]. The common wisdom holds that (1) assembly language should be chosen where execution speed is of the essence, in realizing “signal-processing kernels”, since HLL compilers cannot produce object code of the same efficiency as can be obtained with hand-coded assembly language. However, (2) a high-level language should be used otherwise, in the realization of “control code”, since this allows effective software development and the use of a *top-down* code development strategy.

In PDSP implementations, however, this sensible arrangement is often not possible. The reason for this is that use of a HLL compiler and run-time system makes untoward demands, relatively speaking, on an embedded system where resources such as registers, memory, and instruction cycles are quite scarce. In particular:

1. The settings in the control registers of the processor are often different between signal-processing and control code, and the device is more often than not “in the wrong mode”.

2. The run-time memory organization demanded by a high-level language, typically including a stack on which automatic variables are to be allocated but lacking memory bank control, is one that most system designers are not willing to provide.
3. The standard function-call mechanism of a high-level language does not fit well with the customized register usage demanded in embedded systems programming.

Thus, more often than not, HLL programming is not currently utilized in PDSP systems. This will change, however, as PDSP HLL compilers become more sophisticated and as PDSP architectures become more “microprocessor-like”.

Specialized vs. Standard High Level Languages

Specialized languages are often developed as dialects of standard high level programming languages by the authors of compilers. DSP/C, for example, is an extension of the C language that contains special vector and signal processing operations [10]. While they appear to be quite useful for target code development for speech processing applications, the lack of general support means that these languages are not often used for either algorithm or target code development.

Extensible languages, on the other hand, allow “dialects” of standard programming languages to be created by the end-user. C++ and Ada allow the construction of specialized arithmetic support via *class* and *generic* constructs, respectively. While these languages are quite useful for algorithm development, they generally cannot produce efficient realizations of the kind desired in target code for speech processing applications.

More often than not, when standard high level languages are used, they are simply augmented by libraries of operations. The Signal Processing Toolbox for MatlabTM and the Basic Operators for the C language used in standard speech codecs are good examples of these [6]–[7].

Block vs. Single-Sample Processing

Speech coding applications lend themselves quite well to *block processing*, where individual time-domain signal samples are buffered into vectors or *frames* [11]. This is often done for algorithmic reasons, as in LPC analysis, but significant performance gains can be realized by choosing this processing structure as well, when this is possible.¹

Buffered data can be processed much more efficiently than single samples with typical PDSP architectures because the overhead associated with data transfer and instruction pipelining in these devices can be amortized over the entire vector rather than occurring for each sample. For example, the ubiquitous multiply-accumulate operation can be performed in a single instruction cycle by most PDSPs, but only *within the instruction execution pipeline*, meaning that overhead of several instruction cycles are required to set up for this level of performance. In single-sample processing, this instruction execution rate cannot be achieved.

Frames can be processed *in toto* or divided into *subframes* that are to be processed individually. This technique provides algorithmic flexibility without sacrificing the significant performance enhancement to be achieved with block processing.

Static vs. Dynamic Run-Time Operation

Two disparate philosophies on the operation of any real-time software system are particularly evident in speech processing implementations. *Static* and *dynamic* here indicate that run-time

¹Not all algorithms can use block processing—modems and other signaling systems with very low delay requirements cannot. This technique is generally useful, however, for speech processing applications.

resource requirements, outlined in Table 49.1, can be computed and known at compile-time or only at run-time, respectively. Of course, some mix of these two philosophies can be found in any system, but the emphasis will usually be placed on one or the other.

TABLE 49.1 Static vs. Dynamic Operation

Resource	Static operation	Dynamic operation
Memory allocation	Global	Stack/heap
→ Address computation	Fixed	Stack-relative dynamic
Vector size	Fixed	Data dependent
Execution time	Fixed	Data dependent
→ Branch paths	Time-equivalent	Time-disparate
→ Wait-state insertion ^a	Must be computed	Can be ignored
Data transfer	Polling possible	DMA required
→ Fifo buffers	Not necessary	Required
→ Fifo overflow	Impossible	Possible
Operating system	Not typical	Typical

^a Wait states may be inserted by an interlocked pipeline.

Exact vs. Approximate Arithmetic

The terms *exact* and *approximate* here refer to the concern on the part of the programmer as to whether the results produced by a given arithmetic operation are fully specified by the programmer in a *bit-exact* manner, or whether the best, approximate numerical performance that can be produced by a particular processor is acceptable [12]. For example, IEEE floating-point arithmetic is exact, while machine-dependent floating-point formats can be considered approximate from the point of view of a programmer porting code to that architecture from another. The most important form of exact arithmetic for speech processing applications is that provided by the Basic Operators, which are used in the C language specification provided as part of modern speech coding standards [6]–[7]. As a general rule, the integral and fractional fixed-point arithmetic forms, discussed in Section 49.4, can be considered exact and approximate, respectively.

Approximate arithmetic is much simpler to specify than exact arithmetic, but it is harder to evaluate. In the former case, implementation details are left up to the target architecture, but if the numerical performance of a particular realization does not meet some criteria, gross changes are required in the source code. The problem here is that the criteria are not defined as part of the source code and must be supplied elsewhere. Exact arithmetic, on the other hand, requires excruciating detail in the specification of the algorithm from the outset, but no evaluation of the realization is required since this realization must adhere to the specification.

Approximate arithmetic is the form promoted by the C language where, for example, the data type `int` does not define the precision of the integer or the results of operations that overflow.² It is also the form preferred by software developers working in a native code development environment.³ Exact arithmetic, on the other hand, is preferred by developers who produce standards and who work in cross-code development environments because it eases the task of porting the algorithm from one environment to the other. Care must be exercised in this case, however, as any cross-development

²This is not to say that the C language cannot be *used* to realize exact arithmetic, which it often is through the machine-dependent declaration of data types such as `int16` and `int32`, but rather that the language was not *designed* for use with exact arithmetic.

³*Native* indicates that code for a particular processor is developed on that processor, while *cross* indicates that the host and target processors are different.

introduces inherent biases into an implementation that may be difficult or impractical to realize on a particular target processor [7].

It is well-known that a trade-off always exists between numerical and execution performance, as discussed in Section 49.4. It is not so well-known, however, that approximate arithmetic will always allow an equivalent or better balance to be struck in this trade-off than exact arithmetic. This is because the excruciating detail provided as part of an exact specification supplies not a minimum numerical requirement, but an exact one. In the case where a particular architecture can provide more precision than is specified, extra code must be inserted to remove that precision, resulting in less efficient execution performance. And, precisely because of this, an exact specification is in fact always targeted to a particular PDSP or microprocessor architecture—no algorithm can be specified in an exact manner and be truly portable or architecturally neutral.

49.3 Assembly Language Basics

Assembly languages for PDSPs are closely matched with the PDSP architecture for which they are designed, but they all share common elements [1]–[5]. In particular, multiple processing units must be programmed at the same time:

- adder
- multiplier
- fixed-point logic, such as shifter(s), rounding logic, saturation logic, etc.
- address generation unit
- program memory, for instruction fetch or data fetch
- data memories, perhaps multiple

In some cases, these units operate by default. For example, instruction fetches occur each machine cycle unless program memory is otherwise used. And in other cases, these units are utilized in combination. For example, (1) the DSP56000 multiply-accumulate instructions and (2) all address generation and memory fetch operations are indivisible and not pipelined. In all other cases, however, these processing units must be programmed within the *instruction execution pipeline* in which the outputs of one processing unit are connected directly to the inputs of another.

Coding Paradigms

Distinct coding paradigms are required by the architectures of various PDSPs, basically determined by the pipeline of that device, in order to perform this programming [13, 14]. Several assembly language forms are presented by PDSPs to realize these coding paradigms:

Data stationary coding specifies ultimately the *data* that is operated on by an instruction, but not the *time* at which the operation takes place—the latter is implicit in the form of the instruction. For example, the AT&T DSP32 instruction

$$*r0++ = a0 = *r1++ + *r2++ \quad (49.1)$$

specifies the locations in memory from which the addends should be read and to which the sum should be written, but it is implicit that the sum will be written to memory in the third instruction cycle following this one.

Because of such delays, *illegal* and *erroneous* instruction combinations can be written that cause conflicts in the use of data from both memory and registers—the former can be detected by the assembler, but the latter will simply produce data manipulations different from those intended by programmer.

Time stationary coding specifies the operations that should occur at the *time* that this instruction is executed, while the *data* to be used is whatever is present in the “pipeline registers” at this time. For example, the AT&T DSP16 instruction

$$a1 = a0 + y \qquad y = *r0++ \qquad (49.2)$$

specifies that a sum should occur at this time between the named registers and that a memory read should occur to the *y* register in parallel. No illegal or erroneous instruction combinations are possible in this case.

Interlocked coding solves the instruction combination problems of data stationary coding by automatically introducing extra machine cycles or *wait states* to ensure that conflicts do not occur. While this is convenient for the programmer, it does not produce more efficient execution than pure data stationary coding—on the contrary, it encourages programmers to be less savvy about their product.

Data flow coding is appropriate for machines that realize an applicative paradigm directly, such as the Hughes DFSP or the NEC μ PD7281.

It must be pointed out that a mixture of these coding paradigms is often used in real PDSPs for control of different processing units. For example, the AT&T DSP16, while ostensibly a time-stationary device, utilizes a form of interlocking to allow multiple accesses to the same memory bank in a single instruction cycle [1].

Assembly Languages Forms

Within the four coding paradigms presented above, several assembly language forms can be utilized. First, either an infix form as given in Eq. 49.1 or the traditional assembly language prefix form using instruction mnemonics, as shown in Eq. 49.3 for the Motorola DSP56000, can be used:

$$\text{clr} \quad a \qquad (49.3)$$

Second, the instruction may consist of a single field, as in Eq. 49.1 or Eq. 49.3, or it may contain multiple fields to be executed in parallel, as in Eq. 49.2 or Eq. 49.4:

$$\text{mac} \quad x0, y0, a \quad x: (r0)+, x0 \quad y: (r4)+, y0 \qquad (49.4)$$

Note, however, that even within the multiple fields more than one operation is specified—in both Eq. 49.2 and Eq. 49.4 address register updates are specified along with the memory move. Pure *horizontal microcode*, in which a dedicated field in each instruction word controls a particular processing unit, is used in only a few modern PDSP architectures, but the multiple-field instructions are similar.

Additionally, all PDSPs contain “mode registers” which control operation of particular elements of the device. For example, the *auc* register of the AT&T DSP16 controls the multiplier-shift, and thus the type of arithmetic realized by this processor’s $p=x*y$ instruction. Such mode registers, while prevalent and powerful in extending the effective instruction encoding space of a PDSP, are quite difficult to manage in large programming systems, especially in the design of function libraries.

49.4 Arithmetic

The most fundamental problem encountered during the implementation of speech processing algorithms is that the algorithm must be realized (1) using the finite-precision arithmetic capabilities of real processors rather than the infinite-precision available in mathematic formulae (2) under typically severe cost constraints in terms of the processing capabilities of the target system [15]–[17].

Any arbitrary level of arithmetic performance can be achieved by any processor, but the cost of this performance in terms of machine cycles can be prohibitive, and so an engineering trade-off is required.

Finite-precision arithmetic effects can be broadly classified as *representational* and *operational errors*.

- The bit pattern used to represent a finite-precision value can be of many forms, but all restrict the *range* of values over which a representation can be provided as well as the *precision* or number of bits used for the representation of a given value. No forms of arithmetic allow values outside the range to be represented, but some invoke an exception handler when such is requested. This is not appropriate in most speech processing systems, however, and in this case a finite-precision representation must be provided to approximate this value.

The difference between an infinite-precision value and its finite-precision representation is the representational error, and there are two sources of such error: *truncation error* results from finite precision and *overflow error* results from range violations.

- Finite-precision operators used to transform values can also introduce error. In the case of simple arithmetic operators, this is equivalent to representational error, but it is often useful to conceptualize more complicated operators, such as an FIR or IIR filter, and to characterize the error introduced by that entity.

The engineering trade-off thus becomes an exercise in balancing the *numerical performance* of a realization of an algorithm in terms of truncation error and overflow error under the considerations introduced by possibly wide variance in input signal strengths or *dynamic range*, against implementation cost constraints in terms of target processor choice and available machine cycles on that processor. Because of the importance of this trade-off, it is important to examine different *types of arithmetic* and to evaluate the numerical performance and implementation cost of each type.

For example, floating-point arithmetic produces adequate numerical performance for most speech processing applications. However, the cost of floating-point processors is often prohibitive in dollar terms, and the cost of realizing floating-point arithmetic on a less expensive, fixed-point processor is prohibitive in terms of machine cycles. For this reason, some other type of arithmetic is often a better choice even though it may be numerically inferior and much harder to implement.

Regardless of the type of arithmetic chosen, however, it will be used in speech processing applications as a proxy or *abstraction* for the real-valued, infinite-precision arithmetic of mathematics. An important aspect that must be considered in evaluating finite-precision arithmetic types, then, is the effectiveness of the abstraction they provide for real-valued arithmetic. For example, all arithmetic needed for speech processing applications can be provided by integers, but determining what bit pattern to use to represent π or how to add two values of different scales can be quite difficult with this data abstraction.

Arithmetic Errors as Noise

Considering that most numerical values used in a speech processing algorithm are *signals*, in that they take on distinct values at distinct sample points, the difference between a finite-precision realization and the infinite-precision mathematical model on which it is based can be considered an *error* or *noise signal* that is injected into an algorithm at the point at which that arithmetic is used, as illustrated in Fig. 49.1. Given this model for the error as simply a noise source, finite-precision arithmetic effects can be analyzed in a manner similar to that used for other noise sources in a signal processing system.

An important corollary to this fact is that speech processing algorithms should be, and typically are, designed to be robust in the presence of arithmetic noise, just as they are designed to be robust in the presence of other noise sources.

The model for the noise that is injected at each point is a function of the type of arithmetic used in that operation, however. This noise model is an important element in understanding the motivation for using various types of arithmetic, and is presented where appropriate in the sections that follow.

FIGURE 49.1: Noise model of arithmetic error.

Floating Point

A *floating-point number* consists of a sign bit, a mantissa, and an exponent, and it presents a well-known model for realizing an approximation to real-valued arithmetic, where the value of the number V is given by

$$V = M \cdot \beta^E \quad (49.5)$$

with β the radix of the representation, usually 2, and M and E the effective values of the signed mantissa and the exponent, respectively. A wide variety of floating-point formats exist, especially for PDSPs, of which the IEEE 754 Floating-Point Standard is the most widely utilized for general-purpose processors. These different formats are distinguished chiefly by the precision of the exponent and the mantissa, and the behavior of the arithmetic at the limits of the representable range.

Floating-point arithmetic is usually used only in applications in which such arithmetic capabilities are provided in hardware by the processor—it is not often simulated via software by a processor that provides only fixed-point arithmetic capabilities, but rather another, similar data abstraction is used. While quite powerful and easy-to-use, floating-point arithmetic is actually of little practical value in the realization of speech processing algorithms.

Block Floating Point

A *block floating-point representation* of a vector of length N of numbers \bar{v} consists of a single signed, 2's complement integer of precision B_e representing the exponent e for the block computed

as⁴

$$e = \max_{i \in N} \lceil \log_2 (|v_i|) \rceil \quad (49.6)$$

along with an array of N signed, 2s complement fractions of precision $B_m = b_m + 1$ representing the mantissas m_i to which the exponent can be applied to yield the represented values \hat{v}_i as

$$\hat{v}_i = m_i \cdot 2^{b_m - e} \quad (49.7)$$

The precision of the exponent B_e and of the mantissas B_m are almost always chosen as the word length of the target machine, yielding a *single-precision block floating-point vector*.

Arithmetic on the exponent and mantissas in a block floating-point representation are controlled separately, since significant savings in computation can often be supplied directly by the programmer. For example, if a block floating-point vector is to be computed as the result of a correlation, it is known that the zeroeth lag will produce the value with the largest magnitude, and so the exponent for the vector can be immediately determined. In the absence of such direct support from the programmer, block floating-point computations require either (1) that high precision results be saved in a temporary buffer to be scaled after all values have been computed and the maximum exponent found or (2) that all results be computed twice—once to determine the exponent and a second time to compute the mantissas.

An array of length L of block floating-point vectors of length N can be constructed, yielding a construct consisting of L exponents and $L \cdot N$ mantissa values. This *segmented block floating-point representation* allows better representation of values over a wide dynamic range than is available with a single exponent. It is also quite suited to applications in which a segment of values is known to be of one scale that can be quite different from that of neighboring segments.

In the limit with $N = 1$, (segmented) block floating-point yields the *scalar (segmented) block floating-point representation* which is quite like the well-known (vector) floating-point representation, except that normalization occurs only on demand. This is an appropriate representation to use for quantities of large dynamic range in speech processing applications realized on fixed-point processors where true floating-point would be prohibitively expensive.

Fixed Point

A *fixed-point number* consists of a field of $B = b + 1$ data bits that is interpreted as a binary, 2's complement number relative to a scale factor or *size* that is multiplied by the field to yield a value. The two basic forms of fixed-point numbers are the *integral* and *fractional* forms, in which the *justification* of the data bits within the field determines how the value of a bit pattern is interpreted:

Justification	Field	Size	Value	Range
Right	Integer i	Stepsize Δ	$\Delta \cdot i$	$[-\Delta \cdot 2^b, \Delta \cdot 2^b)$
Left	Fraction f	Fieldsize ϕ	$\phi \cdot f$	$[-\phi, \phi)$

Regardless of the representation, note that the stepsize Δ and fieldsize ϕ are always related as $\phi = \Delta \cdot 2^b$ for quantities of precision $B = b + 1$.

Among other possible fixed-point representations, *center-justified* or *mixed numbers* are quite rare in speech processing applications, and all other common representations are easily derived from the integral and fractional forms.

⁴This is a simplified exponent definition used for purposes of illustration. The actual value used in any particular implementation will be machine dependent, but this is of no consequence except as regards the point at which exponent overflow or underflow occurs, rare occurrences in most systems.

Given the basic machine word length or precision, usually 16 or 24 bits, fixed-point PDSPs universally provide signed, single-precision multiplication producing a double-precision product, along with double-precision addition, which allows numerically efficient computation of a sum-of-products. *Multiple-precision operations* of greater precision, discussed below, must be simulated in software.

The additive operators (addition, subtraction, negation, and absolute value) are equivalent for any fixed-point representation, with the caveat that only numbers of the same type can be combined with the binary additive operators. That is, only numbers of the same precision, form, and size can be added together directly—other combinations require conversion of one or both quantities to another, possibly a third, type before the operation can take place. Given this equivalency, it can be seen that it is the kind of multiplication, controlled by the shift that occurs at the output of the multiplier and the input to the ALU in all processors, that determines the type of arithmetic realized by a device, as shown in Table 49.2.

TABLE 49.2 Multiplier-Shift Determines

Processor Type	
Processor type	Shift ^a
Integral	0
Fractional	1
Biquadratic ^b	2
Summation ^b	-N

^a This value is a relative one—the value zero could just as easily have been assigned to the fractional machine.

^b These names derive from the use of this type of arithmetic in second-order IIR filter sections and long summations, respectively.

Fixed-point PDSPs abound with shifters—at the ALU inputs, the multiplier output, accumulator outputs, and perhaps within an independent barrel shifter. Because of a dearth of instruction encoding space, however, these are often fixed or controlled from mode registers rather than instructions or general registers, as discussed in Section 49.3.

The kind of multiplication realized by a processor also defines the kinds of data abstractions that are most useful given that machine architecture:

Q-notation is a natural extension of integer notation that is useful for right-justified arithmetic.

A B -bit Q_n fixed-point number is defined to have a binary point to the right of bit n , where bit 0 is the Least Significant Bit (LSB), yielding a stepsize $\Delta = 2^B$ a range $[-2^{B-n-1}, 2^{B-n-1})$. Multiplication is defined as producing a product with a precision and Q -value that are the sums of those of the multiplicands, respectively:

$$B_{x \star y} = B_x + B_y \quad (49.8)$$

$$n_{x \star y} = n_x + n_y \quad (49.9)$$

When precision is increased or reduced, it is naturally done on the left of a right-justified quantity, as with an integer. This seemingly simple operation is catastrophic when Q -notation is used to model real-valued arithmetic, however, since it produces overflow. Thus, precision must not be omitted at any point when Q -notation is in use—the term “a Q_n number” should always be qualified as “a B -bit, Q_n number”.

Scaled fractions are a natural extension of fractions that are useful for left-justified arithmetic.

A $b + 1$ -bit fractional number of fieldsize ϕ has a range $[-\phi, \phi)$, and multiplication is defined as producing a product with a precision and fieldsize that are the sum and product of those of the multiplicands, respectively:

$$b_{x \star y} = b_x + b_y \quad (49.10)$$

$$\phi_{x \star y} = \phi_x \cdot \phi_y \quad (49.11)$$

With this notation, biquadratic quantities can be seen to be simply scaled-fractions of fieldsize 2.0.

Precision is much less important for scaled-fractions than for Q-values. This is because increasing or reducing the precision of a left-justified quantity naturally occurs on the right, which simply raises or lowers the accuracy of the representation. Thus, while important as regards numerical performance, precision is not required in describing a quantity as “a scaled-fractional of fieldsize ϕ ”.

It should be pointed out that use of a right-justified data abstraction on a left-justified machine, or vice versa, is quite difficult.

Reduction describes the common response to overflow in fixed-point additive operations, where a sum is simply allowed to “wrap around” in the 2’s complement representation:

$$x+y \equiv \text{sgn}(x+y) \cdot [(|x+y| + \phi) \bmod 2\phi - \phi] \quad (49.12)$$

Saturation describes an alternate response to overflow where the result is set to the maximum representable value of the appropriate sign:

$$x+y \equiv \begin{cases} \phi - \Delta & x+y \geq \phi \\ x+y & -\phi \geq x+y < \phi \\ -\phi & x+y < -\phi \end{cases} \quad (49.13)$$

The bit patterns that result from saturation are 0x7f...f and 0x80...0 in the cases of positive and negative overflow, respectively. Fixed-point PDSPs typically provide hardware to realize saturation because it gives a significant boost to the numerical performance of many speech processing algorithms in the presence of overflow. In most cases, when reduction arithmetic is in use *no* overflow can be tolerated, even in extremely unlikely situations, while *some* overflow can be tolerated with saturation arithmetic in most algorithms.

General-purpose microprocessors traditionally provide only a single overflow-detection bit. Fixed-point PDSPs, on the other hand, typically provide $N > 1$ overflow bits for each register that can be the destination of an additive operation in the ALU, usually termed *accumulators*. This feature allows summations of up to 2^N terms to be performed while the result can be saturated correctly if overflow does occur. The overflow bits are alternately called *secondary overflow bits*, *guard bits*, or *extension words* by different manufacturers.

For summations involving more than 2^N terms, it is often useful to determine if overflow occurred during the summation, even though enough information to saturate the result is not available—this capability is also required for the support of block floating-point operations. *Sticky* or *permanent* overflow bits are set when overflow occurs, but they are only cleared under programmer control, allowing such overflow detection. And, it is sometimes useful to provide such permanent overflow detection at a saturation value other than the range, as noted in Section 49.5.

Another option in the case of summations involving more than 2^N terms is to scale the inputs to the summation and then perform saturation at the end of the summation during a *rescaling* operation. As with all scaling operations, however, this one trades off overflow error for truncation error, and

it may introduce unacceptable noise levels. For example, in the case of a summation of K i.i.d. Gaussian random variables, prescaling introduces a $3\lceil\log_2 K\rceil$ dB SNR degradation relative to an unscaled summation.

The nature of fixed-point PDSPs as single-precision multiply/double-precision add machines means that conversions between single- and double-precision quantities is quite common. *Extension* from single- to double-precision always takes place on the right for fixed-point quantities, except in the rare cases where integers are involved, and the extension is always with zeroes. Conversion from double- to single-precision, however, can be performed by *truncation* where the extra bits are simply removed,

$$(x \& ((-1) << B)) \quad (49.14)$$

where B is the basic machine precision, or by *rounding*:

$$((x + (1 << B - 1)) \& ((-1) << B)) \quad (49.15)$$

Fixed-point PDSPs typically provide hardware to realize rounding because it gives a significant boost to the numerical performance of many speech processing algorithms. In most applications, it can be safely assumed that the low bits of the 2s complement value that are removed as part of a conversion operation are neither deterministic nor correlated and that they represent values that are uniformly distributed over the range $[0, \Delta)$. In this case, rounding produces errors that statistically are approximately zero-mean, while truncation produces errors with mean $\mu \approx \frac{1}{2}\Delta$, and this *bias error* can be significant in many situations.

Multiple-precision operations can be simulated in software in many ways, but usually one or more of the following formats is used to represent them:

Native format represents double- and higher-precision numbers as simply the appropriate bit pattern broken into multiple machine words. High-precision additive operations can be directly realized in this format using a carry flag, but multiplication of such quantities requires unsigned multiplication capabilities, which are lacking in most PDSPs and many general-purpose processors.

Double precision format (DPF) allows double-precision fractional multiplication, with double-precision inputs and double-precision output, to be realized using signed multiplier capabilities by representing a double-precision value as the concatenation of the high-order word with the low-order word logically right-shifted by one bit.

Double round format (DRF) allows double-precision multiplication, both integral and fractional, to be realized using signed multiplier capabilities by representing a double-precision value as the concatenation of the high-order word that would result from rounding the double-precision quantity to single-precision, with the original low-order word.

These representations are illustrated in Table 49.3.

TABLE 49.3 Double-Precision
Formats

Format	High word	Low word
Native	0x89AB	0xCDEF
DPF	0x89AB	0x66F7
DRF	0x89AC	0xCDEF

49.5 Algorithmic Constructs

The second major distinction between implementations of digital speech processing algorithms and general-purpose algorithms concerns the algorithmic constructs used in their realization, and the most important of these are discussed below.

Delay Lines

Delay lines, which allow the storage of sample values from one operational cycle to the next, are an important component of speech processing systems, and they can be realized in a variety of ways with PDSPs:

Registers, including implicit pipeline registers, can be used to effectively realize short delays, including the one- and two-tap delays required in IIR filters.

Modulo addressing causes an address register to “wrap around” within a defined range to the start of a buffer when an attempt is made to increment that register past the end of the defined range. A delay line can be realized using modulo addressing by utilizing the location containing the expired data at a given step for the new data and by bumping the address register accordingly.

Most PDSPs do provide modulo-addressing capabilities, but often in only a limited manner. For example, strides greater than one or negative strides may not be supported, and the buffer may require a certain alignment in memory.

Writeback causes a delay line element to be written back to memory at a new location after it is read and used in a computation. While this technique is quite powerful as regards the rearrangement of data in memory, it is quite expensive in terms of memory bandwidth requirements.

These techniques are most useful for fixed delays, but equivalent methods can be used to realize variable delays.

Transforms

Modern PDSPs provide specialized support for transforms, and inverse transforms as well, especially the radix-2 FFT. This can include the ability to

- Compute both a sum and a difference on the same data in parallel.
- Compute addresses using *reverse-carry addition*, where the carry propagates to the right rather than to the left as in ordinary addition. This allows straightforward computation of the bit-reversed addresses needed to unscramble the results of many transform calculations.
- Detect overflow in fixed-point computations at a point other than the saturation point. This can be used to predict that overflow is likely to occur at the current transform stage based on the output of the previous stage *before computation of the current stage begins*. With this capability, the data can be scaled as part of the current processing stage if and only if it is necessary, efficiently producing an optimally scaled transform output.

Vector Structure Organization

Vectors of atomic components are always laid out simply as an array of the elements. When the components are not atomic, however, as with segmented block floating-point or complex quantities, an alternative is to organize the vector as two arrays: an exponent array and a mantissa array for segmented block floating-point quantities, or a real array and an imaginary array for complex quantities.

The choice of *interleaved* or *separate* arrays, as these two techniques are known, is a trade-off between resource demands, in terms of the number of address registers needed to access a single element, vs. flexibility, in terms of the order of access and stride control that is possible.

Zippering

Zippering is a generic term that is used to refer to the process of performing a sequence of multiply-accumulate operations on input arrays to realize the signal processing tasks of scaling, windowing, convolution, auto- and cross-correlation, and FIR filtering. The only real difference between these conceptually distinct tasks is (1) the choice of data or constant input arrays and (2) the order of access within these arrays.

PDSPs are designed to implement this operation, above all others, efficiently—their performance here is what distinguishes them most from general-purpose and RISC microprocessors. Regardless of the coding paradigm used,⁵ all PDSPs allow in a single instruction cycle the following:

- two memory accesses, either data-constant or data-data
- two address register updates
- a single-precision multiply
- a double-precision accumulate

Programming contortions are often required to achieve this throughput in the face of processor limitations and memory access penalties, but the holy grail single-cycle operation is always attainable.

Mathematical Functions

As in general-purpose programming, higher level mathematical functions can be realized within speech processing applications in one of three ways:

Bitwise computation can be used to build an exact representation one bit at a time. This technique is often used to implement single-precision division and square root functions, and some PDSPs even include special iterative instructions to accomplish these operations in a single cycle per output bit. For example, unsigned division can be realized for the Motorola 56000 as follows:

```
and  #$fe,ccr ; Clear quotient sign bit
rep  #24      ; Form 24 bit quotient,
div  x0,a     ; ... one bit at a time. (49.16)
```

Approximate computation, such as Newton's method, is often used to produce a double-precision result from a single-precision estimate.

Table lookup is often used, along with linear interpolation between sample points, especially for trigonometric, logarithmic, and inverse functions. Several PDSPs even include the necessary tables in ROM.

Looping Constructs

Loop counting can be done with general registers, and this is required in deeply nested loops, but hardware support is often provided by PDSPs for low- and zero-overhead loops. *Low-overhead loops* utilize a special counter register to realize a branching construct similar to the well-known decrement-and-branch instruction of the Motorola 68000 microprocessor. They are “low overhead”

⁵Coding paradigms are discussed in Section 49.3.

in that the cost of the loop is typically only that of the branch instruction per iteration—separate increment (or decrement) and test instructions are not needed. *Zero-overhead loops* go one step further and eliminate even the cost of the branch instruction per iteration. They do this via special-purpose hardware to perform the program counter manipulations normally handled in the branch instruction. There is an overhead cost at the start of the loop, but the cost per iteration is truly zero.

Loop reversal is an important concept that often allows more efficient coding of speech processing constructs. In its simplest form, a loop counter is run backward to allow more efficient counting of iterations, or an address register is run backward to allow it to be reused without having to reinitialize it. In both of these cases, the reversal of the counter or address register is only possible when there are no dependencies from one loop iteration to the next. More powerful, however, is to perform memory access via a temporary register to allow loops that need to run in one direction for algorithmic reasons to be coded in the opposite direction. This technique can be used to exploit the pipelined nature of PDSPs to great effect.

50.1 Introduction

Experts in every field of study depend on specialized tools. In the case of speech research and development, the dominant tools today are computer programs. In this article, we present an overview of key technical approaches and features that are prevalent today.

We restrict the discussion to software intended to support R&D, as opposed to software for commercial applications of speech processing. For example, we ignore DSP programming (which is discussed in the previous article). Also, we concentrate on software intended to support the special-

ities of speech analysis, coding, synthesis, and recognition, since these are the main subjects of this chapter. However, much of what we have to say applies as well to the needs of those in such closely related areas as psycho-acoustics, clinical voice analysis, sound and vibration, etc.

We do not attempt to survey available software packages, as the result would likely be obsolete by the time this book is printed. The examples mentioned are illustrative, and not intended to provide a thorough or balanced review. Our aim is to provide sufficient background so that readers can assess their needs and understand the differences among available tools. Up-to-date surveys are readily available online (see Section 50.13).

In general, there are three common uses of speech R&D software:

- *Teaching*, e.g., homework assignments for a basic course in speech processing
- *Interactive, free-form exploration*, e.g., designing a filter and evaluating its effects on a speech processing system
- *Batch experiments*, e.g., training and testing speech coders or speech recognizers using a large database

The relative importance of various features differs among these uses. For example, in conducting batch experiments, it is important that large signals can be handled, and that complicated algorithms execute efficiently. For teaching, on the other hand, these features are less important than simplicity, quick experimentation, and ease-of-use. Because of practical limitations, such differences in priority mean that no one software package today can meet all needs.

To explain the variation among current approaches, we identify a number of distinguishing characteristics. These characteristics are not independent (i.e., there is considerable overlap), but they do help to present the overall view.

For simplicity, we will refer to any particular speech R&D software as “the speech software”.

50.2 Historical Highlights

Early or significant examples of speech R&D software include “Visible Speech” [5], *MITSYN* [1], and Lloyd Rice’s *WAVE* program of the mid 1970s (not to be confused with David Talkin’s *waves* [8]).

The first general, commercial system that achieved widespread acceptance was the Interactive Laboratory System (*ILS*) from Signal Technology Incorporated, which was popular in the late 1970s and early 1980s. Using the terminology defined below, *ILS* is compute-oriented software with an operating-system-based environment. The first popular, display-oriented, workspace-based speech software was David Shipman’s LISP-machine application called *Spire* [6].

50.3 The User’s Environment (OS-Based vs. Workspace-Based)

In some cases, the user sees the speech software as an extension of the computer’s operating system. We call this “operating-system-based” (or OS-based); an example is the Entropic Signal Processing System (*ESPS*) [7].

In other cases, the software provides its own operating environment. We call this “workspace-based” (from the term used in implementations of the programming language *APL*); an example is *MATLAB*TM (from The Mathworks).

50.3.1 Operating-System-Based Environment

In this approach, signals are represented as files under the native operating system (e.g., Unix, DOS), and the software consists of a set of programs that can be invoked separately to process or display signals in various ways. Thus, the user sees the software as an extension of an already-familiar operating system. Because signals are represented as files, the speech software inherits file manipulation capabilities from the operating system. Under Unix, for example, signals can be copied and moved respectively using the *cp* and *mv* programs, and they can be organized as directory trees in the Unix hierarchical file system (including NFS).

Similarly, the speech software inherits extension capabilities inherent in the operating system. Under Unix, for example, extensions can be created using shell scripts in various languages (*sh*, *cs*, *Tcl*, *perl*, etc.), as well as such facilities as pipes and remote execution. OS-based speech software packages are often called command-line packages because usage typically involves providing a sequence of commands to some type of shell.

50.3.2 Workspace-Based Environment

In this approach, the user interacts with a single application program that takes over from the operating system. Signals, which may or may not correspond to files, are typically represented as variables in some kind of virtual space. Various commands are available to process or display the signals. Such a workspace is often analogous to a personal blackboard.

Workspace-based systems usually offer means for saving the current workspace contents and for loading previously saved workspaces.

An extension mechanism is typically provided by a command interpreter for a simple language that includes the available operations and a means for encapsulating and invoking command sequences (e.g., in a function or procedure definition). In effect, the speech software provides its own shell to the user.

50.4 Compute-Oriented vs. Display-Oriented

This distinction concerns whether the speech software emphasizes computation or visualization or both.

50.4.1 Compute-Oriented Software

If there is a large number of signal processing operations relative to the number of signal display operations, we say that the software is compute-oriented. Such software typically can be operated without a display device and the user thinks of it primarily as a computation package that supports such functions as spectral analysis, filtering, linear prediction, quantization, analysis/synthesis, pattern classification, Hidden Markov Model (HMM) training, speech recognition, etc.

Compute-oriented software can be either OS-based or workspace based. Examples include *ESPS*, *MATLAB*TM, and the Hidden Markov Model Toolkit (*HTK*) (from Cambridge University and Entropic).

50.4.2 Display-Oriented Software

In contrast, display-oriented speech software is not intended to and often cannot operate without a display device. The primary purpose is to support visual inspection of waveforms, spectrograms, and other parametric representations. The user typically interacts with the software using a mouse or other pointing device to initiate display operations such as scrolling, zooming, enlarging, etc.

While the software may also provide computations that can be performed on displayed signals (or marked segments of displayed signals), the user thinks of the software as supporting visualization more than computation. An example is the *waves* program [8].

50.4.3 Hybrid Compute/Display-Oriented Software

Hybrid compute/display software combines the best of both. Interactions are typically by means of a display device, but computational capabilities are rich. The computational capabilities may be built-in to workspace-based speech software, or may be OS-based but accessible from the display program. Examples include the Computerized Speech Lab (*CSL*) from Kay Elemetrics Corp., and the combination of *ESPS* and *waves*.

50.5 Compiled vs. Interpreted

Here we distinguish according to whether the bulk of the signal processing or display code (whether written by developers or users) is interpreted or compiled.

50.5.1 Interpreted Software

The interpreter language may be specially designed for the software (e.g., S-PLUS from Statistical Sciences, Inc., and *MATLAB*TM), or may be an existing, general purpose language (e.g., LISP is used in *N!Power* from Signal Technology, Inc.).

Compared to compiler languages, interpreter languages tend to be simpler and easier to learn. Furthermore, it is usually easier and faster to write and test programs under an interpreter. The disadvantage, relative to compiled languages, is that the resulting programs can be quite slow to run. As a result, interpreted speech software is usually better suited for teaching and interactive exploration than for batch experiments.

50.5.2 Compiled Software

Compared to interpreted languages, compiled languages (e.g., FORTRAN, C, C++) tend to be more complicated and harder to learn. Compared to interpreted programs, compiled programs are slower to write and test, but considerably faster to run. As a result, compiled speech software is usually better suited for batch experiments than for teaching.

50.5.3 Hybrid Interpreted/Compiled Software

Some interpreters make it possible to create new language commands with an underlying implementation that is compiled. This allows a hybrid approach that can combine the best of both.

Some languages provide a hybrid approach in which the source code is pre-compiled quickly into intermediate code that is then (usually!) interpreted. *Java* is a good example.

If compiled speech software is OS-based, signal processing scripts can typically be written in an interpretive language (e.g., a *sh* script containing a sequence of calls to *ESPS* programs). Thus, hybrid systems can also be based on compiled software.

50.5.4 Computation vs. Display

The distinction between compiled and interpreted languages is relevant mostly to the computational aspects of the speech software. However, the distinction can apply as well to display software, since

some display programs are compiled (e.g., using Motif) while others exploit interpreters (e.g., *Tcl/Tk*, *Java*).

50.6 Specifying Operations Among Signals

Here we are concerned with the means by which users specify what operations are to be done and on what signals. This consideration is relevant to how speech software can be extended with user-defined operations (see Section 50.7), but is an issue even in software that is not extensible.

The main distinction is between a text-based interface and a visual (“point-and-click”) interface. Visual interfaces tend to be less general but easier to use.

50.6.1 Text-Based Interfaces

Traditional interfaces for specifying computations are based on a textual-representation in the form of scripts and programs. For OS-based speech software, operations are typically specified by typing the name of a command (with possible options) directly to a shell. One can also enter a sequence of such commands into a text editor when preparing a script.

This style of specifying operations also is available for workspace-based speech software that is based on a command interpreter. In this case, the text comprises legal commands and programs in the interpreter language.

Both OS-based and workspace-based speech software may also permit the specification of operations using source code in a high-level language (e.g., C) that gets compiled.

50.6.2 Visual (“Point-and-Click”) Interfaces

The point-and-click approach has become the ubiquitous user-interface of the 1990s. Operations and operands (signals) are specified by using a mouse or other pointing device to interact with on-screen graphical user-interface (GUI) controls such as buttons and menus. The interface may also have a text-based component to allow the direct entry of parameter values or formulas relating signals.

Visual Interfaces for Display-Oriented Software

In display-oriented software, the signals on which operations are to be performed are visible as waveforms or other directly representative graphics.

A typical user-interaction proceeds as follows: A relevant signal is specified by a mouse-click operation (if a signal segment is involved, it is selected by a click-and-drag operation or by a pair of mouse-click operations). The operation to be performed is then specified by mouse click operations on screen buttons, pull-down menus, or pop-up menus.

This style works very well for unary operations (e.g., compute and display the spectrogram of a given signal segment), and moderately well for binary operations (e.g., add two signals). But it is awkward for operations that have more than two inputs. It is also awkward for specifying chained calculations, especially if you want to repeat the calculations for a new set of signals.

One solution to these problems is provided by a “calculator-style” interface that looks and acts like a familiar arithmetic calculator (except the operands are signal names and the operations are signal processing operations).

Another solution is the “spreadsheet-style” interface. The analogy with spreadsheets is tight. Imagine a spreadsheet in which the cells are replaced by images (waveforms, spectrograms, etc.) connected logically by formulas. For example, one cell might show a test signal, a second might show the results of filtering it, and a third might show a spectrogram of a portion of the filtered signal. This exemplifies a spreadsheet-style interface for speech software.

A spreadsheet-style interface provides some means for specifying the “formulas” that relate the various “cells”. This formula interface might itself be implemented in a point-and-click fashion, or it might permit direct entry of formulas in some interpretive language. Speech software with a spreadsheet-style interface will maintain consistency among the visible signals. Thus, if one of the signals is edited or replaced, the other signal graphics change correspondingly, according to the underlying formulas.

DADisp (from DSP Development Corporation) is an example of a spreadsheet-style interface.

Visual Interfaces for Compute-Oriented Software

In a visual interface for display-oriented software, the focus is on the signals themselves. In a visual interface for compute-oriented software, on the other hand, the focus is on the operations. Operations among signals typically are represented as icons with one or more input and output lines that interconnect the operations. In effect, the representation of a signal is reduced to a straight line indicating its relationship (input or output) with respect to operations. Such visual interfaces are often called block-diagram interfaces. In effect, a block-diagram interface provides a visual representation of the computation chain. Various point-and-click means are provided to support the user in creating, examining, and modifying block diagrams.

Ptolomy [4] and *N!Power* are examples of systems that provide a block-diagram interface.

Limitations of Visual Interfaces

Although much in vogue, visual interfaces are inherently limited as a means for specifying signal computations.

For example, the analogy between spreadsheets and spreadsheet-style speech software continues. For simple signal computations, the spreadsheet-style interface can be very useful; computations are simple to set up and informative when operating. For complicated computations, however, the spreadsheet-style interface inherits all of the worst features of spreadsheet programming. It is difficult to encapsulate common sub-calculations, and it is difficult to organize the “program” so that the computational structure is self-evident. The result is that spreadsheet-style programs are hard to write, hard to read, and error-prone.

In this respect, block-diagram interfaces do a better job since their main focus is on the underlying computation rather than on the signals themselves. Thus, screen “real-estate” is devoted to the computation rather than to the signal graphics. However, as the complexity of computations grows, the geometric and visual approach eventually becomes unwieldy. When was the last time you used a flowchart to design or document a program?

It follows that visual interfaces for specifying computations tend to be best suited for teaching and interactive exploration.

50.6.3 Parametric Control of Operations

Speech processing operations often are based on complicated algorithms with numerous parameters. Consequently, the means for specifying parameters is an important issue for speech software.

The simplest form of parametric control is provided by command-line options on command-line programs. This is convenient, but can be cumbersome if there are many parameters. A common alternative is to read parameter values from parameter files that are prepared in advance. Typically, command-line values can be used to override values in the parameter file. A third input source for parameter values is directly from the user in response to prompts issued by the program.

Some systems offer the flexibility of a hierarchy of inputs for parameter values, for example:

- default values

- values from a global parameter file read by all programs
- values from a program-specific parameter file
- values from the command line
- values from the user in response to run-time prompts

In some situations, it is helpful if a current default value is replaced by the most recent input from a given parameter source. We refer to this property as “parameter persistence”.

50.7 Extensibility (Closed vs. Open Systems)

Speech software is “closed” if there is no provision for the user to extend it. There is a fixed set of operations available to process and display signals. What you get is all you get.

OS-based systems are always extensible to a degree because they inherit scripting capabilities from the OS, which permits the creation of new commands. They may also provide programming libraries so that the user can write and compile new programs and use them as commands.

Workspace-based systems may be extensible if they are based on an interpreter whose programming language includes the concept of an encapsulated procedure. If so, then users can write scripts that define new commands. Some systems also allow the interpreter to be extended with commands that are implemented by underlying code in C or some other compiled language.

In general, for speech software to be extensible, it must be possible to specify operations (see Section 50.6) and also to re-use the resulting specifications in other contexts. A block-diagram interface is extensible, for example, if a given diagram can be reduced to an icon that is available for use as a single block in another diagram.

For speech software with visual interfaces, extensibility considerations also include the ability to specify new GUI controls (visible menus and buttons), the ability to tie arbitrary internal and external computations to GUI controls, and the ability to define new display methods for new signal types.

In general, extended commands may behave differently from the built-in commands provided with the speech software. For example, built-in commands may share a common user interface that is difficult to implement in an independent script or program (such a common interface might provide standard parameters for debug control, standard processing of parameter files, etc.).

If user-defined scripts, programs, and GUI components are indistinguishable from built-in facilities, we say that the speech software provides seamless extensibility.

50.8 Consistency Maintenance

A speech processing chain involves signals, operations, and parameter sets. An important consideration for speech software is whether or not consistency is maintained among all of these. Thus, for example, if one input signal is replaced with another, are all intermediate and output signals recalculated automatically? Consistency maintenance is primarily an issue for speech software with visual interfaces, namely whether or not the software guarantees that all aspects of the visible displays are consistent with each other.

Spreadsheet-style interfaces (for display-oriented software) and block-diagram interfaces (for compute-oriented software) usually provide consistency maintenance.

50.9 Other Characteristics of Common Approaches

50.9.1 Memory-based vs. File-based

“Memory-based” speech software carries out all of its processing and display operations on signals that are stored entirely within memory, regardless of whether or not the signals also have an external representation as a disk file. This approach has obvious limitations with respect to signal size, but it simplifies programming and yields fast operation. Thus, memory-based software is well-suited for teaching and the interactive exploration of small samples.

In “file-based” speech software, on the other hand, signals are represented and manipulated as disk files. The software partially buffers portions of the signal in memory as required for processing and display operations. Although programming can be more complicated, the advantage is that there are no inherent limitations on signal size. The file-based approach is, therefore, well-suited for large scale experiments.

50.9.2 Documentation of Processing History

Modern speech processing involves complicated algorithms with many processing steps and operating parameters. As a result, it is often important to be able to reconstruct exactly how a given signal was produced. Speech software can help here by creating appropriate records as signal and parameter files are processed.

The most common method for recording this information about a given signal is to put it in the same file as the signal. Most modern speech software uses a file format that includes a “file header” that is used for this purpose. Most systems store at least some information in the header, e.g., the sampling rate of the signal. Others, such as *ESPS*, attempt to store all relevant information. In this approach, the header of a signal file produced by any program includes the program name, values of processing parameters, and the names and headers of all source files. The header is a recursive structure, so that the headers of the source files themselves contain the names and headers of files that were prior sources. Thus, a signal file header contains the headers of all source files in the processing chain. It follows that files contain a complete history of the origin of the data in the file and all the intermediate processing steps. The importance of record keeping grows with the complexity of computation chains and the extent of available parametric control.

50.9.3 Personalization

There is considerable variation in the extent to which speech software can be customized to suit personal requirements and tastes. Some systems cannot be personalized at all; they start out the same way, every time. But most systems store personal preferences and use them again next time. Savable preferences may include color selections, button layout, button semantics, menu contents, currently loaded signals, visible windows, window arrangement, and default parameter sets for speech processing operations.

At the extreme, some systems can save a complete “snapshot” that permits exact resumption. This is particularly important for the interactive study of complicated signal configurations across repeated software sessions.

50.9.4 Real-Time Performance

Software is generally described as “real-time” if it is able to keep up with relevant, changing inputs. In the case of speech software, this usually means that the software can keep up with input speech.

Even this definition is not particularly meaningful unless the input speech is itself coming from a

human speaker and digitized in real-time. Otherwise, the real-issue is whether or not the software is fast enough to keep up with interactive use.

For example, if one is testing speech recognition software by directly speaking into the computer, real-time performance is important. It is less important, on the other hand, if the test procedure involves running batch scripts on a database of speech files.

If the speech software is designed to take input directly from devices (or pipes, in the case of Unix), then the issue becomes one of CPU speed.

50.9.5 Source Availability

It is unfortunate but true that the best documentation for a given speech processing command is often the source code. Thus, the availability of source code may be an important factor for this reason alone. Typically, this is more important when the software is used in advanced R&D applications. Sources also are needed if users have requirements to port the speech software to additional platforms. Source availability may also be important for extensibility, since it may not be possible to extend the speech software without the sources.

If the speech software is interpreter-based, sources of interest will include the sources for any built-in operations that are implemented as interpreter scripts.

50.9.6 Hardware Requirements

Speech software may require the installation of special purpose hardware. There are two main reasons for such requirements: to accelerate particular computations (e.g., spectrograms), and to provide speech I/O with A/D and D/A converters.

Such hardware has several disadvantages. It adds to the system cost, and it decreases the overall reliability of the system. It may also constrain system software upgrades; for example, the extra hardware may use special device drivers that do not survive OS upgrades. Special purpose hardware used to be common, but is less so now owing to the continuing increase in CPU speeds and the prevalence of built-in audio I/O. It is still important, however, when maximum speed and high-quality audio I/O are important. *CSL* is a good example of an integrated hardware/software approach.

50.9.7 Cross-Platform Compatibility

If your hardware platform may change or your site has a variety of platforms, then it is important to consider whether the speech software is available across a variety of platforms. Source availability (Section 50.9.5) is relevant here.

If you intend to run the speech software on several platforms that have different underlying numeric representations (a byte order difference being most likely), then it is important to know whether the file formats and signal I/O software support transparent data exchange.

50.9.8 Degree of Specialization

Some speech software is intended for general purpose work in speech (e.g., *ESPS/waves*, *MATLAB*TM). Other software is intended for more specialized usage. Some of the areas where specialized software tools may be relevant include linguistics, recognition, synthesis, coding, psycho-acoustics, clinical-voice, music, multi-media, sound and vibration, etc. Two examples are *HTK* for recognition, and *Delta* (from Eloquent Technology) for synthesis.

50.9.9 Support for Speech Input and Output

In the past, built-in speech I/O hardware was uncommon in workstations and PCs, so speech software typically supported speech I/O by means of add-on hardware supplied with the software or available from other third parties. This provided the desired capability, albeit with the disadvantages mentioned earlier (see Section 50.9.6).

Today most workstations and PCs have built-in audio support that can be used directly by the speech software. This avoids the disadvantages of add-on hardware, but the resulting A/D-D/A quality can be too noisy or otherwise inadequate for use in speech R&D (the built-in audio is typically designed for more mundane requirements). There are various reasons why special-purpose hardware may still be needed, including:

- need for more than two channels
- need for very high sampling rates
- compatibility with special hardware (e.g., DAT tape)

50.10 File Formats (Data Import/Export)

Signal file formats are fundamentally important because they determine how easy it is for independent programs to read and write the files (interoperability). Furthermore, the format determines whether files can contain all of the information that a program might need to operate on the file's primary data (e.g., can the file contain the sampling frequency in addition to a waveform itself?).

The best way to design speech file formats is hotly debated, but the clear trend has been towards “self-describing” file formats that include information about the names, data types, and layout of all data in the file. (For example, this permits programs to retrieve data by name.)

There are many popular file formats, and various programs are available for converting among them (e.g., SOX). For speech sampled data, the most important file format is Sphere (from NIST), which is used in the speech databases available from the Linguistic Data Consortium (LDC). Sphere supports several data compression formats in a variety of standard and specialized formats.

Sphere works well for sampled data files, but is limited for more general speech data files. A general purpose, public-domain format (*Esignal*) has recently been made available by Entropic.

50.11 Speech Databases

Numerous databases (or corpora) of speech are available from various sources. For a current list, see the comp.speech Frequently Asked Questions (FAQ) (see Section 50.13). The largest supplier of speech data is the Linguistic Data Consortium, which publishes a large number of CDs containing speech and linguistic data.

50.12 Summary of Characteristics and Uses

In Section 50.1, we mentioned that the three most common uses for speech software are teaching, interactive exploration, and batch experiments. And at various points during the discussion of speech software characteristics, we mentioned their relative importance for the different classes of software uses. We attempt to summarize this in Table 50.1, where the symbol “•” indicates that a characteristic is particularly useful or important.

It is important not to take Table 50.1 too seriously. As we mentioned at the outset, the various distinguishing characteristics discussed in this section are not independent (i.e., there is considerable

overlap). Furthermore, the three classes of software use are broad and not always easily distinguishable; i.e., the importance of particular software characteristics depends a lot on the details of intended use. Nevertheless, Table 50.1 is a reasonable starting point for evaluating particular software in the context of intended use.

TABLE 50.1 Relative Importance of Software Characteristics

	Teaching	Interactive exploration	Batch experiments
OS-based (50.3.1)			•
Workspace-based (50.3.2)	•		
Compute-oriented (50.4.1)			•
Display-oriented (50.4.2)	•	•	
Compiled (50.5.2)			•

50.13 Sources for Finding Out What is Currently Available

The best single online source of general information is the Internet news group comp.speech, and in particular its FAQ (see <http://svr-www.eng.cam.ac.uk/comp.speech/>). Use this as a starting point.

Here are some other WWW sites that (at this writing) contain speech software information or pointers to other sites:

<http://svr-www.eng.cam.ac.uk>
<http://mambo.ucsc.edu/psl/speech.html>
http://www.bdti.com/faq/dsp_faq.html
<http://www ldc.upenn.edu>
<http://www.entropy.com>

50.14 Future Trends

From the user's viewpoint, speech software will continue to become easier to use, with a heavier reliance on visual interfaces with consistency maintenance.

Calculator, spreadsheet, and block-diagram interfaces will become more common, but will not eliminate text-based (programming, scripting) interfaces for specifying computations and system extensions.

Software will become more open. Seamless extensibility will be more common, and extensions will be easier. GUI extensions as well as computation extensions will be supported.

There will be less of a distinction between compute-oriented and display-oriented speech software. Hybrid compute/display-oriented software will dominate.

Visualization will become more important and more sophisticated, particularly for multidimensional data. "Movies" will be used to show arbitrary 3D data. Sound will be used to represent an arbitrary dimension. Various methods will be available to project N-dimensional data into 2- or 3-space. (This will be used, for example, to show aspects of vector quantization or HMM clustering.)

Public-domain file formats will dominate proprietary formats. Networked computers will be used for parallel computation if available. *Tcl/Tk* and *Java* will grow in popularity as a base for graphical data displays and user interfaces.

IMAGE AND VIDEO SIGNAL PROCESSING is quite different from other forms of signal processing for a variety of reasons. The most obvious difference lies in the fact that these signals are two or three dimensional. This means that some familiar techniques used for processing one-dimensional signals, for example, those that require factorization of polynomials, have to be abandoned. Other techniques for filtering, sampling, and transform computation have to be modified. Even more compromises have to be made, however, because of the signals' size. Images and sequences of images can be huge. For example, processing sequences of color images each of which contains 780 rows and 1024 columns at a frame rate of 30 frames per second requires a data rate of 72 megabytes per second. Successful image processing techniques reward careful attention to problem requirements, algorithmic complexity, and machine architecture. The past decade has been particularly exciting as each new wave of faster computing hardware has opened the door to new applications. This is a trend that will likely continue for some time.

The following chapters, written by experts in their fields, highlight the state-of-the-art in several aspects of image and video processing. The range of topics is quite broad. While it includes some discussions of techniques that go back more than a decade, the emphasis is on current practice. There is some danger in this, because the field is changing very rapidly, but, on the other hand, many of the concepts on which these current techniques are based should be around for some time.

Chapter 51 is a very long and thorough discussion of image processing fundamentals. For a novice to the field, this material is important for a complete understanding. It discusses the basics of how images differ from other types of signals and how the limitations of cameras, displays, and the human visual system affect the kinds of processing that can be done. It also defines the basic theory of multidimensional digital signal processing, particularly with respect to how linear and nonlinear filtering, transform computation, and sampling are generalized from the one-dimensional case. Other topics treated include statistical models for images, models for recording distortions, histogram-based methods for image processing, and image segmentation.

Probably the most visible image processing is occurring in the development of standards for image and video compression. JPEG, MPEG, and digital television are all highly visible success stories. Chapter 52 looks at methods for still image compression including JPEG, wavelet, and fractal coders. Image compression is successful because image samples are spatially correlated with their neighbors. Operators such as the discrete cosine transform (DCT) largely remove this correlation and capture the essence of an image block in a few parameters that can be quantized and transmitted. The transform domain also enables these coders to exploit limitations in the human visual system. Chapters 55 and 56 extend these approaches to video and television compression, respectively. Video compression achieves significant additional compression gains by exploiting the temporal redundancy that is present in video sequences. This is done by using simple models for modeling object motion within a scene, using these models to predict the current frame, and then encoding only the model parameters and the quantized prediction errors.

Images are often distorted when they are recorded. This might be caused by out-of-focus optics, motion blur, camera noise, or coding errors. Chapter 53 looks at methods for image and video restoration. This is the most mathematically based area of image processing, and it is also one of the areas with the longest history. It has applications in the analysis of astronomical images, in forensic

imaging, and in the production of high-quality stills from video sequences.

Chapter 54 looks at methods for motion estimation and video scan conversion. Motion estimation is a key technique for removing temporal redundancy in image sequences and, as a result, it is a key component in all of the video compression standards. It is also, however, a highly time-consuming numerically ill-posed operation. As a result it continues to be highly studied, particularly with respect to more sophisticated motion models. A related problem is the problem of scanning format conversion. This is a major issue in television systems where both interlaced and progressively scanned images are encountered.

Chapter 57 explores stereoscopic and multiview image processing. Traditional image processing assumes that only one camera is present. As a result depth information in a three-dimensional scene is lost. When explicit depth information is needed, multiple cameras can be used. Differences in the displacement of objects in the left and right images can be converted to depth measurements. Mammals do this naturally with their two eyes. Stereoscopic image processing techniques are becoming increasingly used in problems of computer vision and computer graphics. This chapter discusses the state-of-the-art in this emerging area.

The final two chapters in this section, Chapters 58 and 59, look at software and hardware systems for doing image processing. Chapter 58 provides an overview of a representative set of image software packages that embody the core capabilities required by many image processing applications. It also provides a list of Internet addresses for a number of image databases. Chapter 59 provides an overview of VLSI architectures for implementing many of the video compression standards.

51.1 Introduction

Modern digital technology has made it possible to manipulate multidimensional signals with systems that range from simple digital circuits to advanced parallel computers. The goal of this manipulation can be divided into three categories:

- Image Processing *image in* → *image out*
- Image Analysis *image in* → *measurements out*
- Image Understanding *image in* → *high-level description out*

In this section we will focus on the fundamental concepts of *image processing*. Space does not permit us to make more than a few introductory remarks about *image analysis*. *Image understanding* requires an approach that differs fundamentally from the theme of this handbook, *Digital Signal Processing*. Further, we will restrict ourselves to two-dimensional (2D) image processing although most of the concepts and techniques that are to be described can be extended easily to three or more dimensions.

We begin with certain basic definitions. An image defined in the “real world” is considered to be a function of two real variables, for example, $a(x, y)$ with a as the amplitude (e.g., brightness) of the image at the *real* coordinate position (x, y) . An image may be considered to contain sub-images sometimes referred to as *regions-of-interest*, *ROIs*, or simply *regions*. This concept reflects the fact that images frequently contain collections of objects each of which can be the basis for a region. In a sophisticated image processing system it should be possible to apply specific image processing operations to selected regions. Thus, one part of an image (region) might be processed to suppress motion blur while another part might be processed to improve color rendition.

The amplitudes of a given image will almost always be either real numbers or integer numbers. The latter is usually a result of a quantization process that converts a continuous range (say, between 0 and 100%) to a discrete number of levels. In certain image-forming processes, however, the signal may involve photon counting which implies that the amplitude would be inherently quantized. In other image forming procedures, such as magnetic resonance imaging, the direct physical measurement yields a complex number in the form of a real magnitude and a real phase. For the remainder of this introduction we will consider amplitudes as reals or integers unless otherwise indicated.

51.2 Digital Image Definitions

A digital image $a[m, n]$ described in a 2D discrete space is derived from an analog image $a(x, y)$ in a 2D continuous space through a *sampling* process that is frequently referred to as digitization. The mathematics of that sampling process will be described in section 51.5. For now we will look at some basic definitions associated with the digital image. The effect of digitization is shown in Fig. 51.1.

FIGURE 51.1: Digitization of a continuous image. The pixel at coordinates $[m = 10, n = 3]$ has the integer brightness value 110.

The 2D continuous image $a(x, y)$ is divided into N rows and M columns. The intersection of a row and a column is termed a *pixel*. The value assigned to the integer coordinates $[m, n]$ with $\{m = 0, 1, 2, \dots, M - 1\}$ and $\{n = 0, 1, 2, \dots, N - 1\}$ is $a[m, n]$. In fact, in most cases $a(x, y)$

— which we might consider to be the physical signal that impinges on the face of a 2D sensor — is actually a function of many variables including depth (z), color (λ), and time (t). Unless otherwise stated, we will consider the case of 2D, monochromatic, static images in this chapter.

The image shown in Fig. 51.1 has been divided into $N = 16$ rows and $M = 16$ columns. The value assigned to every pixel is the average brightness in the pixel rounded to the nearest integer value. The process of representing the amplitude of the 2D signal at a given coordinate as an integer value with L different gray levels is usually referred to as amplitude quantization or simply *quantization*.

51.2.1 Common Values

There are standard values for the various parameters encountered in digital image processing. These values can be caused by video standards, algorithmic requirements, or the desire to keep digital circuitry simple. Table 51.1 gives some commonly encountered values.

TABLE 51.1
Common Values of Digital Image Parameters

Parameter	Symbol	Typical Values
Rows	N	256, 512, 525, 625, 1024, 1035
Columns	M	256, 512, 768, 1024, 1320
Gray levels	L	2, 64, 256, 1024, 4096, 16384

Quite frequently we see cases of $M = N = 2^K$ where $\{K = 8, 9, 10\}$. This can be motivated by digital circuitry or by the use of certain algorithms such as the (fast) Fourier transform (see section 51.3.3).

The number of distinct gray levels is usually a power of 2, that is, $L = 2^B$ where B is the number of bits in the binary representation of the brightness levels. When $B > 1$, we speak of a *gray-level image*; when $B = 1$, we speak of a *binary image*. In a binary image there are just two gray levels which can be referred to, for example, as “black” and “white” or “0” and “1”.

51.2.2 Characteristics of Image Operations

There is a variety of ways to classify and characterize image operations. The reason for doing so is to understand what type of results we might expect to achieve with a given type of operation or what might be the computational burden associated with a given operation.

Types of Operations

The types of operations that can be applied to digital images to transform an input image $a[m, n]$ into an output image $b[m, n]$ (or another representation) can be classified into three categories as shown in Table 51.2.

This is shown graphically in Fig. 51.2.

Types of Neighborhoods

Neighborhood operations play a key role in modern digital image processing. It is therefore important to understand how images can be sampled and how that relates to the various neighborhoods that can be used to process an image.

- Rectangular sampling — In most cases, images are sampled by laying a rectangular grid over an image as illustrated in Fig. 51.1. This results in the type of sampling shown in Fig. 51.3(a) and 51.3(b).

TABLE 51.2 Types of Image Operations

Operation	Characterization	Generic Complexity / Pixel
• <i>Point</i>	- the output value at a specific coordinate is dependent only on the input value at that same coordinate.	<i>constant</i>
• <i>Local</i>	- the output value at a specific coordinate is dependent on the input values in the <i>neighborhood</i> of that same coordinate.	p^2
• <i>Global</i>	- the output value at a specific coordinate is dependent on all the values in the input image.	N^2

Note: Image size = $N \times N$; neighborhood size = $P \times P$. Note that the complexity is specified in operations per pixel.

FIGURE 51.2: Illustration of various types of image operations.

- Hexagonal sampling — An alternative sampling scheme is shown in Fig. 51.3(c) and is termed hexagonal sampling.

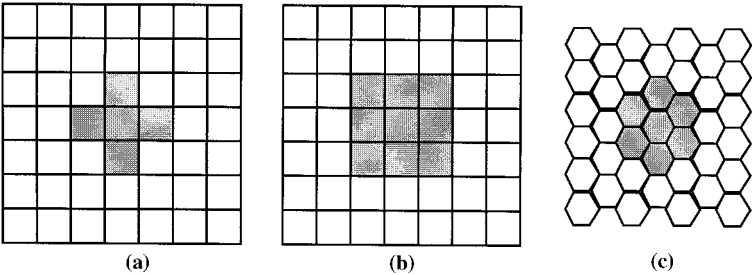

FIGURE 51.3: (a) Rectangular sampling 4-connected; (b) rectangular sampling 8-connected; (c) hexagonal sampling 6-connected.

Both sampling schemes have been studied extensively and both represent a possible periodic tiling of the continuous image space. We will restrict our attention, however, to only rectangular sampling as it remains, due to hardware and software considerations, the method of choice.

Local operations produce an output pixel value $b[m = m_0, n = n_0]$ based on the pixel values in the *neighborhood* of $a[m = m_0, n = n_0]$. Some of the most common neighborhoods are the 4-connected neighborhood and the 8-connected neighborhood in the case of rectangular sampling

and the 6-connected neighborhood in the case of hexagonal sampling illustrated in Fig. 51.3.

51.2.3 Video Parameters

We do not propose to describe the processing of dynamically changing images in this introduction. It is appropriate — given that many static images are derived from video cameras and frame grabbers — to mention the standards that are associated with the three standard video schemes currently in worldwide use — NTSC, PAL, and SECAM. This information is summarized in Table 51.3.

TABLE 51.3 Standard Video Parameters

Property	NTSC	Standard	
		PAL	SECAM
images/second	29.97	25	25
ms/image	33.37	40.0	40.0
lines/image	525	625	625
(horiz./vert.) = aspect ratio	4:3	4:3	4:3
interlace	2:1	2:1	2:1
$\mu\text{s}/\text{line}$	63.56	64.00	64.00

In an interlaced image, the odd numbered lines (1, 3, 5, ...) are scanned in half of the allotted time (e.g., 20 ms in PAL) and the even numbered lines (2, 4, 6, ...) are scanned in the remaining half. The image display must be coordinated with this scanning format. (See section 51.8.2.) The reason for interlacing the scan lines of a video image is to reduce the perception of flicker in a displayed image. If one is planning to use images that have been scanned from an interlaced video source, it is important to know if the two half-images have been appropriately “shuffled” by the digitization hardware or if that should be implemented in software. Further, the analysis of moving objects requires special care with interlaced video to avoid “zigzag” edges.

The number of rows (N) from a video source generally corresponds one-to-one with lines in the video image. The number of columns, however, depends on the nature of the electronics that is used to digitize the image. Different frame grabbers for the same video camera might produce $M = 384, 512$, or 768 columns (pixels) per line.

51.3 Tools

Certain tools are central to the processing of digital images. These include mathematical tools such as *convolution*, *Fourier analysis*, and *statistical* descriptions, and manipulative tools such as *chain codes* and *run codes*. We will present these tools without any specific motivation. The motivation will follow in later sections.

51.3.1 Convolution

There are several possible notations to indicate the convolution of two (multidimensional) signals to produce an output signal. The most common are:

$$c = a \otimes b = a * b \quad (51.1)$$

We shall use the first form, $c = a \otimes b$, with the following formal definitions.

In 2D continuous space:

$$c(x, y) = a(x, y) \otimes b(x, y) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} a(\chi, \zeta) b(x - \chi, y - \zeta) d\chi d\zeta \quad (51.2)$$

In 2D discrete space:

$$c[m, n] = a[m, n] \otimes b[m, n] = \sum_{j=-\infty}^{+\infty} \sum_{k=-\infty}^{+\infty} a[j, k] b[m-j, n-k] \quad (51.3)$$

51.3.2 Properties of Convolution

There are a number of important mathematical properties associated with convolution.

- Convolution is *commutative*.

$$c = a \otimes b = b \otimes a \quad (51.4)$$

- Convolution is *associative*.

$$c = a \otimes (b \otimes d) = (a \otimes b) \otimes d = a \otimes b \otimes d \quad (51.5)$$

- Convolution is *distributive*.

$$c = a \otimes (b + d) = (a \otimes b) + (a \otimes d) \quad (51.6)$$

where a , b , c , and d are all images, either continuous or discrete.

51.3.3 Fourier Transforms

The Fourier transform produces another representation of a signal, specifically a representation as a weighted sum of complex exponentials. Because of Euler's formula:

$$e^{jq} = \cos(q) + j \sin(q) \quad (51.7)$$

where $j^2 = -1$, we can say that the Fourier transform produces a representation of a (2D) signal as a weighted sum of sines and cosines. The defining formulas for the forward Fourier and the inverse Fourier transforms are as follows. Given an image a and its Fourier transform A , the forward transform goes from the spatial domain (either continuous or discrete) to the frequency domain which is always continuous.

$$\text{Forward - } A = \mathcal{F}\{a\} \quad (51.8)$$

The inverse Fourier transform goes from the frequency domain back to the spatial domain

$$\text{Inverse - } a = \mathcal{F}^{-1}\{A\} \quad (51.9)$$

The Fourier transform is a unique and invertible operation so that:

$$a = \mathcal{F}^{-1}\{\mathcal{F}\{a\}\} \quad \text{and} \quad A = \mathcal{F}\{\mathcal{F}^{-1}\{A\}\} \quad (51.10)$$

The specific formulas for transforming back and forth between the spatial domain and the frequency domain are given below.

In 2D continuous space:

$$\text{Forward - } A(u, v) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} a(x, y) e^{-j(ux+vy)} dx dy \quad (51.11)$$

$$\text{Inverse - } a(x, y) = \frac{1}{4\pi^2} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} A(u, v) e^{j(ux+vy)} du dv \quad (51.12)$$

In 2D discrete space:

$$\text{Forward - } A(\Omega, \Psi) = \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} a[m, n] e^{-j(\Omega m + \Psi n)} \quad (51.13)$$

$$\text{Inverse - } a[m, n] = \frac{1}{4\pi^2} \int_{-\pi}^{+\pi} \int_{-\pi}^{+\pi} A(\Omega, \Psi) e^{+j(\Omega m + \Psi n)} d\Omega d\Psi \quad (51.14)$$

51.3.4 Properties of Fourier Transforms

There are a variety of properties associated with the Fourier transform and the inverse Fourier transform. The following are some of the most relevant for digital image processing.

- The Fourier transform is, in general, a complex function of the real frequency variables. As such, the transform can be written in terms of its magnitude and phase.

$$A(u, v) = |A(u, v)| e^{j\varphi(u, v)} \quad A(\Omega, \Psi) = |A(\Omega, \Psi)| e^{j\varphi(\Omega, \Psi)} \quad (51.15)$$

- A 2D signal can also be complex and thus written in terms of its magnitude and phase.

$$a(x, y) = |a(x, y)| e^{j\vartheta(x, y)} \quad a[m, n] = |a[m, n]| e^{j\vartheta[m, n]} \quad (51.16)$$

- If a 2D signal is real, then the Fourier transform has certain symmetries.

$$A(u, v) = A^*(-u, -v) \quad A(\Omega, \Psi) = A^*(-\Omega, -\Psi) \quad (51.17)$$

The symbol (*) indicates complex conjugation. For real signals Eq. (51.17) leads directly to:

$$\begin{aligned} |A(u, v)| &= |A(-u, -v)| & \varphi(u, v) &= -\varphi(-u, -v) \\ |A(\Omega, \Psi)| &= |A(-\Omega, -\Psi)| & \varphi(\Omega, \Psi) &= -\varphi(-\Omega, -\Psi) \end{aligned} \quad (51.18)$$

- If a 2D signal is real and even, then the Fourier transform is real and even.

$$A(u, v) = A(-u, -v) \quad A(\Omega, \Psi) = A(-\Omega, -\Psi) \quad (51.19)$$

- The Fourier and the inverse Fourier transforms are linear operations.

$$\begin{aligned} \mathcal{F}\{w_1 a + w_2 b\} &= \mathcal{F}\{w_1 a\} + \mathcal{F}\{w_2 b\} = w_1 A + w_2 B \\ \mathcal{F}^{-1}\{w_1 A + w_2 B\} &= \mathcal{F}^{-1}\{w_1 A\} + \mathcal{F}^{-1}\{w_2 B\} = w_1 a + w_2 b \end{aligned} \quad (51.20)$$

where a and b are 2D signals (images) and w_1 and w_2 are arbitrary, complex constants.

- The Fourier transform in discrete space, $A(\Omega, \Psi)$, is periodic in both Ω and Ψ . Both periods are 2π .

$$A(\Omega + 2\pi j, \Psi + 2\pi k) = A(\Omega, \Psi) \quad j, k \text{ integers} \quad (51.21)$$

- The energy, E , in a signal can be measured either in the spatial domain or the frequency domain. For a signal with finite energy:

Parseval's theorem (2D continuous space):

$$E = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} |a(x, y)|^2 dx dy = \frac{1}{4\pi^2} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} |A(u, v)|^2 du dv \quad (51.22)$$

Parseval's theorem (2D discrete space):

$$E = \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} |a[m, n]|^2 = \frac{1}{4\pi^2} \int_{-\pi}^{+\pi} \int_{-\pi}^{+\pi} |A(\Omega, \Psi)|^2 d\Omega d\Psi \quad (51.23)$$

This “signal energy” is not to be confused with the physical energy in the phenomenon that produced the signal. If, for example, the value $a[m, n]$ represents a photon count, then the *physical* energy is proportional to the amplitude, a , and not the square of the amplitude. This is generally the case in video imaging.

- Given three, multi-dimensional signals a , b , and c and their Fourier transforms A , B , and C :

$$c = a \otimes b \quad \begin{matrix} \mathcal{F} \\ \leftrightarrow \end{matrix} \quad C = A \bullet B$$

and

$$c = a \bullet b \quad \begin{matrix} \mathcal{F} \\ \leftrightarrow \end{matrix} \quad C = \frac{1}{4\pi^2} A \otimes B \quad (51.24)$$

In words, convolution in the spatial domain is equivalent to multiplication in the Fourier (frequency) domain and vice-versa. This is a central result which provides not only a methodology for the implementation of a convolution but also insight into how two signals interact with each other — under convolution — to produce a third signal. We shall make extensive use of this result later.

- If a two-dimensional signal $a(x, y)$ is scaled in its spatial coordinates then:

$$\begin{aligned} \text{If } a(x, y) &\rightarrow a(M_x \bullet x, M_y \bullet y) \\ \text{Then } A(u, v) &\rightarrow A(u / M_x, v / M_y) / |M_x \bullet M_y| \end{aligned} \quad (51.25)$$

- If a two-dimensional signal $a(x, y)$ has Fourier spectrum $A(u, v)$ then:

$$\begin{aligned} A(u = 0, v = 0) &= \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} a(x, y) dx dy \\ a(x = 0, y = 0) &= \frac{1}{4\pi^2} \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} A(u, v) du dv \end{aligned} \quad (51.26)$$

- If a two-dimensional signal $a(x, y)$ has Fourier spectrum $A(u, v)$ then:

$$\begin{aligned} \frac{\partial a(x, y)}{\partial x} &\xleftrightarrow{\mathcal{F}} juA(u, v) & \frac{\partial a(x, y)}{\partial y} &\xleftrightarrow{\mathcal{F}} jvA(u, v) \\ \frac{\partial^2 a(x, y)}{\partial x^2} &\xleftrightarrow{\mathcal{F}} -u^2 A(u, v) & \frac{\partial^2 a(x, y)}{\partial y^2} &\xleftrightarrow{\mathcal{F}} -v^2 A(u, v) \end{aligned} \quad (51.27)$$

Importance of Phase and Magnitude

Equation (51.15) indicates that the Fourier transform of an image can be complex. This is illustrated below in Fig. 51.4(a-c). Figure 51.4(a) shows the original image $a[m, n]$, Fig. 51.4(b) the magnitude in a scaled form as $\log(|A(\Omega, \Psi)|)$, and Fig. 51.4(c) the phase $\varphi(\Omega, \Psi)$.

Both the magnitude and the phase functions are necessary for the complete reconstruction of an image from its Fourier transform. Figure 51.5(a) shows what happens when Fig. 51.4(a) is

FIGURE 51.4: (a) Original; (b) $\log(|A(\Omega, \Psi)|)$; (c) $\varphi(\Omega, \Psi)$.

FIGURE 51.5: (a) $\varphi(\Omega, \Psi) = 0$ and (b) $|A(\Omega, \Psi)| = \text{constant}$.

restored solely on the basis of the magnitude information and Fig. 51.5(b) shows what happens when Fig. 51.4(a) is restored solely on the basis of the phase information.

Neither the magnitude information nor the phase information is sufficient to restore the image. The magnitude-only image, Fig. 51.5(a), is unrecognizable and has severe dynamic range problems. The phase-only image, Fig. 51.5(b), is barely recognizable, that is, severely degraded in quality.

Circularly Symmetric Signals

An arbitrary 2D signal $a(x, y)$ can always be written in a polar coordinate system as $a(r, \theta)$. When the 2D signal exhibits a circular symmetry this means that:

$$a(x, y) = a(r, \theta) = a(r) \quad (51.28)$$

where $r^2 = x^2 + y^2$ and $\tan \theta = y/x$. As a number of physical systems, such as lenses, exhibit circular symmetry, it is useful to be able to compute an appropriate Fourier representation.

The Fourier transform $A(u, v)$ can be written in polar coordinates $A(\omega_r, \xi)$ and then, for a circularly symmetric signal, rewritten as a *Hankel transform*:

$$A(u, v) = \mathcal{F}\{a(x, y)\} = 2\pi \int_0^\infty a(r) J_0(\omega_r r) r dr = A(\omega_r) \quad (51.29)$$

where $\omega_r^2 = u^2 + v^2$ and $\tan \xi = v/u$ and $J_0(\bullet)$ is a Bessel function of the first kind of order zero.

The inverse *Hankel transform* is given by:

$$a(r) = \frac{1}{2\pi} \int_0^\infty A(\omega_r) J_0(\omega_r r) \omega_r d\omega_r \quad (51.30)$$

The Fourier transform of a circularly symmetric 2D signal is a function of only the radial frequency, ω_r . The dependence on the angular frequency, ξ , has vanished. Further, if $a(x, y) = a(r)$ is real,

then it is automatically even due to the circular symmetry. According to Eq. (51.19), $A(\omega_r)$ will then be real and even.

Examples of 2D Signals and Transforms

Table 51.4 shows some basic and useful signals and their 2D Fourier transforms. In using the table entries in the remainder of this chapter, we will refer to a spatial domain term as the *point spread function* (PSF) or the *2D impulse response* and its Fourier transforms as the *optical transfer function* (OTF) or simply *transfer function*. Two standard signals used in this table are $u(\bullet)$, the unit step function, and $J_1(\bullet)$, the Bessel function of the first kind. Circularly symmetric signals are treated as functions of r as in Eq. (51.28).

51.3.5 Statistics

In image processing, it is quite common to use simple statistical descriptions of images and sub-images. The notion of a statistic is intimately connected to the concept of a probability distribution, generally the distribution of signal amplitudes. For a given region — which could conceivably be an entire image — we can define the probability *distribution* function of the brightnesses in that region and the probability *density* function of the brightnesses in that region. We will assume in the discussion that follows that we are dealing with a digitized image $a[m, n]$.

Probability Distribution Function of the Brightnesses

The probability distribution function, $P(a)$, is the probability that a brightness chosen from the region is less than or equal to a given brightness value a . As a increases from $-\infty$ to $+\infty$, $P(a)$ increases from 0 to 1. $P(a)$ is monotonic, nondecreasing in a and thus $dP/da \geq 0$.

Probability Density Function of the Brightnesses

The probability that a brightness in a region falls between a and $a + \Delta a$, given the probability distribution function $P(a)$, can be expressed as $p(a)\Delta a$ where $p(a)$ is the probability density function:

$$p(a)\Delta a = \left(\frac{dP(a)}{da} \right) \Delta a \quad (51.31)$$

Because of the monotonic, nondecreasing character of $P(a)$ we have that:

$$p(a) \geq 0 \text{ and } \int_{-\infty}^{+\infty} p(a)da = 1 \quad (51.32)$$

For an image with quantized (integer) brightness amplitudes, the interpretation of Δa is the width of a brightness interval. We assume constant width intervals. The brightness probability *density* function is frequently estimated by counting the number of times that each brightness occurs in the region to generate a *histogram*, $h[a]$. The histogram can then be normalized so that the total area under the histogram is 1 [Eq. (51.32)]. Said another way, the $p[a]$ for a region is the normalized count of the number of pixels, Λ , in a region that have quantized brightness a :

$$p[a] = \frac{1}{\Lambda} h[a] \text{ with } \Lambda = \sum_a h[a] \quad (51.33)$$

The brightness probability *distribution* function for the image shown in Fig. 51.4(a) is shown in Fig. 51.6(a). The (unnormalized) brightness histogram of Fig. 51.4(a), which is proportional to the estimated brightness probability density function, is shown in Fig. 51.6(b). The height in this histogram corresponds to the number of pixels with a given brightness.

(b)

FIGURE 51.6: (a) Brightness distribution function of Fig. 51.4(a) with *minimum*, *median*, and *maximum* indicated. See text for explanation. (b) Brightness histogram of Fig. 51.4(a).

Both the distribution function and the histogram as measured from a region are a statistical description of that region. It should be emphasized that both $P[a]$ and $p[a]$ should be viewed as *estimates* of true distributions when they are computed from a specific region. That is, we view an image and a specific region as one realization of the various random processes involved in the formation of that image and that region. In the same context, the statistics defined below must be viewed as estimates of the underlying parameters.

Average

The average brightness of a region is defined as the *sample mean* of the pixel brightnesses within that region. The average, m_a , of the brightnesses over the Λ pixels within a region (\mathfrak{R}) is given by:

$$m_a = \frac{1}{\Lambda} \sum_{(m,n) \in \mathfrak{R}} a[m, n] \quad (51.34)$$

Alternatively, we can use a formulation based on the (unnormalized) brightness histogram, $h(a) = \Lambda \bullet p(a)$, with discrete brightness values a . This gives:

$$m_a = \frac{1}{\Lambda} \sum_a a \bullet h[a] \quad (51.35)$$

The average brightness, m_a , is an estimate of the mean brightness, μ_a , of the underlying brightness probability distribution.

Standard Deviation

The *unbiased estimate* of the standard deviation, s_a , of the brightness within a region (\mathfrak{R}) with Λ pixels is called the *sample standard deviation* and is given by:

$$\begin{aligned} s_a &= \sqrt{\frac{1}{\Lambda - 1} \sum_{m,n \in \mathfrak{R}} (a[m, n] - m_a)^2} \\ &= \sqrt{\frac{\sum_{m,n \in \mathfrak{R}} a^2[m, n] - \Lambda m_a^2}{\Lambda - 1}} \end{aligned} \quad (51.36)$$

Using the histogram formulation gives:

$$s_a = \sqrt{\frac{\left(\sum_a a^2 \bullet h[a]\right) - \Lambda \bullet m_a^2}{\Lambda - 1}} \quad (51.37)$$

The standard deviation, s_a , is an estimate of σ_a of the underlying brightness probability distribution.

Coefficient-of-Variation

The dimensionless *coefficient-of-variation*, CV , is defined as:

$$CV = \frac{s_a}{m_a} \times 100\% \quad (51.38)$$

Percentiles

The percentile, $p\%$, of an *unquantized* brightness distribution is defined as that value of the brightness a such that:

$$P(a) = p\%$$

or equivalently

$$\int_{-\infty}^a p(\alpha) d\alpha = p\% \quad (51.39)$$

Three special cases are frequently used in digital image processing.

- 0% the *minimum* value in the region
- 50% the *median* value in the region
- 100% the *maximum* value in the region

All three of these values can be determined from Fig. 51.6(a).

Mode

The mode of the distribution is the most frequent brightness value. There is no guarantee that a mode exists or that it is unique.

Signal-to-Noise Ratio

The signal-to-noise ratio, SNR , can have several definitions. The noise is characterized by its standard deviation, s_n . The characterization of the signal can differ. If the signal is known to lie between two boundaries, $a_{\min} \leq a \leq a_{\max}$, then the SNR is defined as:

Bounded signal -

$$SNR = 20 \log_{10} \left(\frac{a_{\max} - a_{\min}}{s_n} \right) dB \quad (51.40)$$

If the signal is not bounded but has a statistical distribution, then two other definitions are known:

Stochastic signal -

$$S \& N \text{ inter-dependent } SNR = 20 \log_{10} \left(\frac{m_a}{s_n} \right) dB \quad (51.41)$$

$$S \& N \text{ independent } SNR = 20 \log_{10} \left(\frac{s_a}{s_n} \right) dB \quad (51.42)$$

where m_a and s_a are defined above.

The various statistics are given in Table 51.5 for the image and the region shown in Fig. 51.7.

FIGURE 51.7: Region is the interior of the circle.

TABLE 51.5 Statistics from Fig. 51.7

<i>Statistic</i>	<i>Image</i>	<i>ROI</i>
Average	137.7	219.3
Standard deviation	49.5	4.0
Minimum	56	202
Median	141	220
Maximum	241	226
Mode	62	220
SNR (db)	<i>NA</i>	33.3

A SNR calculation for the *entire* image based on Eq. (51.40) is not directly available. The variations in the image brightnesses that lead to the large value of s ($= 49.5$) are not, in general, due to noise but to the variation in local information. With the help of the region, there is a way to estimate the SNR . We can use the $s_{\mathfrak{R}}$ ($= 4.0$) and the dynamic range, $a_{\max} - a_{\min}$, for the image ($= 241 - 56$) to calculate a global SNR ($= 33.3$ dB). The underlying assumptions are that (1) the signal is approximately constant in that region and the variation in the region is, therefore, due to noise, and that (2) the noise is the same over the entire image with a standard deviation given by $s_n = s_{\mathfrak{R}}$.

51.3.6 Contour Representations

When dealing with a region or object, several compact representations are available that can facilitate manipulation of and measurements on the object. In each case we assume that we begin with an image representation of the object as shown in Fig. 51.8(a) and (b). Several techniques exist to represent the region or object by describing its contour.

Chain Code

This representation is based on the work of Freeman. We follow the contour in a clockwise manner and keep track of the directions as we go from one contour pixel to the next. For the standard implementation of the chain code, we consider a contour pixel to be an object pixel that has a background (nonobject) pixel as one or more of its 4-connected neighbors. See Figs. 51.3(a) and 51.8(c).

The codes associated with eight possible directions are the chain codes and, with x as the current contour pixel position, the codes are generally defined as:

$$\begin{array}{rcl} \text{Chain codes} = & \begin{array}{ccc} 3 & 2 & 1 \\ 4 & x & 0 \\ 5 & 6 & 7 \end{array} & (51.43) \end{array}$$

Chain Code Properties

- Even codes $\{0, 2, 4, 6\}$ correspond to horizontal and vertical directions: odd codes $\{1, 3, 5, 7\}$

FIGURE 51.8: Region (shaded) as it is transformed from (a) continuous to (b) discrete form and then considered as a (c) contour or (d) run lengths illustrated in alternating colors.

correspond to the diagonal directions.

- Each code can be considered as the angular direction, in multiples of 45° , that we must move to go from one contour pixel to the next.
- The absolute coordinates $[m, n]$ of the first contour pixel (e.g., top, leftmost) together with the chain code of the contour represent a complete description of the discrete region contour.
- When there is a change between two consecutive chain codes, then the contour has changed direction. This point is defined as a *corner*.

“Crack” Code

An alternative to the chain code for contour encoding is to use neither the contour pixels associated with the object nor the contour pixels associated with background but rather the line, the “crack”, in between. This is illustrated with an enlargement of a portion of Fig. 51.8 in Fig. 51.9.

The “crack” code can be viewed as a chain code with four possible directions instead of eight.

$$\text{Crack codes} = \begin{matrix} & 1 \\ 2 & x & 0 \\ & 3 \end{matrix} \quad (51.44)$$

The chain code for the enlarged section of Fig. 51.9(b), from top to bottom, is $\{5, 6, 7, 7, 0\}$. The crack code is $\{3, 2, 3, 3, 0, 3, 0, 0\}$.

FIGURE 51.9: (a) Object including part to be studied. (b) Contour pixels as used in the chain code are diagonally shaded. The “crack” is shown with the thick black line.

Run Codes

A third representation is based on coding the consecutive pixels along a row — a run — that belongs to an object by giving the starting position of the run and the ending position of the run. Such runs are illustrated in Fig. 51.8(d). There are a number of alternatives for the precise definition of the positions. Which alternative should be used depends on the application and thus will not be discussed here.

51.4 Perception

Many image processing applications are intended to produce images that are to be viewed by human observers (as opposed to, say, automated industrial inspection.) It is, therefore, important to understand the characteristics and limitations of the human visual system — to understand the “receiver” of the 2D signals. At the outset it is important to realize that (1) the human visual system is not well understood, (2) no objective measure exists for judging the quality of an image that corresponds to human assessment to image quality, and (3) the “typical” human observer does not exist. Nevertheless, research in perceptual psychology has provided some important insights into the visual system.

51.4.1 Brightness Sensitivity

There are several ways to describe the sensitivity of the human visual system. To begin, let us assume that a homogeneous region in an image has an intensity as a function of wavelength (color) given by $I(\lambda)$. Further, let us assume that $I(\lambda) = I_o$, a constant.

Wavelength Sensitivity

The perceived intensity as a function of λ , the spectral sensitivity, for the “typical observer” is shown in Fig. 51.10.

Stimulus Sensitivity

If the constant intensity (brightness) I_o is allowed to vary, then, to a good approximation, the visual response, R , is proportional to the logarithm of the intensity. This is known as the Weber-Fechner law:

$$R = \log(I_o) \quad (51.45)$$

The implications of this are easy to illustrate. Equal *perceived* steps brightness, $\Delta R = k$, require

FIGURE 51.10: Spectral sensitivity of the “typical” human observer.

that the physical brightness (the stimulus) increases exponentially. This is illustrated in Fig. 51.11(a) and (b).

FIGURE 51.11: (a) (Top) brightness step $\Delta I = k$, (bottom) brightness step $\Delta I = k \cdot I$. (b) Actual brightnesses plus interpolated values.

A horizontal line through the top portion of Fig. 51.11(a) shows a linear increase in objective brightness (Fig. 51.11(b)) but a logarithmic increase in subjective brightness. A horizontal line through the bottom portion of Fig. 51.11(a) shows an exponential increase in objective brightness Fig. 51.11(b) but a linear increase in subjective brightness.

The *Mach band effect* is visible in Fig. 51.11(a). Although the physical brightness is constant across each vertical stripe, the human observer perceives an “undershoot” and “overshoot” in brightness at what is physically a step edge. Thus, just before the step, we see a slight decrease in brightness compared to the true physical value. After the step we see a slight overshoot in brightness compared to the true physical value. The total effect is one of increased, local, *perceived* contrast at a step edge in brightness.

51.4.2 Spatial Frequency Sensitivity

If the constant intensity (brightness) I_0 is replaced by a sinusoidal grating with increasing spatial frequency (Fig. 51.12(a)), it is possible to determine the spatial frequency sensitivity. The result is shown in Fig. 51.12(b).

To translate these data into common terms, consider an “ideal” computer monitor at a viewing distance of 50 cm. The spatial frequency that will give maximum response is at 10 cycles per degree. (See Fig. 51.12(b)). The one degree at 50 cm translates to $50 \tan(1^\circ) = 0.87$ cm on the computer

FIGURE 51.12: (a) Sinusoidal test grating and (b) spatial frequency sensitivity.

screen. Thus, the spatial frequency of maximum response $f_{\max} = 10 \text{ cycles}/0.87 \text{ cm} = 11.46 \text{ cycles/cm}$ at this viewing distance. Translating this into a general formula gives:

$$f_{\max} = \frac{10}{d \bullet \tan(1^\circ)} = \frac{572.9}{d} \text{ cycles / cm} \quad (51.46)$$

where d = viewing distance measured in centimeters.

51.4.3 Color Sensitivity

Human color perception is an exceedingly complex topic. As such we can only present a brief introduction here. The physical perception of color is based on three color pigments in the retina.

Standard Observer

Based on psychophysical measurements, standard curves have been adopted by the CIE (Commission Internationale de l'Eclairage) as the sensitivity curves for the “typical” observer for the three “pigments” $\bar{x}(\lambda)$, $\bar{y}(\lambda)$, and $\bar{z}(\lambda)$. These are shown in Fig. 51.13. These are not the *actual* pigment absorption characteristics found in the “standard” human retina but rather sensitivity curves derived from actual data.

FIGURE 51.13: Standard observer color pigment sensitivity curves.

For an arbitrary homogeneous region in an image that has an intensity as a function of wavelength (color) given by $I(\lambda)$, the three pigment responses are called the *tristimulus values*:

$$X = \int_0^\infty I(\lambda)\bar{x}(\lambda)d\lambda \quad Y = \int_0^\infty I(\lambda)\bar{y}(\lambda)d\lambda \quad Z = \int_0^\infty I(\lambda)\bar{z}(\lambda)d\lambda \tag{51.47}$$

CIE Chromaticity Coordinates

The *chromaticity coordinates*, which describe the perceived color information, are defined as:

$$x = \frac{X}{X + Y + Z} \quad y = \frac{Y}{X + Y + Z} \quad z = 1 - (x + y) \tag{51.48}$$

The red chromaticity coordinate is given by x and the green chromaticity coordinate by y . The tristimulus values are linear in $I(\lambda)$, and thus the absolute intensity information has been lost in the calculation of the chromaticity coordinates $\{x, y\}$. All color distributions, $I(\lambda)$, that appear to an observer as having the same color will have the same chromaticity coordinates.

If we use a tunable source of pure color (such as dye laser), then the intensity can be modeled as $I(\lambda) = \delta(\lambda - \lambda_0)$ with $\delta(\bullet)$ as the impulse function. The collection of chromaticity coordinates $\{x, y\}$ that will be generated by varying λ_0 gives the *CIE chromaticity triangle* as shown in Fig. 51.14.

FIGURE 51.14: Chromaticity diagram containing the *CIE chromaticity triangle* associated with pure spectral colors and the triangle associated with CRT phosphors.

Pure spectral colors are along the boundary of the chromaticity triangle. All other colors are inside the triangle. The chromaticity coordinates for some standard sources are given in Table 51.6.

TABLE 51.6
Chromaticity Coordinates for Standard Sources

Source	x	y
Fluorescent lamp @ 4800 °K	0.35	0.37
Sun @ 6000 °K	0.32	0.33
Red phosphor (europium yttrium vanadate)	0.68	0.32
Green phosphor (zinc cadmium sulfide)	0.28	0.60
Blue phosphor (zinc sulfide)	0.15	0.07

The description of color on the basis of chromaticity coordinates not only permits an analysis of color but provides a synthesis technique as well. Using a mixture of two color sources, it is possible to generate any of the colors along the line connecting their respective chromaticity coordinates. Since we cannot have a negative number of photons, this means the mixing coefficients must be positive. Using three color sources such as the red, green, and blue phosphors on CRT monitors leads to the set of colors defined by the *interior* of the “phosphor triangle” shown in Fig. 51.14.

The formulas for converting from the tristimulus values (X, Y, Z) to the well-known CRT colors (R, G, B) and back are given by:

$$\begin{bmatrix} R \\ G \\ B \end{bmatrix} = \begin{bmatrix} 1.9107 & -0.5326 & -0.2883 \\ -0.9843 & 1.9984 & -0.0283 \\ 0.0583 & -0.1185 & 0.8986 \end{bmatrix} \bullet \begin{bmatrix} X \\ Y \\ Z \end{bmatrix} \quad (51.49)$$

and

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \begin{bmatrix} 0.6067 & 0.1736 & 0.2001 \\ 0.2988 & 0.5868 & 0.1143 \\ 0.0000 & 0.0661 & 1.1149 \end{bmatrix} \bullet \begin{bmatrix} R \\ G \\ B \end{bmatrix} \quad (51.50)$$

As long as the position of a desired color (X, Y, Z) is inside the phosphor triangle in Fig. 51.14, the values R, G , and B as computed by Eq. (51.49) will be positive and therefore can be used to drive a CRT monitor.

It is incorrect to assume that a small displacement anywhere in the chromaticity diagram (Fig. 51.14) will produce a proportionally small change in the *perceived* color. An empirically derived chromaticity space where this property is approximated is the (u', v') space:

$$u' = \frac{4x}{-2x + 12y + 3} \quad v' = \frac{9y}{-2x + 12y + 3}$$

and

$$x = \frac{9u'}{6u' - 16v' + 12} \quad y = \frac{4v'}{6u' - 16v' + 12} \quad (51.51)$$

Small changes almost anywhere in the (u', v') chromaticity space produce equally small changes in the perceived colors.

51.4.4 Optical Illusions

The description of the human visual system presented above is couched in standard engineering terms. This could lead one to conclude that there is sufficient knowledge of the human visual system to permit modeling the visual system with standard system analysis techniques. Two simple examples of optical illusions, shown in Fig. 51.15, illustrate that this system approach would be a gross oversimplification. Such models should only be used with extreme care.

The left illusion induces the illusion of gray values in the eye that the brain “knows” do not exist. Further, there is a sense of dynamic change in the image due, in part, to the saccadic movements of the eye. The right illusion, Kanizsa’s triangle, shows enhanced contrast and false contours, neither of which can be explained by the system-oriented aspects of visual perception described above.

51.5 Image Sampling

Converting from a continuous image $a(x, y)$ to its digital representation $b[m, n]$ requires the process of sampling. In the ideal sampling system, $a(x, y)$ is multiplied by an ideal 2D impulse train:

FIGURE 51.15: Optical illusions.

$$\begin{aligned}
 b_{\text{ideal}}[m, n] &= a(x, y) \bullet \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} \delta(x - mX_o, y - nY_o) \\
 &= \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} a(mX_o, nY_o) \delta(x - mX_o, y - nY_o)
 \end{aligned} \quad (51.52)$$

where X_o and Y_o are the sampling distances or intervals and $\delta(\bullet, \bullet)$ is the ideal impulse function. (At some point, of course, the impulse function $\delta(x, y)$ is converted to the discrete impulse function $\delta[m, n]$.) *Square sampling* implies that $X_o = Y_o$. Sampling with an impulse function corresponds to sampling with an infinitesimally small point. This, however, does not correspond to the usual situation as illustrated in Fig. 51.1. To take the effects of a *finite* sampling aperture $p(x, y)$ into account, we can modify the sampling model as follows:

$$b[m, n] = (a(x, y) \otimes p(x, y)) \bullet \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} \delta(x - mX_o, y - nY_o) \quad (51.53)$$

The combined effect of the aperture and sampling are best understood by examining the Fourier domain representation.

$$B(\Omega, \Psi) = \frac{1}{4\pi^2} \sum_{m=-\infty}^{+\infty} \sum_{n=-\infty}^{+\infty} A(\Omega - m\Omega_s, \Psi - n\Psi_s) \bullet P(\Omega - m\Omega_s, \Psi - n\Psi_s) \quad (51.54)$$

where $\Omega_s = 2\pi/X_o$ is the sampling frequency in the x direction and $\Psi_s = 2\pi/Y_o$ is the sampling frequency in the y direction. The aperture $p(x, y)$ is frequently square, circular, or Gaussian with the associated $P(\Omega, \Psi)$ (see Table 51.4). The periodic nature of the spectrum, described in Eq. (51.21) is clear from Eq. (51.54).

51.5.1 Sampling Density for Image Processing

To prevent the possible *aliasing* (overlapping) of spectral terms that is inherent in Eq. (51.54), two conditions must hold:

- *Bandlimited* $A(u, v)$ -

$$|A(u, v)| \equiv 0 \quad \text{for } |u| > u_c \quad \text{and } |v| > v_c \quad (51.55)$$

- *Nyquist sampling frequency* -

$$\Omega_s > 2 \bullet u_c \text{ and } \Psi_s > 2 \bullet v_c \quad (51.56)$$

where u_c and v_c are the *cutoff frequencies* in the x and y direction, respectively. Images that are acquired through lenses that are circularly symmetric, aberration-free, and diffraction-limited will, in general, be bandlimited. The lens acts as a lowpass filter with a cutoff frequency in the frequency domain [Eq. (51.11)] given by:

$$u_c = v_c = \frac{2NA}{\lambda} \quad (51.57)$$

where NA is the numerical aperture of the lens and λ is the shortest wavelength of light used with the lens. If the lens does not meet one or more of these assumptions, then it will still be bandlimited but at lower cutoff frequencies than those given in Eq. (51.57). When working with the F-number (F) of the optics instead of the NA and in air (with *index of refraction* = 1.0), Eq. (51.57) becomes:

$$u_c = v_c = \frac{2}{\lambda} \left(\frac{1}{\sqrt{4F^2 + 1}} \right) \quad (51.58)$$

Sampling Aperture

The aperture $p(x, y)$ described above will have only a marginal effect on the final signal if the two conditions, Eqs. (51.56) and (51.57), are satisfied. Given, for example, the distance between samples X_o equals Y_o and a sampling aperture that is not wider than X_o , the effect on the overall spectrum — due to the $A(u, v)P(u, v)$ behavior implied by Eq. (51.53) — is illustrated in Fig. 51.16 for square and Gaussian apertures.

FIGURE 51.16: Aperture spectra $P(u, v = 0)$ for frequencies up to half the Nyquist frequency. For explanation of “fill” see text.

The spectra are evaluated along one axis of the 2D Fourier transform. The Gaussian aperture in Fig. 51.16 has a width such that the sampling interval X_o contains $\pm 3\sigma$ (99.7%) of the Gaussian. The rectangular apertures have a width such that one occupies 95% of the sampling interval and the other occupies 50% of the sampling interval. The 95% width translates to a *fill factor* of 90% and the 50% width to a *fill factor* of 25%. The *fill factor* is discussed in section 51.7.5.

51.5.2 Sampling Density for Image Analysis

The “rules” for choosing the sampling density when the goal is image analysis — as opposed to image processing — are different. The fundamental difference is that the digitization of objects in an image into a collection of pixels introduces a form of spatial quantization noise that is not bandlimited. This leads to the following results for the choice of sampling density when one is interested in the measurement of area and (perimeter) length.

Sampling for Area Measurements

Assuming square sampling, $X_o = Y_o$ and the unbiased algorithm for estimating area which involves simple pixel counting, the CV [see Eq. (51.38)] of the area measurement is related to the sampling density by:

$$2D : \lim_{S \rightarrow \infty} CV(S) = k_2 S^{-3/2} \quad 3D : \lim_{S \rightarrow \infty} CV(S) = k_3 S^{-2} \quad (51.59)$$

and in D dimensions:

$$\lim_{S \rightarrow \infty} CV(S) = k_D S^{-(D+1)/2} \quad (51.60)$$

where S is the number of samples *per object diameter*. In 2D, the measurement is area; in 3D, volume; and in D -dimensions, hypervolume.

Sampling for Length Measurements

Again assuming square sampling and algorithms for estimating length based on the Freeman chain-code representation (see section 51.3.6), the CV of the length measurement is related to the sampling density *per unit length* as shown in Fig. 51.17.

FIGURE 51.17: CV of length measurement for various algorithms.

The curves in Fig. 51.17 were developed in the context of straight lines but similar results have been found for curves and closed contours. The specific formulas for length estimation use a chain code representation of a line and are based on a linear combination of three numbers:

$$L = \alpha \bullet N_e + \beta \bullet N_0 + \gamma \bullet N_c \quad (51.61)$$

where N_e is the number of even chain codes, N_0 the number of odd chain codes, and N_c the number of corners. The specific formulas are given in Table 51.7.

TABLE 51.7 Length Estimation Formulas
Based on Chain Code Counts (N_e , N_0 , N_c)

Formula	Coefficients		
	α	β	γ
Pixel count	1	1	0
Freeman	1	$\sqrt{2}$	0
Kulpa	0.9481	$0.9481 \bullet \sqrt{2}$	0
Corner count	0.980	1.406	-0.091

Conclusions on Sampling

If one is interested in image processing, one should choose a sampling density based on classical signal theory, that is, the Nyquist sampling theory. If one is interested in image analysis, one should choose a sampling density based on the desired measurement accuracy (*bias*) and precision (*CV*). In a case of uncertainty, one should choose the higher of the two sampling densities (frequencies).

51.6 Noise

Images acquired through modern sensors may be contaminated by a variety of noise sources. By noise we refer to stochastic variations as opposed to deterministic distortions such as shading or lack of focus. We will assume for this section that we are dealing with images formed from light using modern electro-optics. In particular we will assume the use of modern, charge-coupled device (CCD) cameras where photons produce electrons that are commonly referred to as photoelectrons. Nevertheless, most of the observations we shall make about noise and its various sources hold equally well for other imaging modalities.

While modern technology has made it possible to reduce the noise levels associated with various electro-optical devices to almost negligible levels, one noise source can never be eliminated and thus forms the limiting case when all other noise sources are “eliminated”.

51.6.1 Photon Noise

When the physical signal that we observe is based on light, then the quantum nature of light plays a significant role. A single photon at $\lambda = 500$ nm carries an energy of $E = h\nu = hc/\lambda = 3.97 \times 10^{-19}$ Joules. Modern CCD cameras are sensitive enough to be able to count individual photons. (Camera sensitivity will be discussed in section 51.7.2). The noise problem arises from the fundamentally statistical nature of photon production. We cannot assume that, in a given pixel for two consecutive but independent observation intervals of length T , the same number of photons will be counted. Photon production is governed by the laws of quantum physics which restrict us to talking about an average number of photons within a given observation window. The probability distribution for p photons in an observation window of length T seconds is known to be Poisson:

$$P(p|\rho, T) = \frac{(\rho T)^p e^{-\rho T}}{p!} \quad (51.62)$$

where ρ is the rate or intensity parameter measured in photons per second. It is critical to understand that even if there were no other noise sources in the imaging chain, the statistical fluctuations associated with photon counting over a finite time interval T would still lead to a finite signal-to-noise ratio (*SNR*). If we use the appropriate formula for the *SNR* [Eq. (51.41)], then due to the fact that the average value and the standard deviation are given by:

Poisson process -

$$\begin{aligned} \text{average} &= \rho T \\ \sigma &= \sqrt{\rho T} \end{aligned} \quad (51.63)$$

we have for the SNR :

Photon noise -

$$SNR = 10 \log_{10}(\rho T) \text{ dB} \quad (51.64)$$

The three traditional assumptions about the relationship between signal and noise do not hold for photon noise:

- photon noise is not independent of the signal;
- photon noise is not Gaussian; and
- photon noise is not additive.

For very bright signals, where ρT exceeds 10^5 , the noise fluctuations due to photon statistics can be ignored if the sensor has a sufficiently high saturation level. This will be discussed further in section 51.7.3 and, in particular, Eq. (51.73).

51.6.2 Thermal Noise

An additional, stochastic source of electrons in a CCD well is thermal energy. Electrons can be freed from the CCD material itself through thermal vibration and then, trapped in the CCD well, be indistinguishable from “true” photoelectrons. By cooling the CCD chip, it is possible to reduce significantly the number of “thermal electrons” that give rise to thermal noise or *dark current*. As the integration time T increases, the number of thermal electrons increases. The probability distribution of thermal electrons is also a Poisson process where the rate parameter is an increasing function of temperature. There are alternative techniques (to cooling) for suppressing dark current and these usually involve estimating the *average* dark current for the given integration time and then subtracting this value from the CCD pixel values before the A/D converter. While this does reduce the dark current *average*, it does not reduce the dark current *standard deviation* and it also reduces the possible dynamic range of the signal.

51.6.3 On-Chip Electronic Noise

This noise originates in the process of reading the signal from the sensor, in this case through the field effect transistor (FET) of a CCD chip. The general form of the power spectral density of readout noise is:

$$\text{Readout noise - } S_{nn}(\omega) \propto \begin{cases} \omega^{-\beta} & \omega < \omega_{\min} & \beta > 0 \\ k & \omega_{\min} < \omega < \omega_{\max} \\ \omega^{\alpha} & \omega > \omega_{\max} & \alpha > 0 \end{cases} \quad (51.65)$$

where α and β are constants and ω is the (radial) frequency at which the signal is transferred from the CCD chip to the “outside world”. At very low readout rates ($\omega < \omega_{\min}$) the noise has a $1/f$ character. Readout noise can be reduced to manageable levels by appropriate readout rates and proper electronics. At very low signal levels [see Eq. (51.64)], however, readout noise can still become a significant component in the overall SNR .

51.6.4 KTC Noise

Noise associated with the gate capacitor of an FET is termed *KTC noise* and can be nonnegligible. The output RMS value of this noise voltage is given by:

KTC noise (voltage) -

$$\sigma_{KTC} = \sqrt{\frac{kT}{C}} \quad (51.66)$$

where C is the FET gate switch capacitance, k is Boltzmann's constant, and T is the absolute temperature of the CCD chip measured in K. Using the relationships $Q = C \bullet V = N_{e^-} \bullet e^-$, the output RMS value of the KTC noise expressed in terms of the number of photoelectrons (N_{e^-}) is given by:

KTC noise (electrons) -

$$\sigma_{N_e} = \frac{\sqrt{kTC}}{e^-} \quad (51.67)$$

where e^- is the electron charge. For $C = 0.5$ pF and $T = 233$ K, this gives $N_{e^-} = 252$ electrons. This value is a "one time" noise per pixel that occurs during signal readout and is thus independent of the integration time (see sections 51.6.1 and 51.7.7). Proper electronic design that makes use, for example, of correlated double sampling and dual-slope integration can almost completely eliminate KTC noise.

51.6.5 Amplifier Noise

The standard model for this type of noise is additive, Gaussian, and independent of the signal. In modern well-designed electronics, amplifier noise is generally negligible. The most common exception to this is in color cameras where more amplification is used in the blue color channel than in the green channel or red channel leading to more noise in the blue channel. (See also section 51.7.6.)

51.6.6 Quantization Noise

Quantization noise is inherent in the amplitude quantization process and occurs in the analog-to-digital converter, ADC. The noise is additive and independent of the signal when the number of levels $L \geq 16$. This is equivalent to $B \geq 4$ bits. (See section 51.2.1). For a signal that has been converted to electrical form and thus has a minimum and maximum electrical value, Eq. (51.40) is the appropriate formula for determining the SNR . If the ADC is adjusted so that 0 corresponds to the minimum electrical value and $2^B - 1$ corresponds to the maximum electrical value then:

Quantization noise -

$$SNR = 6B + 11 \text{ dB} \quad (51.68)$$

For $B \geq 8$ bits, this means a $SNR \geq 59$ dB. Quantization noise can usually be ignored as the total SNR of a complete system is typically dominated by the smallest SNR . In CCD cameras, this is photon noise.

51.7 Cameras

The cameras and recording media available for modern digital image processing applications are changing at a significant pace. To dwell too long in this section on one major type of camera, such as the CCD camera, and to ignore developments in areas such as charge injection device (CID) cameras and CMOS cameras, is to run the risk of obsolescence. Nevertheless, the techniques that are used to characterize the CCD camera remain "universal" and the presentation that follows is given in the context of modern CCD technology for purposes of illustration.

51.7.1 Linearity

It is generally desirable that the relationship between the input physical signal (e.g., photons) and the output signal (e.g., voltage) be linear. Formally this means [as in Eq. (51.20)] that if we have two images, a and b , and two arbitrary complex constants, w_1 and w_2 , and a linear camera response, then:

$$c = \mathcal{R}\{w_1 a + w_2 b\} = w_1 \mathcal{R}\{a\} + w_2 \mathcal{R}\{b\} \quad (51.69)$$

where $\mathcal{R}\{\bullet\}$ is the camera response and c is the camera output. In practice, the relationship between input a and output c is frequently given by:

$$c = \text{gain} \bullet a^\gamma + \text{offset} \quad (51.70)$$

where γ is the *gamma* of the recording medium. For a truly linear recording system we must have $\gamma = 1$ and *offset* = 0. Unfortunately, the offset is almost never zero and thus we must compensate for this if the intention is to extract intensity measurements. Compensation techniques are discussed in section 51.10.1.

Typical values of γ that may be encountered are listed in Table 51.8. Modern cameras often have the ability to switch electronically between various values of γ .

TABLE 51.8 Comparison of γ of Various Sensors

Sensor	Surface	γ	Possible advantages
CCD chip	Silicon	1.0	Linear
Vidicon tube	Sb ₂ S ₃	0.6	Compresses dynamic range → high contrast scenes
Film	Silver halide	< 1.0	Compresses dynamic range → high contrast scenes
Film	Silver halide	> 1.0	Expands dynamic range → low contrast scenes

51.7.2 Sensitivity

There are two ways to describe the sensitivity of a camera. First, we can determine the minimum number of detectable photoelectrons. This can be termed the *absolute* sensitivity. Second, we can describe the number of photoelectrons necessary to change from one digital brightness level to the next, that is, to change one *analog-to-digital unit* (ADU). This can be termed the *relative* sensitivity.

Absolute Sensitivity

To determine the absolute sensitivity we need a characterization of the camera in terms of its noise. If the noise has a σ of, say, 100 photoelectrons, then to ensure detectability of a signal we could then say that, at the 3σ level, the minimum detectable signal (or absolute sensitivity) would be 300 photoelectrons. If all the noise sources listed in section 51.6, with the exception of photon noise, can be reduced to negligible levels, this means that an absolute sensitivity of less than 10 photoelectrons is achievable with modern technology.

Relative Sensitivity

The definition of relative sensitivity, S , given above when coupled to the linear case, Eq. (51.70) with $\gamma = 1$, leads immediately to the result:

$$S = 1 / \text{gain} = \text{gain}^{-1} \quad (51.71)$$

The measurement of the *sensitivity* or *gain* can be performed in two distinct ways.

- If following Eq. (51.70), the input signal a can be precisely controlled by either “shutter” time or intensity (through neutral density filters), then the gain can be estimated by estimating the slope of the resulting straight-line curve. To translate this into the desired units, however, a standard source must be used that emits a known number of photons onto the camera sensor and the quantum efficiency (η) of the sensor must be known. The quantum efficiency refers to how many photoelectrons are produced — on the average — per photon at a given wavelength. In general $0 \leq \eta(\lambda) \leq 1$.
- If, however, the limiting effect of the camera is only the photon (Poisson) noise (see section 51.6.1), then an easy-to-implement, alternative technique is available to determine the sensitivity. Using Eqs. (51.63), (51.70), and (51.71) and after compensating for the *offset* (see section 51.10.1), the *sensitivity* measured from an image c is given by:

$$S = \frac{E\{c\}}{\text{Var}\{c\}} = \frac{m_c}{s_c^2} \quad (51.72)$$

where m_c and s_c are defined in Eqs. (51.34) and (51.36).

Measured data for five modern (1995) CCD camera configurations are given in Table 51.9.

TABLE 51.9 Sensitivity Measurements

Camera label	Pixels	Pixel size ($\mu m \times \mu m$)	Temp. (K)	S (e^-/ADU)	Bits
C-1	1320×1035	6.8×6.8	231	7.9	12
C-2	578×385	22.0×22.0	227	9.7	16
C-3	1320×1035	6.8×6.8	293	48.1	10
C-4	576×384	23.0×23.0	238	90.9	12
C-5	756×581	11.0×5.5	300	109.2	8

Note: The lower the value of S , the more sensitive the camera is.

The extraordinary sensitivity of modern CCD cameras is clear from these data. In a scientific-grade CCD camera (C-1), only 8 photoelectrons (approximately 16 photons) separate two gray levels in the digital representation of the image. For a considerably less expensive video camera (C-5), only about 110 photoelectrons (approximately 220 photons) separate two gray levels.

51.7.3 SNR

As described in section 51.6 in modern camera systems the noise is frequently limited by:

- amplifier noise in the case of color cameras;
- thermal noise which, itself, is limited by the chip temperature K and the exposure time T ; and/or
- photon noise, which is limited by the photon production rate ρ and the exposure time T .

Thermal Noise (Dark Current)

Using cooling techniques based on Peltier cooling elements, it is straightforward to achieve chip temperatures of 230 to 250 K. This leads to low thermal electron production rates. As a measure of the thermal noise, we can look at the number of seconds necessary to produce a sufficient number of thermal electrons to go from one brightness level to the next, an ADU, in the absence of photoelectrons. This last condition — the absence of photoelectrons — is the reason for the name *dark current*. Measured data for the five cameras described above are given in Table 51.10.

TABLE 51.10 Thermal Noise

Characteristics

Camera label	Temp. (K)	Dark current (seconds/ADU)
C-1	231	526.3
C-2	227	0.2
C-3	293	8.3
C-4	238	2.4
C-5	300	23.3

The *video* camera (C-5) has on-chip dark current suppression (see section 51.6.2). Operating at room temperature this camera requires more than 20 seconds to produce one ADU change due to thermal noise. This means at the conventional video frame and integration rates of 25 to 30 images per second (see Table 51.3), the thermal noise is negligible.

Photon Noise

From Eq. (51.64) we see that it should be possible to increase the SNR by increasing the integration time of our image and thus “capturing” more photons. The pixels in CCD cameras have, however, a finite well capacity. This finite capacity, C , means that the maximum SNR for a CCD camera per pixel is given by:

Capacity-limited photon noise -

$$SNR = 10 \log_{10}(C) \text{ dB} \quad (51.73)$$

Theoretical as well as measured data for the five cameras described above are given in Table 51.11.

TABLE 51.11 Photon Noise Characteristics

Camera label	C #e ⁻	Theor. SNR (dB)	Meas. SNR (dB)	Pixel size ($\mu m \times \mu m$)	Well depth (#e ⁻ / μm^2)
C-1	32,000	45	45	6.8×6.8	692
C-2	340,000	55	55	22.0×22.0	702
C-3	32,000	45	43	6.8×6.8	692
C-4	400,000	56	52	23.0×23.0	756
C-5	40,000	46	43	11.0×5.5	661

Note that for certain cameras, the measured SNR achieves the theoretical maximum indicating that the SNR is, indeed, photon and well capacity limited. Further, the curves of SNR vs. T (integration time) are consistent with Eqs. (51.64) and (51.73). (Data not shown.) It can also be seen that, as a consequence of CCD technology, the “depth” of a CCD pixel well is constant at about $0.7 \text{ ke}^- / \mu m^2$.

51.7.4 Shading

Virtually all imaging systems produce shading. By this we mean that if the physical input image $a(x, y) = \text{constant}$, then the digital version of the image will not be constant. The source of the shading might be outside the camera, such as in the scene illumination, or the result of the camera itself where a *gain* and *offset* might vary from pixel to pixel. The model for shading is given by:

$$c[m, n] = \text{gain}[m, n] \bullet a[m, n] + \text{offset}[m, n] \quad (51.74)$$

where $a[m, n]$ is the digital image that would have been recorded if there were no shading in the image, that is, $a[m, n] = \text{constant}$. Techniques for reducing or removing the effects of shading are discussed in section 51.10.1.

51.7.5 Pixel Form

While the pixels shown in Fig. 51.1 appear to be square and to “cover” the continuous image, it is important to know the geometry for a given camera/digitizer system. In Fig. 51.18 we define possible parameters associated with a camera and digitizer and the effect they have on the pixel.

FIGURE 51.18: Pixel form parameters.

The parameters X_o and Y_o are the spacing between the pixel centers and represent the sampling distances from Eq. (51.52). The parameters X_a and Y_a are the dimensions of that portion of the camera’s surface that is sensitive to light. As mentioned in section 51.2.3 different video digitizers (frame grabbers) can have different values for X_o while they have a common value for Y_o .

Square Pixels

As mentioned in section 51.5, square sampling implies that $X_o = Y_o$ or alternatively $X_o/Y_o = 1$. It is not uncommon, however, to find frame grabbers where $X_o/Y_o = 1.1$ or $X_o/Y_o = 4/3$. (This latter format matches the format of commercial television. See Table 51.3). The risk associated with nonsquare pixels is that isotropic objects scanned with nonsquare pixels might appear isotropic on a camera-compatible monitor but analysis of the objects (such as length-to-width ratio) will yield nonisotropic results. This is illustrated in Fig. 51.19.

FIGURE 51.19: Effect of nonsquare pixels.

The ratio X_o/Y_o can be determined for any specific camera/digitizer system by using a calibration test chart with known distances in the horizontal and vertical direction. These are straightforward to make with modern laser printers. The test chart can then be scanned and the sampling distances X_o and Y_o determined.

Fill Factor

In modern CCD cameras it is possible that a portion of the camera surface is not sensitive to light and is instead used for the CCD electronics or to prevent *blooming*. Blooming occurs when a CCD well is filled (see Table 51.11) and additional photoelectrons spill over into adjacent CCD wells. Antiblooming regions between the active CCD sites can be used to prevent this. This means, of course, that a fraction of the incoming photons are lost as they strike the nonsensitive portion of the CCD chip. The fraction of the surface that is sensitive to light is termed the *fill factor* and is given by:

$$\text{fill factor} = \frac{X_a \bullet Y_a}{X_o \bullet Y_o} \times 100\% \quad (51.75)$$

The larger the *fill factor*, the more light will be captured by the chip up to the maximum of 100%. This helps improve the *SNR*. As a tradeoff, however, larger values of the fill factor mean more spatial smoothing due to the aperture effect described in section 51.5.1. This is illustrated in Fig. 51.16.

51.7.6 Spectral Sensitivity

Sensors, such as those found in cameras and film, are not equally sensitive to all wavelengths of light. The spectral sensitivity for the CCD sensor is given in Fig. 51.20.

FIGURE 51.20: Spectral characteristics of silicon, the sun, and the human visual system. UV = ultraviolet and IR = infra-red.

The high sensitivity of silicon in the infra-red means that for applications where a CCD (or other silicon-based) camera is to be used as a source of images for digital image processing and analysis, consideration should be given to using an IR blocking filter. This filter blocks wavelengths above 750 nm and thus prevents “fogging” of the image from the longer wavelengths found in sunlight. Alternatively, a CCD-based camera can make an excellent sensor for the near infrared wavelength range of 750 to 1000 nm.

51.7.7 Shutter Speeds (Integration Time)

The length of time that an image is exposed — that photons are collected — may be varied in some cameras or may vary on the basis of video formats (see Table 51.3). For reasons that have to do with the parameters of photography, this exposure time is usually termed *shutter speed* although integration time would be a more appropriate description.

Video Cameras

Values of the shutter speed as low as 500 ns are available with commercially available CCD *video* cameras, although the more conventional speeds for video are 33.37 ms (NTSC) and 40.0 ms (PAL, SECAM). Values as high as 30 s may also be achieved with certain video cameras although this means sacrificing a continuous stream of video images that contain signal in favor of a single integrated image among a stream of otherwise empty images. Subsequent digitizing hardware must be capable of handling this situation.

Scientific Cameras

Again, values as low as 500 ns are possible and, with cooling techniques based on Peltier-cooling or liquid nitrogen cooling, integration times in excess of one hour are readily achieved.

51.7.8 Readout Rate

The rate at which data is read from the sensor chip is termed the *readout rate*. The readout rate for standard video cameras depends on the parameters of the frame grabber as well as the camera. For standard video — see section 51.2.3 — the readout rate is given by:

$$R = \left(\frac{\text{images}}{\text{sec}} \right) \cdot \left(\frac{\text{lines}}{\text{image}} \right) \cdot \left(\frac{\text{pixels}}{\text{line}} \right) \quad (51.76)$$

While the appropriate unit for describing the readout rate should be *pixels/second*, the term *Hz* is frequently found in the literature and in camera specifications; we shall therefore use the latter unit. As illustration, readout rates for a video camera with square pixels are given in Table 51.12 (see also section 51.7.5).

TABLE 51.12 Video Camera Readout Rates

Format	lines/sec	pixels/line	$R(\text{MHz})$
NTSC	15,750	$(4/3) * 525$	≈ 11.0
PAL/SECAM	15,625	$(4/3) * 625$	≈ 13.0

Note that the values in Table 51.12 are approximate. Exact values for square-pixel systems require exact knowledge of the way the video digitizer (frame grabber) samples each video line.

The readout rates used in video cameras frequently mean that the electronic noise described in section 51.6.3 occurs in the region of the noise spectrum [Eq. (51.65)] described by $\omega > \omega_{\max}$ where the noise power increases with increasing frequency. Readout noise can thus be significant in video cameras.

Scientific cameras frequently use a slower readout rate in order to reduce the readout noise. Typical values of readout rate for scientific cameras, such as those described in Tables 51.9, 51.10, and 51.11 are 20 kHz, 500 kHz, and 1 to 8 MHz.

51.8 Displays

The displays used for image processing — particularly the display systems used with computers — have a number of characteristics that help determine the quality of the final image.

51.8.1 Refresh Rate

The *refresh rate* is defined as the number of complete images that are written to the screen per second. For standard video, the refresh rate is fixed at the values given in Table 51.3, either 29.97 or 25 images/s. For computer displays, the refresh rate can vary with common values being 67 images/s and 75 images/s. At values above 60 images/s, visual flicker is negligible at virtually all illumination levels.

51.8.2 Interlacing

To prevent the appearance of visual flicker at refresh rates below 60 images/s, the display can be interlaced as described in section 51.2.3. Standard interlace for video systems is 2:1. Since interlacing is not necessary at refresh rates above 60 images/s, an interlace of 1:1 is used with such systems. In other words, lines are drawn in an ordinary sequential fashion: 1, 2, 3, 4 . . . , N .

51.8.3 Resolution

The pixels stored in computer memory, although they are derived from regions of finite area in the original scene (see sections 51.5.1 and 51.7.5), may be thought of as mathematical points having no physical extent. When displayed, the space between the points must be filled in. This generally happens as a result of the finite spot size of a cathode-ray tube (CRT). The brightness profile of a CRT spot is approximately Gaussian and the number of spots that can be resolved on the display depends on the quality of the system. It is relatively straightforward to obtain display systems with a resolution of 72 spots per inch (28.3 spots per cm.) This number corresponds to standard printing conventions. If printing is not a consideration, then higher resolutions, in excess of 30 spots per cm, are attainable.

51.9 Algorithms

In this section we will describe operations that are fundamental to digital image processing. These operations can be divided into four categories: operations based on the image histogram, on simple mathematics, on convolution, and on mathematical morphology. Further, these operations can also be described in terms of their implementation as a point operation, a local operation, or a global operation as described in section 51.2.2.

51.9.1 Histogram-Based Operations

An important class of point operations is based on the manipulation of an image histogram or a *region* histogram. The most important examples are described below.

Contrast Stretching

Frequently, an image is scanned in such a way that the resulting brightness values do not make full use of the available dynamic range. This can be easily observed in the histogram of the brightness values shown in Fig. 51.6. By stretching the histogram over the available dynamic range, we attempt

to correct this situation. If the image is intended to go from brightness 0 to brightness $2^B - 1$ (see section 51.2.1), then one generally maps the 0% value (or *minimum* as defined in section 51.3.5) to the value 0 and the 100% value (or *maximum*) to the value $2^B - 1$. The appropriate transformation is given by:

$$b[m, n] = (2^B - 1) \bullet \frac{a[m, n] - \text{minimum}}{\text{maximum} - \text{minimum}} \quad (51.77)$$

This formula, however, can be somewhat sensitive to outliers and a less sensitive and more general version is given by:

$$b[m, n] = \begin{cases} 0 & a[m, n] \leq p_{\text{low}}\% \\ (2^B - 1) \bullet \frac{a[m, n] - p_{\text{low}}\%}{p_{\text{high}}\% - p_{\text{low}}\%} & p_{\text{low}}\% < a[m, n] < p_{\text{high}}\% \\ (2^B - 1) & a[m, n] \geq p_{\text{high}}\% \end{cases} \quad (51.78)$$

In this second version, one might choose the 1% and 99% values for $p_{\text{low}}\%$ and $p_{\text{high}}\%$, respectively, instead of the 0% and 100% values represented by Eq. (51.77). It is also possible to apply the contrast-stretching operation on a regional basis using the histogram from a region to determine the appropriate limits for the algorithm. Note that in Eqs. (51.77) and (51.78) it is possible to suppress the term $2^B - 1$ and simply normalize the brightness range to $0 \leq b[m, n] \leq 1$. This means representing the final pixel brightnesses as reals instead of integers, but modern computer speeds and RAM capacities make this quite feasible.

Equalization

When one wishes to compare two or more images on a specific basis, such as texture, it is common to first normalize their histograms to a “standard” histogram. This can be especially useful when the images have been acquired under different circumstances. The most common histogram normalization technique is *histogram equalization* where one attempts to change the histogram through the use of a function $b = f(a)$ into a histogram that is constant for all brightness values. This would correspond to a brightness distribution where all values are equally probable. Unfortunately, for an arbitrary image, one can only approximate this result.

For a “suitable” function $f(\bullet)$ the relation between the input probability density function, the output probability density function, and the function $f(\bullet)$ is given by:

$$p_b(b)db = p_a(a)da \quad \Rightarrow \quad df = \frac{p_a(a)da}{p_b(b)} \quad (51.79)$$

From Eq. (51.79) we see that “suitable” means that $f(\bullet)$ is differentiable and that $df/da \geq 0$. For histogram equalization, we desire that $p_b(b) = \text{constant}$ and this means that:

$$f(a) = (2^B - 1) \bullet P(a) \quad (51.80)$$

where $P(a)$ is the probability distribution function defined in section 51.3.5 and illustrated in Fig. 51.6(a). In other words, the *quantized* probability distribution function normalized from 0 to $2^B - 1$ is the look-up table required for histogram equalization. Figures 51.21(a-c) illustrate the effect of contrast stretching and histogram equalization on a standard image. The histogram equalization procedure can also be applied on a regional basis.

Other Histogram-Based Operations

The histogram derived from a local region can also be used to drive local filters that are to be applied to that region. Examples include *minimum* filtering, *median* filtering, and *maximum* filtering. The concepts minimum, median, and maximum were introduced in Fig. 51.6. The filters based on these concepts will be presented formally in sections 51.9.4 and 51.9.6.

FIGURE 51.21: (a) Original, (b) contrast stretched, and (c) histogram equalized.

51.9.2 Mathematics-Based Operations

In this section we distinguish between binary arithmetic and ordinary arithmetic. In the binary case there are two brightness values “0” and “1”. In the ordinary case we begin with 2^B brightness values or levels but the processing of the image can easily generate many more levels. For this reason, many *software* systems provide 16- or 32-bit representations for pixel brightnesses in order to avoid problems with arithmetic overflow.

Binary Operations

Operations based on binary (Boolean) arithmetic form the basis for a powerful set of tools that will be described here and extended in section 51.9.6 mathematical morphology. The operations described below are point operations and thus admit a variety of efficient implementations including simple look-up tables. The standard notation for the basic set of binary operations is:

$$\begin{aligned}
 \text{NOT} \quad c &= \bar{a} \\
 \text{OR} \quad c &= a + b \\
 \text{AND} \quad c &= a \bullet b \\
 \text{XOR} \quad c &= a \oplus b = a \bullet \bar{b} + \bar{a} \bullet b \\
 \text{SUB} \quad c &= a \setminus b = a - b = a \bullet \bar{b}
 \end{aligned} \tag{51.81}$$

The implication is that each operation is applied on a pixel-by-pixel basis. For example, $c[m, n] = a[m, n] \bullet \bar{b}[m, n] \forall m, n$. The definition of each operation is:

NOT	
<i>a</i>	
0	1
1	0

OR	<i>b</i>	
<i>a</i>	0	1
0	0	1
1	1	1

AND	<i>b</i>	
<i>a</i>	0	1
0	0	0
1	0	1

↑ ↑
 input output

XOR	<i>b</i>	
<i>a</i>	0	1
0	0	1
1	1	0

SUB	<i>b</i>	
<i>a</i>	0	1
0	0	0
1	1	0

(51.82)

These operations are illustrated in Fig. 51.22 where the binary value “1” is shown in black and the value “0” in white.

The SUB(•) operation can be particularly useful when the image a represents a region-of-interest that we want to analyze systematically and the image b represents objects that, having been analyzed, can now be discarded, that is subtracted, from the region.

FIGURE 51.22: Examples of the various binary point operations. (a) Image a ; (b) Image b ; (c) $\text{NOT}(b) = \bar{b}$; (d) $\text{OR}(a, b) = a + b$; (e) $\text{AND}(a, b) = a \bullet b$; (f) $\text{XOR}(a, b) = a \oplus b$; and (g) $\text{SUB}(a, b) = a \setminus b$.

Arithmetic-Based Operations

The gray-value point operations that form the basis for image processing are based on ordinary mathematics and include:

<i>Operation</i>	<i>Definition</i>	<i>Preferred Data Type</i>	(51.83)
ADD	$c = a + b$	Integer	
SUB	$c = a - b$	Integer	
MUL	$c = a \bullet b$	Integer or floating point	
DIV	$c = a / b$	Floating point	
LOG	$c = \log(a)$	Floating point	
EXP	$c = \exp(a)$	Floating point	
SQRT	$c = \text{sqrt}(a)$	Floating point	
TRIG.	$c = \sin / \cos / \tan(a)$	Floating point	
INVERT	$c = (2^B - 1) - a$	Integer	

51.9.3 Convolution-Based Operations

Convolution, the mathematical, *local* operation defined in section 51.3.1, is central to modern image processing. The basic idea is that a window of some finite size and shape — the *support* — is scanned across the image. The output pixel value is the weighted sum of the input pixels within the window where the weights are the values of the filter assigned to every pixel of the window itself. The window with its weights is called the *convolution kernel*. This leads directly to the following variation on Eq. (51.3). If the filter $h[j, k]$ is zero outside the (rectangular) window $\{j = 0, 1, \dots, J - 1; k = 0, 1, \dots, K - 1\}$, then using Eq. (51.4), the convolution can be written as the following finite sum:

$$c[m, n] = a[m, n] \otimes h[m, n] = \sum_{j=0}^{J-1} \sum_{k=0}^{K-1} h[j, k] a[m - j, n - k] \quad (51.84)$$

This equation can be viewed as more than just a pragmatic mechanism for smoothing or sharpening an image. Further, while Eq. (51.84) illustrates the local character of this operation, Eqs. (51.10) and (51.24) suggest that the operation can be implemented through the use of the Fourier domain which requires a global operation, the Fourier transform. Both of these aspects will be discussed below.

Background

In a variety of image-forming systems, an appropriate model for the transformation of the physical signal $a(x, y)$ into an electronic signal $c(x, y)$ is the convolution of the input signal with the impulse response of the sensor system. This system might consist of both an optical as well as an electrical sub-system. If each of these systems can be treated as a linear, shift-invariant (LSI) system, then the convolution model is appropriate. The definitions of these two possible system properties are given below:

$$\begin{aligned} \text{Linearity -} \quad & \text{If } a_1 \rightarrow c_1 \text{ and } a_2 \rightarrow c_2 \\ & \text{Then } w_1 \bullet a_1 + w_2 \bullet a_2 \rightarrow w_1 \bullet c_1 + w_2 \bullet c_2 \end{aligned} \quad (51.85)$$

$$\begin{aligned} \text{Shift-Invariance -} \quad & \text{If } a(x, y) \rightarrow c(x, y) \\ & \text{Then } a(x - x_o, y - y_o) \rightarrow c(x - x_o, y - y_o) \end{aligned} \quad (51.86)$$

where w_1 and w_2 are arbitrary complex constants and x_o, y_o are coordinates corresponding to arbitrary spatial translations.

Two remarks are appropriate at this point. First, linearity implies (by choosing $w_1 = w_2 = 0$) that “zero in” gives “zero out”. The offset described in Eq. (51.70) means that such camera signals are not the output of a linear system and thus (strictly speaking) the convolution result is not applicable. Fortunately, it is straightforward to correct for this nonlinear effect. (See section 51.10.1).

Second, optical lenses with a magnification, M , other than $1 \times$ are not shift invariant; a translation of 1 unit in the input image $a(x, y)$ produces a translation of M units in the output image $c(x, y)$. Due to the Fourier property described in Eq. (51.25), this case can still be handled by linear system theory.

If an impulse point of light $\delta(x, y)$ is imaged through an LSI system, then the impulse response of that system is called the *point spread function (PSF)*. The output image then becomes the convolution of the input image with the *PSF*. The Fourier transform of the *PSF* is called the *optical transfer function (OTF)*. For optical systems that are circularly symmetric, aberration-free, and diffraction-limited, the *PSF* is given by the Airy disk shown in Table 51.4-T.5. The *OTF* of the Airy disk is also presented in Table 51.4-T.5.

If the convolution window is not the diffraction-limited PSF of the lens but rather the effect of defocusing a lens, then an appropriate model for $h(x, y)$ is a pill box of radius a as described in Table 51.4-T.3. The effect on a test pattern is illustrated in Fig. 51.23.

FIGURE 51.23: Convolution of test pattern with a pill box of radius $a = 4.5$ pixels. (a) Test pattern; (b) defocused image.

The effect of the defocusing is more than just simple blurring or smoothing. The almost periodic negative lobes in the transfer function in Table 51.4-T.3 produce a 180° phase shift in which black turns to white and vice-versa. The phase shift is clearly visible in Fig. 51.23(b).

Convolution in the Spatial Domain

In describing filters based on convolution, we will use the following convention. Given a filter $h[j, k]$ of dimensions $J \times K$, we will consider the coordinate $[j = 0, k = 0]$ to be in the center of the filter matrix, \mathbf{h} . This is illustrated in Fig. 51.24. The “center” is well defined when J and K are odd: for the case where they are even, we will use the approximations $(J/2, K/2)$ for the “center” of the matrix.

$$\mathbf{h} = \begin{bmatrix} h[-(J-\frac{1}{2}), -(K-\frac{1}{2})] & \dots & \dots & h[0, -(K-\frac{1}{2})] & \dots & \dots & h[(J-\frac{1}{2}), -(K-\frac{1}{2})] \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ \vdots & \dots & h[-1, -1] & h[0, -1] & h[1, -1] & \dots & \vdots \\ h[-(J-\frac{1}{2}), 0] & \dots & h[-1, 0] & h[0, 0] & h[1, 0] & \dots & h[(J-\frac{1}{2}), 0] \\ \vdots & \dots & h[-1, 1] & h[0, 1] & h[1, 1] & \dots & \vdots \\ \vdots & \ddots & \vdots & \vdots & \ddots & \vdots & \vdots \\ h[-(J-\frac{1}{2}), (K-\frac{1}{2})] & \dots & \dots & h[0, (K-\frac{1}{2})] & \dots & \dots & h[(J-\frac{1}{2}), (K-\frac{1}{2})] \end{bmatrix}$$

FIGURE 51.24: Coordinate system for describing $h[j, k]$.

When we examine the convolution sum [Eq. (51.84)] closely, several issues become evident.

- Evaluation of formula (51.84) for $m = n = 0$ while rewriting the limits of the convolution sum based on the “centering” of $h[j, k]$ shows that values of $a[j, k]$ can be required that

are outside the image boundaries:

$$c[0, 0] = \sum_{j=-J_0}^{+J_0} \sum_{k=-K_0}^{+K_0} h[j, k] a[-j, -k] \quad J_0 = \frac{(J-1)}{2}, \quad K_0 = \frac{(K-1)}{2} \quad (51.87)$$

The question arises — what values should we assign to the image $a[m, n]$ for $m < 0$, $m \geq M$, $n < 0$, and $n \geq N$? There is no “answer” to this question. There are only alternatives among which we are free to choose assuming we understand the possible consequences of our choice. The standard alternatives are (a) extend the images with a constant (possibly zero) brightness value, (b) extend the image periodically, (c) extend the image by mirroring it at its boundaries, or (d) extend the values at the boundaries indefinitely. These alternatives are illustrated in Fig. 51.25.

FIGURE 51.25: Examples of various alternatives to extend an image outside its formal boundaries. See text for explanation.

- When the convolution sum is written in the standard form [Eq. (51.3)] for an image $a[m, n]$ of size $M \times N$:

$$c[m, n] = \sum_{j=0}^{M-1} \sum_{k=0}^{N-1} a[j, k] h[m-j, n-k] \quad (51.88)$$

we see that the convolution kernel $h[j, k]$ is mirrored around $j = k = 0$ to produce $h[-j, -k]$ before it is translated by $[m, n]$ as indicated in Eq. (51.88). While some convolution kernels in common use are symmetric in this respect, $h[j, k] = h[-j, -k]$, many are not. (See section 51.9.5). Care must therefore be taken in the implementation of filters with respect to the mirroring requirements.

- The computational complexity for a $K \times K$ convolution kernel implemented in the spatial domain on an image of $N \times N$ is $O(K^2)$ where the complexity is measured *per pixel* on the basis of the number of multiplies-and-adds (MADDs).
- The value computed by a convolution that begins with integer brightnesses for $a[m, n]$ may produce a rational number or a floating point number in the result $c[m, n]$. Working exclusively with integer brightness values will, therefore, cause roundoff errors.
- Inspection of Eq. (51.84) reveals another possibility for efficient implementation of convolution. If the convolution kernel $h[j, k]$ is *separable*, that is, if the kernel can be written as:

$$h[j, k] = h_{\text{row}}[k] \bullet h_{\text{col}}[j] \quad (51.89)$$

then the filtering can be performed as follows:

$$c[m, n] = \sum_{j=0}^{J-1} \left\{ \sum_{k=0}^{K-1} h_{\text{row}}[k] a[m-j, n-k] \right\} h_{\text{col}}[j] \quad (51.90)$$

This means that instead of applying one two-dimensional filter, it is possible to apply two one-dimensional filters, the first one in the k direction and the second one in j direction. For an $N \times N$ image this, in general, reduces the computational complexity per pixel from $O(J \bullet K)$ to $O(J + K)$.

An alternative way of writing separability is to note that the convolution kernel Fig. 51.24 is a matrix \mathbf{h} and, if separable, \mathbf{h} can be written as:

$$\begin{aligned} [\mathbf{h}] &= [\mathbf{h}_{\text{col}}] \bullet [\mathbf{h}_{\text{row}}]^t \\ (J \times K) &= (J \times 1) \bullet (1 \times K) \end{aligned} \quad (51.91)$$

where “ t ” denotes the matrix transpose operation. In other words, \mathbf{h} can be expressed as the *outer product* of a column vector $[\mathbf{h}_{\text{col}}]$ and a row vector $[\mathbf{h}_{\text{row}}]$.

- For certain filters it is possible to find an *incremental implementation* for a convolution. As the convolution window moves over the image [see Eq. (51.88)], the leftmost column of image data under the window is shifted out as a new column of image data is shifted in from the right. Efficient algorithms can take advantage of this and, when combined with separable filters as described above, this can lead to algorithms where the computational complexity per pixel is $O(\text{constant})$.

Convolution in the Frequency Domain

In section 51.3.4 we indicated that there was an alternative method to implement the filtering of images through convolution. Based on Eq. (51.24), it appears possible to achieve the same result as in Eq. (51.84) by the following sequence of operations:

$$\begin{aligned} (i) \quad & \text{Compute } A(\Omega, \Psi) = \mathcal{F}\{a[m, n]\} \\ (ii) \quad & \text{Multiply } A(\Omega, \Psi) \text{ by the precomputed } H(\Omega, \Psi) = \mathcal{F}\{h[m, n]\} \\ (iii) \quad & \text{Compute the result } c[m, n] = \mathcal{F}^{-1}\{A(\Omega, \Psi) \bullet H(\Omega, \Psi)\} \end{aligned} \quad (51.92)$$

- While it might seem that the “recipe” given above in Eq. (51.92) circumvents the problems associated with direct convolution in the spatial domain — specifically, determining values for the image outside the boundaries of the image — the Fourier domain approach, in fact, simply “assumes” that the image is repeated periodically outside its boundaries as illustrated in Fig. 51.25(b). This phenomenon is referred to as *circular convolution*.

If circular convolution is not acceptable, then the other possibilities illustrated in Fig. 51.25 can be realized by embedding the image $a[m, n]$ and the filter $H(\Omega, \Psi)$ in larger matrices with the desired image extension mechanism for $a[m, n]$ being explicitly implemented.

- The computational complexity per pixel of the Fourier approach for an image of $N \times N$ and for a convolution kernel of $K \times K$ is $O(\log N)$ *complex* MADDs *independent of* K . Here we assume that $N > K$ and that N is a highly composite number such as a power of two. (See also section 51.2.1). This latter assumption permits use of the computationally efficient fast Fourier transform (*FFT*) algorithm. Surprisingly then, the indirect route described by Eq. (51.92) can be faster than the direct route given in Eq. (51.84). This requires, in general, that $K^2 \gg \log N$. The range of K and N for which this holds depends on the specifics of the implementation. For the machine on which this

manuscript is being written and the specific image processing package that is being used, for an image of $N = 256$, the Fourier approach is faster than the convolution approach when $K \geq 15$. (It should be noted that in this comparison the direct convolution involves only integer arithmetic while the Fourier domain approach requires complex floating point arithmetic.)

51.9.4 Smoothing Operations

These algorithms are applied in order to reduce noise and/or to prepare images for further processing such as segmentation. We distinguish between linear and nonlinear algorithms where the former are amenable to analysis in the Fourier domain and the latter are not. We also distinguish between implementations based on a rectangular support for the filter and implementations based on a circular support for the filter.

Linear Filters

Several filtering algorithms will be presented together with the most useful supports.

Uniform filter – The output image is based on a local averaging of the input filter where all of the values within the filter support have the same weight. In the continuous spatial domain (x, y) the *PSF* and transfer function are given in Table 51.4-T.1 for the rectangular case and in Table 51.4-T.3 for the circular (pill box) case. For the discrete spatial domain $[m, n]$, the filter values are the samples of the continuous domain case. Examples for the rectangular case ($J = K = 5$) and the circular case ($R = 2.5$) are shown in Fig. 51.26.

$$h_{rect}[j, k] = \frac{1}{25} \begin{bmatrix} 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \end{bmatrix} \quad (a)$$

$$h_{circ}[j, k] = \frac{1}{21} \begin{bmatrix} 0 & 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ 1 & 1 & 1 & 1 & 1 \\ 0 & 1 & 1 & 1 & 0 \end{bmatrix} \quad (b)$$

FIGURE 51.26: Uniform filters for image smoothing. (a) Rectangular filter ($J = K = 5$); (b) circular filter ($R = 2.5$).

Note that in both cases the filter is normalized so that $\sum h[j, k] = 1$. This is done so that if the input $a[m, n]$ is a constant, then the output image $c[m, n]$ is the same constant. The justification can be found in the Fourier transform property described in Eq. (51.26). As can be seen from Table 51.4, both of these filters have transfer functions that have negative lobes and can, therefore, lead to phase reversal as seen in Fig. 51.23. The square implementation of the filter is separable and incremental; the circular implementation is incremental.

Triangular filter – The output image is based on a local averaging of the input filter where the values within the filter support have differing weights. In general, the filter can be seen as the convolution of two (identical) uniform filters either rectangular or circular, and this has direct consequences for the computational complexity. (See Table 51.13.) In the continuous spatial domain, the *PSF* and transfer function are given in Table 51.4-T.2 for the rectangular support case and in Table 51.4-T.4 for the circular (pill box) support case. As seen in Table 51.4, the transfer functions of

these filters do not have negative lobes and thus do not exhibit phase reversal.

Examples for the rectangular support case ($J = K = 5$) and the circular support case ($R = 2.5$) are shown in Fig. 51.27. The filter is again normalized so that $\sum h[j, k] = 1$.

$$h_{rect}[j, k] = \frac{1}{81} \begin{bmatrix} 1 & 2 & 3 & 2 & 1 \\ 2 & 4 & 6 & 4 & 2 \\ 3 & 6 & 9 & 6 & 3 \\ 2 & 4 & 6 & 4 & 2 \\ 1 & 2 & 3 & 2 & 1 \end{bmatrix} \quad (a)$$

$$h_{circ}[j, k] = \frac{1}{25} \begin{bmatrix} 0 & 0 & 1 & 0 & 0 \\ 0 & 2 & 2 & 2 & 0 \\ 1 & 2 & 5 & 2 & 1 \\ 0 & 2 & 2 & 2 & 0 \\ 0 & 0 & 1 & 0 & 0 \end{bmatrix} \quad (b)$$

FIGURE 51.27: Triangular filters for image smoothing. (a) Pyramidal filter ($J = K = 5$); (b) Cone filter ($R = 2.5$).

Gaussian filter – The use of the Gaussian kernel for smoothing has become extremely popular. This has to do with certain properties of the Gaussian (e.g., the central limit theorem, minimum space-bandwidth product) as well as several application areas such as edge finding and scale space analysis. The *PSF* and transfer function for the continuous space Gaussian are given in Table 51.4-T.6. The Gaussian filter is separable:

$$\begin{aligned} h(x, y) &= g_{2D}(x, y) = \left(\frac{1}{\sqrt{2\pi}\sigma} e^{-(x^2/2\sigma^2)} \right) \bullet \left(\frac{1}{\sqrt{2\pi}\sigma} e^{-(y^2/2\sigma^2)} \right) \\ &= g_{1D}(x) \bullet g_{1D}(y) \end{aligned} \quad (51.93)$$

There are four distinct ways to implement the Gaussian:

1. Convolution using a finite number of samples (N_o) of the Gaussian as the convolution kernel. It is common to choose $N_o = \lceil 3\sigma \rceil$ or $\lceil 5\sigma \rceil$.

$$g_{1D}[n] = \begin{cases} \frac{1}{\sqrt{2\pi}\sigma} e^{-(n^2/2\sigma^2)} & |n| \leq N_o \\ 0 & |n| > N_o \end{cases} \quad (51.94)$$

2. Repetitive convolution using a uniform filter as the convolution kernel.

$$g_{1D}[n] \approx u[n] \otimes u[n] \otimes u[n]$$

$$u[n] = \begin{cases} 1/(2N_o + 1) & |n| \leq N_o \\ 0 & |n| > N_o \end{cases} \quad (51.95)$$

The actual implementation (in each dimension) is usually of the form:

$$c[n] = ((a[n] \otimes u[n]) \otimes u[n]) \otimes u[n] \quad (51.96)$$

This implementation makes use of the approximation afforded by the central limit theorem. For a desired σ with Eq. (51.96), we use $N_o = \lceil \sigma \rceil$ although this severely restricts

our choice of σ 's to integer values.

3. Multiplication in the frequency domain. As the Fourier transform of a Gaussian is a Gaussian (see Table 51.4-T.6), this means that it is straightforward to prepare a filter $H(\Omega, \Psi) = G_{2D}(\Omega, \Psi)$ for use with Eq. (51.92). To avoid truncation effects in the frequency domain due to the infinite extent of the Gaussian, it is important to choose a σ that is sufficiently large. Choosing $\sigma > k/\pi$ where $k = 3$ or 4 will usually be sufficient.
4. Use of a recursive filter implementation. A recursive filter has an infinite impulse response and thus an infinite support. The separable Gaussian filter can be implemented by applying the following recipe in each dimension when $\sigma \geq 0.5$.

- (i) Choose the σ based on the desired goal of the filtering;
- (ii) Determine the parameter q based on Eq. (51.98);
- (iii) Use Eq. (51.99) to determine the filter coefficients $\{b_0, b_1, b_2, b_3, B\}$; (51.97)
- (iv) Apply the forward difference equation. Eq. (51.100);
- (v) Apply the backward difference equation. Eq. (51.101).

The relation between the desired σ and q is given by:

$$q = \begin{cases} .98711\sigma - 0.96330 & \sigma \geq 2.5 \\ 3.97156 - 4.14554\sqrt{1 - .26891 \sigma} & 0.5 \leq \sigma \leq 2.5 \end{cases} \quad (51.98)$$

The *filter coefficients* $\{b_0, b_1, b_2, b_3, B\}$ are defined by:

$$\begin{aligned} b_0 &= 1.57825 + (2.44413 q) + (1.4281 q^2) + (0.422205 q^3) \\ b_1 &= (2.44413 q) + (2.85619 q^2) + (1.26661 q^3) \\ b_2 &= -(1.4281 q^2) - (1.26661 q^3) \\ b_3 &= 0.422205 q^3 \\ B &= 1 - (b_1 + b_2 + b_3)/b_0 \end{aligned} \quad (51.99)$$

The one-dimensional *forward difference equation* takes an input row (or column) $a[n]$ and produces an intermediate output result $w[n]$ given by:

$$w[n] = Ba[n] + (b_1 w[n-1] + b_2 w[n-2] + b_3 w[n-3]) / b_0 \quad (51.100)$$

The one-dimensional *backward difference equation* takes the intermediate result $w[n]$ and produces the output $c[n]$ given by:

$$c[n] = Bw[n] + (b_1 c[n+1] + b_2 c[n+2] + b_3 c[n+3]) / b_0 \quad (51.101)$$

The forward equation is applied from $n = 0$ up to $n = N - 1$ while the backward equation is applied from $n = N - 1$ down to $n = 0$.

The relative performance of these various implementations of the Gaussian filter can be described as follows. Using the *root-square error* $\sqrt{\sum_{n=-\infty}^{+\infty} |g[n|\sigma] - h[n]|^2}$ between a true, infinite-extent Gaussian, $g[n|\sigma]$, and an approximated Gaussian, $h[n]$, as a measure of accuracy, the various algorithms described above give the results shown in Fig. 51.28(a). The relative speed of the various

algorithms is shown in Fig. 51.28(b).

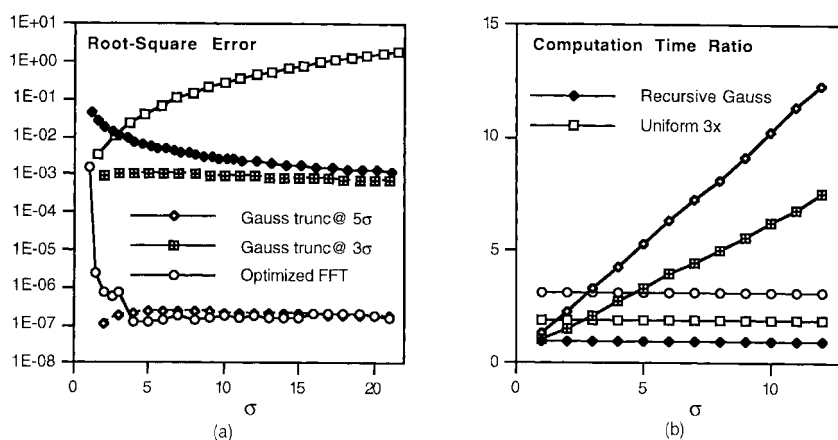

FIGURE 51.28: Comparison of various Gaussian algorithms with $N = 256$. The legend is spread across both graphs. (a) Accuracy comparison; (b) speed comparison.

The root-square error measure is extremely conservative and, thus, all filters, with the exception of “Uniform $3\times$ ” for large σ , are sufficiently accurate. The recursive implementation is the fastest independent of σ : the other implementations can be significantly slower. The FFT implementation, for example, is 3.1 times slower for $N = 256$. Further, the FFT requires that N be a highly composite number.

Other – The Fourier domain approach offers the opportunity to implement a variety of smoothing algorithms. The smoothing filters will then be *lowpass filters*. In general, it is desirable to use a lowpass filter that has zero phase so as not to produce phase distortion when filtering the image. The importance of phase was illustrated in Figs. 51.5 and 51.23. When the frequency domain characteristics can be represented in an analytic form, then this can lead to relatively straightforward implementations of $H(\Omega, \Psi)$. Possible candidates include the lowpass filters “Airy” and “Exponential Decay” found in Table 51.4-T.5 and Table 51.4-T.8, respectively.

Nonlinear Filters

A variety of smoothing filters have been developed that are not linear. While they cannot, in general, be submitted to Fourier analysis, their properties and domains of application have been studied extensively.

Median filter – The median statistic was described in section 51.3.5. A median filter is based on moving a window over an image (as in a convolution) and computing the output pixel as the median value of the brightnesses within the input window. If the window is $J \times K$ in size we can order the $J \cdot K$ pixels in brightness value from smallest to largest. If $J \cdot K$ is odd, then the median will be the $(J \cdot K + 1)/2$ entry in the list of ordered brightnesses. Note that the value selected will be exactly equal to one of the existing brightnesses so that no roundoff error will be involved if we want to work exclusively with integer brightness values. The algorithm as it is described above has a generic complexity per pixel of $O(J \cdot K \cdot \log(J \cdot K))$. Fortunately, a fast algorithm (due to Huang et al.) exists that reduces the complexity to $O(K)$ assuming $J \geq K$.

A useful variation on the theme of the median filter is the *percentile filter*. Here the center pixel in

the window is replaced not by the 50% (median) brightness value but rather by the $p\%$ brightness value where $p\%$ ranges from 0% (the *minimum filter*) to 100% (the *maximum filter*). Values other than $(p = 50)\%$ do not, in general, correspond to smoothing filters.

Kuwahara filter – Edges play an important role in our perception of images (see Fig. 51.15) as well as in the analysis of images. As such, it is important to be able to smooth images without disturbing the sharpness and, if possible, the position of edges. A filter that accomplishes this goal is termed an *edge-preserving filter* and one particular example is the Kuwahara filter. Although this filter can be implemented for a variety of different window shapes, the algorithm will be described for a square window of size $J = K = 4L + 1$ where L is an integer. The window is partitioned into four regions, as shown in Fig. 51.29.

FIGURE 51.29: Four square regions defined for the Kuwahara filter. In this example, $L = 1$ and thus $J = K = 5$. Each region is $[(J + 1)/2] \times [(K + 1)/2]$.

In each of the four regions ($i = 1, 2, 3, 4$), the mean brightness, m_i in Eq. (51.34), and the *variance*, s_i^2 in Eq. (51.36), are measured. The output value of the center pixel in the window is the mean value of that region that has the smallest variance.

Summary of Smoothing Algorithms

Table 51.13 summarizes the various properties of the smoothing algorithms presented above. The filter size is assumed to be bounded by a rectangle of $J \times K$ where, without loss of generality, $J \geq K$. The image size is $N \times N$. Examples of the effect of various smoothing algorithms are shown in Fig. 51.30.

TABLE 51.13 Characteristics of Smoothing Filters

Algorithm	Domain	Type	Support	Separable/incremental	Complexity/pixel
Uniform	Space	Linear	Square	Y/Y	$O(\text{constant})$
Uniform	Space	Linear	Circular	N/Y	$O(K)$
Triangle	Space	Linear	Square	Y/N	$O(\text{constant})^a$
Triangle	Space	Linear	Circular	N/N	$O(K)^a$
Gaussian	Space	Linear	∞^a	Y/N	$O(\text{constant})^a$
Median	Space	Non-Linear	Square	N/Y	$O(K)^a$
Kuwahara	Space	Non-Linear	Square ^a	N/N	$O(J \bullet K)$
Other	Frequency	Linear	—	—/—	$O(\log N)$

51.9.5 Derivative-Based Operations

Just as smoothing is a fundamental operation in image processing, so is the ability to take one or more spatial derivatives of the image. The fundamental problem is that, according to the mathematical definition of a derivative, this cannot be done. A digitized image is not a continuous function $a(x, y)$ of the spatial variables but rather a discrete function $a[m, n]$ of the integer spatial coordinates. As a result, the algorithms we will present can only be seen as *approximations* to the true spatial derivatives of the original spatially continuous image.

Further, as we can see from the Fourier property in Eq. (51.27), taking a derivative multiplies the signal spectrum by either u or v . This means that high frequency noise will be emphasized in the resulting image. The general solution to this problem is to combine the derivative operation with one that suppresses high frequency noise, in short, smoothing in combination with the desired derivative operation.

First Derivatives

As an image is a function of two (or more) variables, it is necessary to define the direction in which the derivative is taken. For the two-dimensional case, we have the horizontal direction, the vertical direction, or an arbitrary direction that can be considered as a combination of the two. If we use \mathbf{h}_x to denote a horizontal derivative filter (matrix), \mathbf{h}_y to denote a vertical derivative filter (matrix), and \mathbf{h}_θ to denote the arbitrary angle derivative filter (matrix), then:

$$[\mathbf{h}_\theta] = \cos \theta \bullet [\mathbf{h}_x] + \sin \theta \bullet [\mathbf{h}_y] \quad (51.102)$$

Gradient filters – It is also possible to generate a vector derivative description as the *gradient*, $\nabla a[m, n]$, of an image:

$$\nabla a = \frac{\partial a}{\partial x} \vec{i}_x + \frac{\partial a}{\partial y} \vec{i}_y = (h_x \otimes a) \vec{i}_x + (h_y \otimes a) \vec{i}_y \quad (51.103)$$

where \vec{i}_x and \vec{i}_y are unit vectors in the horizontal and vertical direction, respectively. This leads to two descriptions:

Gradient magnitude -

$$|\nabla a| = \sqrt{(h_x \otimes a)^2 + (h_y \otimes a)^2} \quad (51.104)$$

and

Gradient direction -

$$\psi(\nabla a) = \arctan \{ (h_y \otimes a) / (h_x \otimes a) \} \quad (51.105)$$

The gradient magnitude is sometimes approximated by:

Approx. gradient magnitude -

$$|\nabla a| \cong |h_x \otimes a| + |h_y \otimes a| \quad (51.106)$$

The final results of these calculations depend strongly on the choices of \mathbf{h}_x and \mathbf{h}_y . A number of possible choices for $(\mathbf{h}_x, \mathbf{h}_y)$ will now be described.

Basic derivative filters – These filters are specified by:

$$\begin{aligned} (i) \quad [\mathbf{h}_x] &= [\mathbf{h}_y]^t = [1 \quad -1] \\ (ii) \quad [\mathbf{h}_x] &= [\mathbf{h}_y]^t = [1 \quad 0 \quad -1] \end{aligned} \quad (51.107)$$

where “ t ” denotes matrix transpose. These two filters differ significantly in their Fourier magnitude and Fourier phase characteristics. For the frequency range $0 \leq \Omega \leq \pi$, these are given by:

$$\begin{aligned} (i) \quad [\mathbf{h}] &= [1 \quad -1] \xleftrightarrow{\mathcal{F}} |H(\Omega)| = 2 |\sin(\Omega/2)|; \quad \varphi(\Omega) = (\pi - \Omega)/2 \\ (ii) \quad [\mathbf{h}] &= [1 \quad 0 \quad -1] \xleftrightarrow{\mathcal{F}} |H(\Omega)| = 2 |\sin(\Omega)|; \quad \varphi(\Omega) = \pi/2 \end{aligned} \quad (51.108)$$

The second form (ii) gives suppression of high frequency terms ($\Omega \approx \pi$) while the first form (i) does not. The first form leads to a phase shift; the second form does not.

Prewitt gradient filters – These filters are specified by:

$$\begin{aligned} [\mathbf{h}_x] &= \frac{1}{3} \begin{bmatrix} 1 & 0 & -1 \\ 1 & 0 & -1 \\ 1 & 0 & -1 \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} \bullet [1 \quad 0 \quad -1] \\ [\mathbf{h}_y] &= \frac{1}{3} \begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \\ -1 & -1 & -1 \end{bmatrix} = \frac{1}{3} \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix} \bullet [1 \quad 1 \quad 1] \end{aligned} \quad (51.109)$$

Both \mathbf{h}_x and \mathbf{h}_y are separable. Beyond the computational implications are the implications for the analysis of the filter. Each filter takes the derivative in one direction using Eq. (51.107 ii) and smoothes in the orthogonal direction using a one-dimensional version of a *uniform* filter as described in section 51.9.4.

Sobel gradient filters – These filters are specified by:

$$\begin{aligned} [\mathbf{h}_x] &= \frac{1}{4} \begin{bmatrix} 1 & 0 & -1 \\ 2 & 0 & -2 \\ 1 & 0 & -1 \end{bmatrix} = \frac{1}{4} \begin{bmatrix} 1 \\ 2 \\ 1 \end{bmatrix} \bullet [1 \quad 0 \quad -1] \\ [\mathbf{h}_y] &= \frac{1}{4} \begin{bmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{bmatrix} = \frac{1}{4} \begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix} \bullet [1 \quad 2 \quad 1] \end{aligned} \quad (51.110)$$

Again, \mathbf{h}_x and \mathbf{h}_y are separable. Each filter takes the derivative in one direction using Eq. (51.107 *ii*) and smoothes in the orthogonal direction using a one-dimensional version of a *triangular* filter as described in section 51.9.4.

Alternative gradient filters – The variety of techniques available from one-dimensional signal processing for the design of digital filters offers us powerful tools for designing one-dimensional versions of \mathbf{h}_x and \mathbf{h}_y . Using the Parks-McClellan filter design algorithm, for example, we can choose the frequency bands where we want the derivative to be taken and the frequency bands where we want the noise to be suppressed. The algorithm will then produce a real, odd filter with a minimum length that meets the specifications.

As an example, if we want a filter that has derivative characteristics in a passband (with weight 1.0) in the frequency range $0.0 \leq \Omega \leq 0.3\pi$ and a stopband (with weight 3.0) in the range $0.32\pi \leq \Omega \leq \pi$, then the algorithm produces the following optimized seven sample filter:

$$[\mathbf{h}_x] = [\mathbf{h}_y]^t = \frac{1}{16348} [-3571 \quad 8212 \quad -15580 \quad 0 \quad 15580 \quad -8212 \quad 3571] \quad (51.111)$$

The gradient can then be calculated as in Eq. (51.103).

Gaussian gradient filters – In modern digital image processing, one of the most common techniques is to use a Gaussian filter (see section 51.9.4) to accomplish the required smoothing and one of the derivatives listed in Eq. (51.107). Thus, we might first apply the recursive Gaussian in Eq. (51.97) followed by Eq. (51.107 *ii*) to achieve the desired, smoothed derivative filters \mathbf{h}_x and \mathbf{h}_y . Further, for computational efficiency, we can combine these two steps as:

$$\begin{aligned} w[n] &= \left(\frac{B}{2} \right) (a[n+1] - a[n-1]) + (b_1 w[n-1] + b_2 w[n-2] + b_3 w[n-3])/b_0 \\ c[n] &= Bw[n] + (b_1 c[n+1] + b_2 c[n+2] + b_3 c[n+3])/b_0 \end{aligned} \quad (51.112)$$

where the various coefficients are defined in Eq. (51.99). The first (forward) equation is applied from $n = 0$ up to $n = N - 1$ while the second (backward) equation is applied from $n = N - 1$ down to $n = 0$.

Summary – Examples of the effect of various *derivative algorithms* on a noisy version of Fig. 51.30(a) ($SNR = 29$ dB) are shown in Figs. 51.31(a-c). The effect of various *magnitude gradient algorithms* on Fig. 51.30(a) are shown in Figs. 51.32(a-c). After processing, all images are contrast stretched as in Eq. (51.77) for display purposes.

The magnitude gradient takes on large values where there are strong edges in the image. Appropriate choice of σ in the Gaussian-based derivative (Fig. 51.31(c)) or gradient (Fig. 51.32(c)) permits computation of virtually any of the other forms — simple, Prewitt, Sobel, etc. In that sense, the Gaussian derivative represents a superset of derivative filters.

Second Derivatives

It is, of course, possible to compute higher-order derivatives of functions of two variables. In image processing, as we shall see in sections 51.10.2 and 51.10.3, the second derivatives or Laplacian

FIGURE 51.31: Application of various algorithms for \mathbf{h}_x — the horizontal derivative. (a) Simple Derivative — Eq. (51.107)ii; (b) Sobel — Eq. (51.110); (c) Gaussian ($\sigma = 1.5$) and Eq. (51.107)ii.

FIGURE 51.32: Various algorithms for the magnitude gradient, $|\nabla a|$. (a) Simple Derivative — Eq. (51.107)ii; (b) Sobel — Eq. (51.110); (c) Gaussian ($\sigma = 1.5$) and Eq. (51.107)ii.

play an important role. The Laplacian is defined as:

$$\nabla^2 a = \frac{\partial^2 a}{\partial x^2} + \frac{\partial^2 a}{\partial y^2} = (h_{2x} \otimes a) + (h_{2y} \otimes a) \quad (51.113)$$

where \mathbf{h}_{2x} and \mathbf{h}_{2y} are second derivative filters. In the frequency domain, we have for the Laplacian filter [from Eq. (51.27)]:

$$\nabla^2 a \underset{\leftrightarrow}{\overset{\mathcal{F}}{=}} -(u^2 + v^2) A(u, v) \quad (51.114)$$

The transfer function of a Laplacian corresponds to a parabola $H(u, v) = -(u^2 + v^2)$.

Basic second derivative filter – This filter is specified by:

$$[\mathbf{h}_{2x}] = [\mathbf{h}_{2y}]^t = \begin{bmatrix} 1 & -2 & 1 \end{bmatrix} \quad (51.115)$$

and the frequency spectrum of this filter, in each direction, is given by:

$$H(\Omega) = \mathcal{F}\{1 \quad -2 \quad 1\} = -2(1 - \cos \Omega) \quad (51.116)$$

over the frequency range $-\pi \leq \Omega \leq \pi$. The two, one-dimensional filters can be used in the manner suggested by Eq. (51.113) or combined into one, two-dimensional filter as:

$$[\mathbf{h}] = \begin{bmatrix} 0 & 1 & 0 \\ 1 & -4 & 1 \\ 0 & 1 & 0 \end{bmatrix} \quad (51.117)$$

and used as in Eq. (51.84).

Frequency domain Laplacian – This filter is the implementation of the general recipe given in Eq. (51.92) and for the Laplacian filter takes the form:

$$c[m, n] = \mathcal{F}^{-1} \left\{ - \left(\Omega^2 + \Psi^2 \right) A(\Omega, \Psi) \right\} \quad (51.118)$$

Gaussian second derivative filter – This is the straightforward extension of the Gaussian first derivative filter described above and can be applied independently in each dimension. We first apply Gaussian smoothing with a σ chosen on the basis of the problem specification. We then apply the desired second derivative filter Eq. (51.115) or Eq. (51.118). Again, there is the choice among the various Gaussian smoothing algorithms.

For efficiency, we can use the recursive implementation and combine the two steps — smoothing and derivative operation — as follows:

$$\begin{aligned} w[n] &= B(a[n] - a[n-1]) + (b_1 w[n-1] + b_2 w[n-2] + b_3 w[n-3])/b_0 \\ c[n] &= B(w[n+1] - w[n]) + (b_1 c[n+1] + b_2 c[n+2] + b_3 c[n+3])/b_0 \end{aligned} \quad (51.119)$$

where the various coefficients are defined in Eq. (51.99). Again, the first (forward) equation is applied from $n = 0$ up to $n = N - 1$ while the second (backward) equation is applied from $n = N - 1$ down to $n = 0$.

Alternative Laplacian filters – Again one-dimensional digital filter design techniques offer us powerful methods to create filters that are optimized for a specific problem. Using the Parks-McClellan design algorithm, we can choose the frequency bands where we want the second derivative to be taken and the frequency bands where we want the noise to be suppressed. The algorithm will then produce a real, even filter with a minimum length that meets the specifications.

As an example, if we want a filter that has second derivative characteristics in a passband (with weight 1.0) in the frequency range $0.0 \leq \Omega \leq 0.3\pi$ and a stopband (with weight 3.0) in the range $0.32\pi \leq \Omega \leq \pi$, then the algorithm produces the following optimized seven sample filter:

$$[\mathbf{h}_x] = [\mathbf{h}_y]^t = \frac{1}{11043} [-3448 \quad 10145 \quad 1495 \quad -16383 \quad 1495 \quad 10145 \quad -3448] \quad (51.120)$$

The Laplacian can then be calculated as in Eq. (51.113).

SDGD filter – A filter that is especially useful in edge finding and object measurement is the *Second-Derivative-in-the-Gradient-Direction (SDGD)* filter. This filter uses five partial derivatives:

$$\begin{aligned} A_{xx} &= \frac{\partial^2 a}{\partial x^2} & A_{xy} &= \frac{\partial^2 a}{\partial x \partial y} & A_x &= \frac{\partial a}{\partial x} \\ A_{yx} &= \frac{\partial^2 a}{\partial x \partial y} & A_{yy} &= \frac{\partial^2 a}{\partial y^2} & A_y &= \frac{\partial a}{\partial y} \end{aligned} \quad (51.121)$$

Note that $A_{xy} = A_{yx}$, which accounts for the five derivatives.

This *SDGD* combines the different partial derivatives as follows:

$$SDGD(a) = \frac{A_{xx}A_x^2 + 2A_{xy}A_xA_y + A_{yy}A_y^2}{A_x^2 + A_y^2} \quad (51.122)$$

As one might expect, the large number of derivatives involved in this filter implies that noise suppression is important and that Gaussian derivative filters — both first and second order — are highly recommended, if not required. It is also necessary that the first and second derivative filters have essentially the same passbands and stopbands. This means that if the first derivative filter h_{1x} is given by $[1 \quad 0 \quad -1]$ Eq. (51.107 *ii*) then the second derivative filter should be given by $h_{1x} \otimes h_{1x} = h_{2x} = [1 \quad 0 \quad -2 \quad 0 \quad 1]$.

Summary – The effects of the various second derivative filters are illustrated in Figs. 51.33(a–e). All images were contrast stretched for display purposes using Eq. (51.78) and the parameters 1% and 99%.

FIGURE 51.33: Various algorithms for the Laplacian and Laplacian-related filters. (a) Laplacian — Eq. (51.117); (b) Fourier parabola — Eq. (51.118); (c) Gaussian ($\sigma = 1.0$) and Eq. (51.117); (d) “Designer” — Eq. (51.120); and (e) SDGD ($\sigma = 1.0$) — Eq. (51.122).

Other Filters

An infinite number of filters, both linear and nonlinear, are possible for image processing. It is, therefore, impossible to describe more than the basic types in this section. The description of others can be found in the reference literature (see section 51.11) as well as in the applications literature. It is important to use a small consistent set of test images that are relevant to the application area to understand the effect of a given filter or class of filters. The effect of filters on images can be frequently understood by the use of images that have pronounced regions of varying sizes to visualize the effect on edges or by the use of test patterns such as sinusoidal sweeps to visualize the effects in the frequency domain. The former have been used previously (Figs. 51.21, 51.23 and 51.30 to 51.33), and the latter are demonstrated in Fig. 51.34.

51.9.6 Morphology-Based Operations

In section 51.1, we defined an image as an (amplitude) function of two, real (coordinate) variables $a(x, y)$ or two discrete variables $a[m, n]$. An alternative definition of an image can be based on the notion that an image consists of a set (or collection) of either continuous or discrete coordinates. In a sense, the set corresponds to the points or pixels that belong to the objects in the image. This is illustrated in Fig. 51.35 which contains two objects or sets A and B . Note that the coordinate system is

FIGURE 51.34: Various convolution algorithms applied to sinusoidal test image. (a) Lowpass filter, (b) bandpass filter, and (c) highpass filter.

required. For the moment, we will consider the pixel values to be binary as discussed in section 51.2.1 and 51.9.2. Further, we shall restrict our discussion to discrete space (Z^2). More general discussions can be found in Giardina and Dougherty [4], Gonzales and Woods [5], and Heijmans [7].

FIGURE 51.35: A binary image containing two objects sets A and B .

The object A consists of those pixels α that share some common property:

Object -

$$A = \{\alpha | \text{property}(\alpha) == \text{TRUE}\} \quad (51.123)$$

As an example, object B in Fig. 51.35 consists of $\{[0, 0], [1, 0], [0, 1]\}$.

The background of A is given by A^c (the *complement* of A) which is defined as those elements that are not in A :

Background -

$$A^c = \{\alpha | \alpha \notin A\} \quad (51.124)$$

In Fig. 51.3, we introduced the concept of neighborhood connectivity. We now observe that if an object A is defined on the basis of C -connectivity ($C = 4, 6$, or 8) then the background A^c has a connectivity given by $12 - C$. The necessity for this is illustrated for the Cartesian grid in Fig. 51.36.

Fundamental Definitions

The fundamental operations associated with an object are the standard set operations *union*, *intersection*, and *complement* $\{\cup, \cap, ^c\}$ plus *translation*:

FIGURE 51.36: A binary image requiring careful definition of object and background connectivity.

Translation – Given a vector \mathbf{x} and a set A , the *translation*, $A + \mathbf{x}$, is defined as:

$$A + \mathbf{x} = \{\alpha + \mathbf{x} | \alpha \in A\} \quad (51.125)$$

Note that, since we are dealing with a digital image composed of pixels at integer coordinate positions (Z^2), this implies restrictions on the allowable translation vectors \mathbf{x} .

The basic *Minkowski set operations* — addition and subtraction — can now be defined. First we note that the individual elements that comprise \mathbf{B} are not only pixels but also *vectors* as they have a clear coordinate position with respect to $[0, 0]$. Given two sets A and \mathbf{B} :

$$\text{Minkowski addition} - A \oplus \mathbf{B} = \bigcup_{\beta \in \mathbf{B}} (A + \beta) \quad (51.126)$$

$$\text{Minkowski subtraction} - A \ominus \mathbf{B} = \bigcap_{\beta \in \mathbf{B}} (A + \beta) \quad (51.127)$$

Dilation and Erosion

From these two Minkowski operations, we define the fundamental mathematical morphology operations *dilation* and *erosion*:

$$\text{Dilation} - D(A, \mathbf{B}) = A \oplus \mathbf{B} = \bigcup_{\beta \in \mathbf{B}} (A + \beta) \quad (51.128)$$

$$\text{Erosion} - E(A, \mathbf{B}) = A \ominus (-\mathbf{B}) = \bigcap_{\beta \in \mathbf{B}} (A - \beta) \quad (51.129)$$

where $-\mathbf{B} = \{-\beta | \beta \in \mathbf{B}\}$. These two operations are illustrated in Fig. 51.37 for the objects defined in Fig. 51.35.

While either set A or \mathbf{B} can be thought of as an “image”, A is usually considered as the image and \mathbf{B} is called a *structuring element*. *The structuring element is to mathematical morphology what the convolution kernel is to linear filter theory.*

Dilation, in general, causes objects to dilate or grow in size; *erosion* causes objects to shrink. The amount and the way that they grow or shrink depend on the choice of the structuring element. Dilating or eroding without specifying the structural element makes no more sense than trying to lowpass filter an image without specifying the filter. The two most common structuring elements (given a Cartesian grid) are the 4-connected and 8-connected sets, N_4 and N_8 . They are illustrated in Fig. 51.38.

Dilation and *erosion* have the following properties:

$$\text{Commutative} - D(A, \mathbf{B}) = A \oplus \mathbf{B} = \mathbf{B} \oplus A = D(\mathbf{B}, A) \quad (51.130)$$

FIGURE 51.37: A binary image containing two object sets A and B . The three pixels in B are “color-coded” as is their effect in the result. (a) Dilation $D(A, B)$ and (b) Erosion $E(A, B)$.

FIGURE 51.38: The standard structuring elements N_4 and N_8 . (a) N_4 and (b) N_8 .

$$\text{Noncommutative} - E(A, B) \neq E(B, A) \quad (51.131)$$

$$\text{Associative} - A \oplus (B \oplus C) = (A \oplus B) \oplus C \quad (51.132)$$

$$\text{Translation Invariance} - A \oplus (B + \mathbf{x}) = (A \oplus B) + \mathbf{x} \quad (51.133)$$

$$\begin{aligned} D^c(A, B) &= E(A^c, -B) \\ \text{Duality} - & \quad (51.134) \end{aligned}$$

$$E^c(A, B) = D(A^c, -B)$$

With A as an object and A^c as the background, Eq. (51.134) says that the *dilation* of an object is equivalent to the *erosion* of the background. Likewise, the *erosion* of the object is equivalent to the *dilation* of the background.

Except for special cases:

$$\text{Noninverses} - D(E(A, B), B) \neq A \neq E(D(A, B), B) \quad (51.135)$$

Erosion has the following translation property:

$$\text{Translation Invariance} - A \ominus (B + \mathbf{x}) = (A + \mathbf{x}) \ominus B = (A \ominus B) + \mathbf{x} \quad (51.136)$$

Dilation and *erosion* have the following important properties. For any arbitrary structuring element B and two image objects A_1 and A_2 such that $A_1 \subset A_2$ (A_1 is a proper subset of A_2):

$$\begin{aligned} D(A_1, B) &\subset D(A_2, B) \\ \text{Increasing in } A - & \quad (51.137) \\ E(A_1, B) &\subset E(A_2, B) \end{aligned}$$

For two structuring elements B_1 and B_2 such that $B_1 \subset B_2$:

$$\text{Decreasing in } B - E(A, B_1) \supset E(A, B_2) \quad (51.138)$$

The *decomposition theorems* below make it possible to find efficient implementations for morphological filters.

$$\text{Dilation} - A \oplus (B \cup C) = (A \oplus B) \cup (A \oplus C) = (B \cup C) \oplus A \quad (51.139)$$

$$\text{Erosion} - A \ominus (B \cup C) = (A \ominus B) \cap (A \ominus C) \quad (51.140)$$

$$\text{Erosion} - (A \ominus B) \ominus C = A \ominus (B \oplus C) \quad (51.141)$$

$$\text{Multiple Dilations} - nB = \underbrace{(B \oplus B \oplus B \oplus \cdots \oplus B)}_{n \text{ times}} \quad (51.142)$$

An important decomposition theorem is due to Vincent. First, we require some definitions. A *convex* set (in R^2) is one for which the straight line joining any two points in the set consists of points that are also in the set. Care must obviously be taken when applying this definition to discrete pixels as the concept of a “straight line” must be interpreted appropriately in Z^2 . A set is *bounded* if each of its elements has a finite magnitude, in this case distance to the origin of the coordinate system. A set is *symmetric* if $B = -B$. The sets N_4 and N_8 in Fig. 51.38 are examples of convex, bounded, symmetric sets.

Vincent’s theorem, when applied to an image consisting of discrete pixels, states that for a bounded, symmetric structuring element B that contains no holes and contains its own center, $[0, 0] \in B$:

$$D(A, B) = A \oplus B = A \cup (\partial A \oplus B) \quad (51.143)$$

where ∂A is the contour of the object. That is, ∂A is the set of pixels that have a background pixel as a neighbor. The implication of this theorem is that it is not necessary to process all the pixels in an object in order to compute a *dilation* or [using Eq. (51.134)] an *erosion*. We only have to process the boundary pixels. This also holds for all operations that can be derived from *dilations* or *erosions*. The processing of boundary pixels instead of object pixels means that, except for pathological images, computational complexity can be reduced from $O(N^2)$ to $O(N)$ for an $N \times N$ image. A number of “fast” algorithms can be found in the literature that are based on this result. The simplest dilation and erosion algorithms are frequently described as follows.

Dilation – Take each binary object pixel (with value “1”) and set all background pixels (with value “0”) that are C -connected to that object pixel to the value “1”.

Erosion – Take each binary object pixel (with value “1”) that is C -connected to a background pixel and set the object pixel value to “0”.

Comparison of these two procedures to Eq. (51.143) where $B = N_{C=4}$ or $N_{C=8}$ shows that they are equivalent to the formal definitions for dilation and erosion. The procedure is illustrated for *dilation* in Fig. 51.39.

Boolean Convolution

An arbitrary *binary* image object (or structuring element) A can be represented as

$$A \leftrightarrow \sum_{k=-\infty}^{+\infty} \sum_{j=-\infty}^{+\infty} a[j, k] \bullet \delta[m - j, n - k] \quad (51.144)$$

where \sum and \bullet are the Boolean operations *OR* and *AND* as defined in Eqs. (51.81) and (51.82), $a[j, k]$ is a *characteristic function* that takes on the Boolean values “1” and “0” as follows:

$$a[j, k] = \begin{cases} 1 & a \in A \\ 0 & a \notin A \end{cases} \quad (51.145)$$

FIGURE 51.39: Illustration of *dilation*. Original object pixels are in gray; pixels added through *dilation* are in black. (a) $B = N_4$ and (b) $B = N_8$.

and $\delta[m, n]$ is a Boolean version of the Dirac delta function that takes on the Boolean values “1” and “0” as follows:

$$\delta[j, k] = \begin{cases} 1 & j = k = 0 \\ 0 & \text{otherwise} \end{cases} \quad (51.146)$$

Dilation for binary images can therefore be written as:

$$D(A, B) = \sum_{k=-\infty}^{+\infty} \sum_{j=-\infty}^{+\infty} a[j, k] \bullet b[m - j, n - k] = a \otimes b \quad (51.147)$$

which, because Boolean *OR* and *AND* are commutative, can also be written as

$$D(A, B) = \sum_{k=-\infty}^{+\infty} \sum_{j=-\infty}^{+\infty} a[m - j, n - k] \bullet b[j, k] = b \otimes a = D(B, A) \quad (51.148)$$

Using De Morgan's theorem:

$$\overline{(a + b)} = \bar{a} \bullet \bar{b} \text{ and } \overline{(a \bullet b)} = \bar{a} + \bar{b} \quad (51.149)$$

on Eq. (51.148) together with Eq. (51.134), *erosion* can be written as:

$$E(A, B) = \prod_{k=-\infty}^{+\infty} \prod_{j=-\infty}^{+\infty} (a[m - j, n - k] + \bar{b}[-j, -k]) \quad (51.150)$$

Thus, *dilation* and *erosion* on binary images can be viewed as a form of convolution over a Boolean algebra.

In section 51.9.3 we saw that, when convolution is employed, an appropriate choice of the boundary conditions for an image is essential. Dilation and erosion — being a Boolean convolution — are no exception. The two most common choices are that either everything outside the binary image is “0” or everything outside the binary image is “1”.

Opening and Closing

We can combine *dilation* and *erosion* to build two important higher order operations:

$$\text{Opening} - O(A, B) = A \circ B = D(E(A, B), B) \quad (51.151)$$

$$\text{Closing} - C(A, B) = A \bullet B = E(D(A, -B), -B) \quad (51.152)$$

The *opening* and *closing* have the following properties:

$$\begin{aligned} \text{Duality - } & C^c(A, B) = O(A^c, B) \\ & O^c(A, B) = C(A^c, B) \end{aligned} \quad (51.153)$$

$$\begin{aligned} \text{Translation - } & O(A + \mathbf{x}, B) = O(A, B) + \mathbf{x} \\ & C(A + \mathbf{x}, B) = C(A, B) + \mathbf{x} \end{aligned} \quad (51.154)$$

For the *opening* with structuring element B and images A , A_1 , and A_2 , where A_1 is a subimage of A_2 ($A_1 \subseteq A_2$):

$$\text{Antiextensivity - } \quad O(A, B) \subseteq A \quad (51.155)$$

$$\text{Increasing monotonicity - } \quad O(A_1, B) \subseteq O(A_2, B) \quad (51.156)$$

$$\text{Idempotence - } \quad O(O(A, B), B) = O(A, B) \quad (51.157)$$

For the *closing* with structuring element B and images A , A_1 , and A_2 , where A_1 is a subimage of A_2 ($A_1 \subseteq A_2$):

$$\text{Extensivity - } \quad A \subseteq C(A, B) \quad (51.158)$$

$$\text{Increasing monotonicity - } \quad C(A_1, B) \subseteq C(A_2, B) \quad (51.159)$$

$$\text{Idempotence - } \quad C(C(A, B), B) = C(A, B) \quad (51.160)$$

The two properties given by Eqs. (51.155) and (51.158) are so important to mathematical morphology that they can be considered as the reason for defining *erosion* with $-B$ instead of B in Eq. (51.129).

Hit-and-Miss Operation

The *hit-or-miss operator* was defined by Serra but we shall refer to it as the *hit-and-miss operator* defined as follows. Given an image A and two structuring elements B_1 and B_2 , the set definition and Boolean definition are:

Hit-and-Miss -

$$\text{HitMiss}(A, B_1, B_2) = \begin{cases} E(A, B_1) \cap E^c(A^c, B_2) \\ E(A, B_1) \bullet \overline{E(\bar{A}, B_2)} \\ E(A, B_1) - E(\bar{A}, B_2) \end{cases} \quad (51.161)$$

where B_1 and B_2 are bounded, disjoint structuring elements. (Note the use of the notation from Eq. (51.81).) Two sets are *disjoint* if $B_1 \cap B_2 = \emptyset$, the empty set. In an important sense the *hit-and-miss operator* is the morphological equivalent of *template matching*, a well-known technique for matching patterns based on cross-correlation. Here, we have a template B_1 for the object and a template B_2 for the background.

Summary of the Basic Operations

The results of the application of these basic operations on a test image are illustrated in Fig. 51.40. In this figure, the various structuring elements used in the processing are defined. The value “—” indicates a “don’t care”. All three structuring elements are symmetric.

The results of processing are shown in Fig. 51.41 where the binary value “1” is shown in black and the value “0” in white.

$$\mathbf{B} = \mathbf{N}_8 = \begin{bmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{bmatrix} \quad (a) \quad \mathbf{B}_1 = \begin{bmatrix} - & - & - \\ - & 1 & - \\ - & - & - \end{bmatrix} \quad (b) \quad \mathbf{B}_2 = \begin{bmatrix} - & 1 & - \\ 1 & - & 1 \\ - & 1 & - \end{bmatrix} \quad (c)$$

FIGURE 51.40: Structuring elements \mathbf{B} , \mathbf{B}_1 , and \mathbf{B}_2 that are 3×3 and symmetric.

FIGURE 51.41: Examples of various mathematical morphology operations. (a) Image A ; (b) *dilation* with $2\mathbf{B}$; (c) *erosion* with $2\mathbf{B}$; (d) *opening* with $2\mathbf{B}$; (e) *closing* with $2\mathbf{B}$; and (f) *hit-and-miss* with \mathbf{B}_1 and \mathbf{B}_2 .

The *opening* operation can separate objects that are connected in a binary image. The *closing* operation can fill in small holes. Both operations generate a certain amount of smoothing on an object contour given a “smooth” structuring element. The *opening* smooths from the inside of the object contour and the *closing* smooths from the outside of the object contour. The *hit-and-miss* example has found the 4-connected contour pixels. An alternative method to find the contour is simply to use the relation:

$$\text{4-connected contour-} \quad \partial A = A - E(A, \mathbf{N}_8) \quad (51.162)$$

or

$$\text{8-connected contour -} \quad \partial A = A - E(A, \mathbf{N}_4) \quad (51.163)$$

Skeleton

The informal definition of a skeleton is a line representation of an object that is:

- (i) one-pixel thick,
 - (ii) through the “middle” of the object, and
 - (iii) preserves the topology of the object.
- (51.164)

These are not always realizable. Fig. 51.42 shows why this is the case.

FIGURE 51.42: Counterexamples to the three requirements.

In the first example, Fig. 51.42(a), it is not possible to generate a line that is one pixel thick and in the center of an object while generating a path that reflects the simplicity of the object. In Fig. 51.42(b) it is not possible to remove a pixel from the 8-connected object and simultaneously preserve the topology — the notion of connectedness — of the object. Nevertheless, there are a variety of techniques that attempt to achieve this goal and to produce a *skeleton*.

A basic formulation is based on the work of Lantuéjoul. The *skeleton subset* $S_k(A)$ is defined as:

$$\text{Skeleton subsets} - S_k(A) = E(A, k\mathbf{B}) - [E(A, k\mathbf{B}) \circ \mathbf{B}] \quad k = 0, 1, \dots, K \quad (51.165)$$

where K is the largest value of k before the set $S_k(A)$ becomes empty. [From Eq. (51.156), $E(A, k\mathbf{B}) \circ \mathbf{B} \subseteq E(A, k\mathbf{B})$]. The structuring element \mathbf{B} is chosen (in Z^2) to approximate a circular disc, that is, convex, bounded, and symmetric. The *skeleton* is then the union of the skeleton subsets:

$$\text{Skeleton} - S(A) = \bigcup_{k=0}^K S_k(A) \quad (51.166)$$

An elegant side effect of this formulation is that the original object can be reconstructed given knowledge of the skeleton subsets $S_k(A)$, the structuring element \mathbf{B} , and K :

$$\text{Reconstruction} - A = \bigcup_{k=0}^K (S_k(A) \oplus k\mathbf{B}) \quad (51.167)$$

This formulation for the skeleton, however, does not preserve the topology, a requirement described in Eq. (51.164).

An alternative point of view is to implement a *thinning*, an erosion that reduces the thickness of an object without permitting it to vanish. A general thinning algorithm is based on the *hit-and-miss* operation:

$$\text{Thinning} - \text{Thin}(A, \mathbf{B}_1, \mathbf{B}_2) = A - \text{HitMiss}(A, \mathbf{B}_1, \mathbf{B}_2) \quad (51.168)$$

Depending on the choice of \mathbf{B}_1 and \mathbf{B}_2 , a large variety of thinning algorithms — and through repeated application skeletonizing algorithms — can be implemented.

A quite practical implementation can be described in another way. If we restrict ourselves to a 3×3 neighborhood, similar to the structuring element $\mathbf{B} = \mathbf{N}_8$ in Fig. 51.40(a), then we can view

the thinning operation as a window that repeatedly scans over the (binary) image and sets the center pixel to “0” under certain conditions. The center pixel is *not* changed to “0” if and only if:

- (i) an isolated pixel is found [e.g., Fig. 51.43(a)],
 - (ii) removing a pixel would change the connectivity [e.g., Fig. 51.43(b)],
 - (iii) removing a pixel would shorten a line [e.g., Fig. 51.43(c)].
- (51.169)

As pixels are (potentially) removed in each iteration, the process is called a *conditional erosion*. Three test cases of Eq. (51.169) are illustrated in Fig. 51.43. In general, all possible rotations and variations have to be checked. As there are only 512 possible combinations for a 3×3 window on a binary image, this can be done easily with the use of a lookup table.

FIGURE 51.43: Test conditions for *conditional erosion* of the center pixel. (a) Isolated pixel, (b) connectivity pixel, and (c) end pixel.

If only condition (i) is used, then each object will be reduced to a single pixel. This is useful if we wish to count the number of objects in an image. If only condition (ii) is used, then holes in the objects will be found. If conditions (i + ii) are used, each object will be reduced to either a single pixel if it does not contain a hole or to closed rings if it does contain holes. If conditions (i + ii + iii) are used, then the “complete skeleton” will be generated as an approximation to Eq. (51.164). Illustrations of these various possibilities are given in Figs. 51.44(a) and (b).

Propagation

It is convenient to be able to reconstruct an image that has “survived” several erosions or to fill an object that is defined, for example, by a boundary. The formal mechanism for this has several names, including *region-filling*, *reconstruction*, and *propagation*. The formal definition is given by the following algorithm. We start with a *seed image* $S^{(0)}$, a *mask image* A , and a structuring element B . We then use dilations of S with structuring element B and masked by A in an iterative procedure as follows:

$$\text{Iteration } k - S^{(k)} = [S^{(k-1)} \oplus B] \cap A \quad \text{until} \quad S^{(k)} = S^{(k-1)} \quad (51.170)$$

With each iteration, the seed image grows (through dilation) but *within* the set (object) defined by A ; S *propagates* to fill A . The most common choices for B are N_4 or N_8 . Several remarks are central to the use of propagation. First, in a straightforward implementation, as suggested by Eq. (51.170), the computational costs are extremely high. Each iteration requires $O(N^2)$ operations for an $N \times N$ image, and with the required number of iterations this can lead to a complexity of $O(N^3)$. Fortunately, a recursive implementation of the algorithm exists in which one or two passes through the image are usually sufficient, meaning a complexity of $O(N^2)$. Second, although we have not paid much attention to the issue of object/background connectivity until now (see Fig. 51.36), it is essential that the connectivity implied by B be matched to be connectivity associated with the boundary definition of A [see Eqs. (51.162) and (51.163)]. Finally, as mentioned earlier, it is important to make the correct choice (“0” or “1”) for the boundary condition of the image. The choice depends on the application.

FIGURE 51.44: Examples of *skeleton* and *propagation*. (a) *Skeleton* with end pixels, condition Eq. (51.169) $i+ii+iii$; (b) *skeleton* without end pixels, condition Eq. (51.169) $i+ii$; (c) *propagation* with N_8 .

Summary of Skeleton and Propagation

The application of these two operations on a test image is illustrated in Fig. 51.44. In (a) and (b) of the figure the skeleton operation is shown with the end pixel condition [Eq. (51.169) $i + ii + iii$] and without the end pixel condition [Eq. (51.169) $i + ii$]. The propagation operation is illustrated in Fig. 51.44(c). The original image, shown in light gray, was eroded by $E(A, 6N_8)$ to produce the *seed* image shown in black. The original was then used as the *mask* image to produce the final result. The border value in both images was “0”.

Several techniques based on the use of *skeleton* and *propagation* operations in combination with other mathematical morphology operations will be given in section 51.10.

Gray-Value Morphological Processing

The techniques of morphological filtering can be extended to gray-level images. To simplify matters, we will restrict our presentation to structuring elements, B , that comprise a finite number of pixels and are convex and bounded. Now, however, the structuring element has gray values associated with every coordinate position as does the image A .

Gray-level dilation, $D_G(\bullet)$, is given by:

$$\text{Dilation} - D_G(A, B) = \max_{[j,k] \in B} \{a[m-j, n-k] + b[j, k]\} \quad (51.171)$$

For a given output coordinate $[m, n]$, the structuring element is summed with a shifted version of the image and the maximum encountered over all shifts within the $J \times K$ domain of B is used as the result. Should the shifting require values of the image A that are outside the $M \times N$ domain of A , then a decision must be made as to which model for image extension, as described in section 51.9.3, should be used.

Gray-level erosion, $E_G(\bullet)$, is given by:

$$\text{Erosion - } E_G(A, B) = \min_{[j,k] \in B} \{a[m+j, n+k] - b[j, k]\} \quad (51.172)$$

The duality between *gray-level erosion* and *gray-level dilation* — the gray-level counterpart of Eq. (51.134) — is somewhat more complex than in the binary case:

$$\text{Duality - } E_G(A, B) = -D_G(-\tilde{A}, B) \quad (51.173)$$

where “ $-\tilde{A}$ ” means that $a[j, k] \rightarrow -a[-j, -k]$.

The definitions of higher order operations such as *gray-level opening* and *gray-level closing* are:

$$\text{Opening - } O_G(A, B) = D_G(E_G(A, B), B) \quad (51.174)$$

$$\text{Closing - } C_G(A, B) = -O_G(-A, -B) \quad (51.175)$$

The important properties that were discussed earlier such as idempotence, translation invariance, increasing in A , and so forth are also applicable to gray level morphological processing. The details can be found in Giardina and Dougherty [4].

In many situations the seeming complexity of gray level morphological processing is significantly reduced through the use of symmetric structuring elements where $b[j, k] = b[-j, -k]$. The most common of these is based on the use of $B = \text{constant} = 0$. For this important case and using again the domain $[j, k] \in B$, the definitions above reduce to:

$$\text{Dilation - } D_G(A, B) = \max_{[j,k] \in B} \{a[m-j, n-k]\} = \max_B(A) \quad (51.176)$$

$$\text{Erosion - } E_G(A, B) = \min_{[j,k] \in B} \{a[m-j, n-k]\} = \min_B(A) \quad (51.177)$$

$$\text{Opening - } O_G(A, B) = \max_B \left(\min_B(A) \right) \quad (51.178)$$

$$\text{Closing - } C_G(A, B) = \min_B \left(\max_B(A) \right) \quad (51.179)$$

The remarkable conclusion is that the *maximum filter* and the *minimum filter*, introduced in section 51.9.4, are gray-level dilation and gray-level erosion for the specific structuring element given by the shape of the filter window with the gray value “0” *inside* the window. Examples of these operations on a simple one-dimensional signal are shown in Fig. 51.45.

For a rectangular window, $J \times K$, the two-dimensional maximum or minimum filter is separable into two one-dimensional windows. Further, a one-dimensional maximum or minimum filter can be written in incremental form (see section 51.9.3). This means that gray-level dilations and erosions have a computational complexity per pixel that is $O(\text{constant})$, that is, independent of J and K (see also Table 51.13).

The operations defined above can be used to produce morphological algorithms for smoothing, gradient determination and a version of the Laplacian. All are constructed from the primitives for *gray-level dilation* and *gray-level erosion* and in all cases the *maximum* and *minimum* filters are taken over the domain $[j, k] \in B$.

Morphological Smoothing

This algorithm is based on the observation that a *gray-level opening* smooths a gray-value image from above the brightness surface given by the function $a[m, n]$ and the *gray-level closing* smooths from below. We use a structuring element B based on Eqs. (51.176) and (51.177).

FIGURE 51.45: Morphological filtering of gray-level data. (a) Effect of 15×1 *dilation* and *erosion*; (b) effect of 15×1 *opening* and *closing*.

$$\begin{aligned} \text{MorphSmooth}(A, B) &= C_G(O_G(A, B)B) \\ &= \min(\max(\max(\min(A)))) \end{aligned} \quad (51.180)$$

Note that we have suppressed the notation for the structuring element B under the *max* and *min* operations to keep the notation simple. Its use, however, is understood.

Morphological Gradient

For linear filters the gradient filter yields a vector representation [Eq. (51.103)] with a magnitude [Eq. (51.104)] and direction [Eq. (51.105)]. The version presented here generates a morphological estimate of the *gradient magnitude*:

$$\begin{aligned} \text{Gradient}(A, B) &= \frac{1}{2} (D_G(A, B) - E_G(A, B)) \\ &= \frac{1}{2} (\max(A) - \min(A)) \end{aligned} \quad (51.181)$$

Morphological Laplacian

The morphologically based Laplacian filter is defined by:

$$\begin{aligned} \text{Laplacian}(A, B) &= \frac{1}{2} ((D_G(A, B) - A) - (A - E_G(A, B))) \\ &= \frac{1}{2} (D_G(A, B) + E_G(A, B) - 2A) \\ &= \frac{1}{2} (\max(A) + \min(A) - 2A) \end{aligned} \quad (51.182)$$

Summary of Morphological Filters

The effect of these filters is illustrated in Fig. 51.46. All images were processed with a 3×3 structuring element as described in Eqs. (51.176) through (51.182). Figure 51.46(e) was contrast stretched for display purposes using Eq. (51.78) and the parameters 1% and 99%. Figures 51.46(c), (d), and (e) should be compared to Figs. 51.30, 51.32, and 51.33.

FIGURE 51.46: Examples of gray-level morphological filters. (a) Dilation; (b) Erosion; (c) Smoothing; (d) Gradient; and (e) Laplacian.

51.10 Techniques

The algorithms presented in section 51.9 can be used to build techniques to solve specific image processing problems. Without presuming to present the solution to all processing problems, the following examples are of general interest and can be used as models for solving related problems.

51.10.1 Shading Correction

The method by which images are produced — the interaction between objects in real space, the illumination, and the camera — frequently leads to situations where the image exhibits significant shading across the field of view. In some cases, the image might be bright in the center and decrease in brightness as one goes to the edge of the field of view. In other cases, the image might be darker on the left side and lighter on the right side. The shading might be caused by nonuniform illumination, nonuniform camera sensitivity, or even dirt and dust on glass (lens) surfaces. In general, this shading effect is undesirable. Eliminating it is frequently necessary for subsequent processing and especially when image analysis or image understanding is the final goal.

Model of Shading

In general, we begin with a model for the shading effect. The illumination $I_{ill}(x, y)$ usually interacts in a multiplicative with the object $a(x, y)$ to produce the image $b(x, y)$:

$$b(x, y) = I_{ill}(x, y) \bullet a(x, y) \quad (51.183)$$

with the object representing various imaging modalities such as:

$$a(x, y) = \begin{cases} r(x, y) & \text{reflectance model} \\ 10^{-OD(x, y)} & \text{absorption model} \\ c(x, y) & \text{fluorescence model} \end{cases} \quad (51.184)$$

where at position (x, y) , $r(x, y)$ is the *reflectance*, $OD(x, y)$ is the *optical density*, and $c(x, y)$ is the concentration of fluorescent material. Parenthetically, we note that the fluorescence model only holds for low concentrations. The camera may then contribute *gain* and *offset* terms, as in Eq. (51.74), so that:

$$c[m, n] = \text{gain}[m, n] \bullet b[m, n] + \text{offset}[m, n]$$

Total shading -

$$= \text{gain}[m, n] \bullet I_{ill}[m, n] \bullet a[m, n] + \text{offset}[m, n] \quad (51.185)$$

In general, we assume that $I_{ill}[m, n]$ is slowly varying compared to $a[m, n]$.

Estimate of Shading

We distinguish between two cases for the determination of $a[m, n]$ starting from $c[m, n]$. In both cases we intend to estimate the shading terms $\{\text{gain}[m, n] \bullet I_{ill}[m, n]\}$ and $\{\text{offset}[m, n]\}$. While in the first case we assume that we have only the recorded image $c[m, n]$ with which to work, in the second case we assume that we can record two, additional, calibration images.

A posteriori estimate – In this case, we attempt to extract the shading estimate from $c[m, n]$. The most common possibilities are the following.

Lowpass filtering – We compute a smoothed version of $c[m, n]$ where the smoothing is large compared to the size of the objects in the image. This smoothed version is intended to be an estimate of the background of the image. We then subtract the smoothed version from $c[m, n]$ and then restore the desired DC value. In formula:

$$\text{Lowpass} - \hat{a}[m, n] = c[m, n] - \text{LowPass}\{c[m, n]\} + \text{constant} \quad (51.186)$$

where $\hat{a}[m, n]$ is the estimate of $a[m, n]$. Choosing the appropriate lowpass filter means knowing the appropriate spatial frequencies in the Fourier domain where the shading terms dominate.

Homomorphic filtering – We note that if the $\text{offset}[m, n] = 0$, then $c[m, n]$ consists solely of multiplicative terms. Further, the term $\{\text{gain}[m, n] \bullet I_{ill}[m, n]\}$ is slowly varying while $a[m, n]$ presumably is not. We therefore take the logarithm of $c[m, n]$ to produce two terms, one of which is low frequency and one of which is high frequency. We suppress the shading by high pass filtering the logarithm of $c[m, n]$ and then take the exponent (inverse logarithm) to restore the image. This procedure is based on *homomorphic filtering* as developed by Oppenheim and Stockham. In formula:

$$\begin{aligned} (i) \quad & c[m, n] = \text{gain}[m, n] \bullet I_{ill}[m, n] \bullet a[m, n] \\ (ii) \quad & \ln\{c[m, n]\} = \ln \left\{ \underbrace{\text{gain}[m, n] \bullet I_{ill}[m, n]}_{\text{slowly varying}} \right\} + \ln \left\{ \underbrace{a[m, n]}_{\text{rapidly varying}} \right\} \\ (iii) \quad & \text{HighPass}\{\ln\{c[m, n]\}\} \approx \ln\{a[m, n]\} \\ (iv) \quad & \hat{a}[m, n] = \exp \{ \text{HighPass}\{\ln\{c[m, n]\}\} \} \end{aligned} \quad (51.187)$$

Morphological filtering – We again compute a smoothed version of $c[m, n]$ where the smoothing is large compared to the size of the objects in the image but this time using morphological smoothing as in Eq. (51.180). This smoothed version is the estimate of the background of the image. We then subtract the smoothed version from $c[m, n]$ and then restore the desired DC value. In formula:

$$\hat{a}[m, n] = c[m, n] - \text{MorphSmooth}\{c[m, n]\} + \text{constant} \quad (51.188)$$

Choosing the appropriate morphological filter window means knowing (or estimating) the size of the largest objects of interest.

A priori estimate – If it is possible to record test (calibration) images through the camera's system, then the most appropriate technique for the removal of shading effects is to record two images — $BLACK[m, n]$ and $WHITE[m, n]$. The $BLACK$ image is generated by covering the lens leading to $b[m, n] = 0$ which in turn leads to $BLACK[m, n] = \text{offset}[m, n]$. The $WHITE$ image is generated by using $a[m, n] = 1$ which gives $WHITE[m, n] = \text{gain}[m, n] \bullet I_{ill}[m, n] + \text{offset}[m, n]$. The correction then becomes:

$$\hat{a}[m, n] = \text{constant} \bullet \frac{c[m, n] - BLACK[m, n]}{WHITE[m, n] - BLACK[m, n]} \quad (51.189)$$

The *constant* term is chosen to produce the desired dynamic range.

The effects of these various techniques on the data from Fig. 51.45 are shown in Fig. 51.47. The shading is a simple, linear ramp increasing from left to right; the objects consist of Gaussian peaks of varying widths.

In summary, if it is possible to obtain $BLACK$ and $WHITE$ calibration images, then Eq. (51.189) is to be preferred. If this is not possible, then one of the other algorithms will be necessary.

51.10.2 Basic Enhancement and Restoration Techniques

The process of image acquisition frequently leads (inadvertently) to image degradation. Due to mechanical problems, out-of-focus blur, motion, inappropriate illumination, and noise, the quality of the digitized image can be inferior to the original. The goal of *enhancement* is — starting from a recorded image $c[m, n]$ — to produce the most visually pleasing image $\hat{a}[m, n]$. The goal of *restoration* is — starting from a recorded image $c[m, n]$ — to produce the best possible estimate $\hat{a}[m, n]$ of the original image $a[m, n]$. The goal of enhancement is beauty; the goal of restoration is truth.

The measure of success in restoration is usually an error measure between the original $a[m, n]$ and the estimate $\hat{a}[m, n]$: $\mathcal{E}\{\hat{a}[m, n], a[m, n]\}$. *No mathematical error function is known that corresponds to human perceptual assessment of error.* The mean-square error function is commonly used because:

1. It is easy to compute;
2. It is differentiable, implying that a minimum can be sought;
3. It corresponds to “signal energy” in the total error; and
4. It has nice properties *vis à vis* Parseval's theorem, Eqs. (51.22) and (51.23).

The *mean-square error* is defined by:

$$\mathcal{E}\{\hat{a}, a\} = \frac{1}{MN} \sum_{m=0}^{M-1} \sum_{n=0}^{N-1} |\hat{a}[m, n] - a[m, n]|^2 \quad (51.190)$$

In some techniques, an error measure will not be necessary; in others it will be essential for evaluation and comparative purposes.

(a) Shaded; (b) correction with lowpass filtering; (c) correction with logarithmic filtering; (d) correction with max/min filtering; and (e) correction with test images.

Unsharp Masking

A well-known technique from photography to improve the visual quality of an image is to enhance the edges of the image. The technique is called *unsharp masking*. Edge enhancement means first isolating the edges in an image, amplifying them, and then adding them back into the image. Examination of Fig. 51.33 shows that the Laplacian is a mechanism for isolating the gray level edges. This leads immediately to the technique:

$$\hat{a}[m, n] = a[m, n] - \left(k \bullet \nabla^2 a[m, n] \right) \quad (51.191)$$

The term k is the amplifying term and $k > 0$. The effect of this technique is shown in Fig. 51.48.

FIGURE 51.48: Edge enhanced compared to original. (Left) Original, (right) Laplacian-enhanced.

The Laplacian used to produce Fig. 51.48 is given by Eq. (51.120) and the amplification term $k = 1$.

Noise Suppression

The techniques available to suppress noise can be divided into those techniques that are based on temporal information and those that are based on spatial information. By temporal information we mean that a sequence of images $\{a_p[m, n] | p = 1, 2, \dots, P\}$ is available that contains *exactly* the same objects and that differs only in the sense of independent noise realizations. If this is the case and if the noise is additive, then simple averaging of the sequence:

$$\text{Temporal averaging-} \quad \hat{a}[m, n] = \frac{1}{P} \sum_{p=1}^P a_p[m, n] \quad (51.192)$$

will produce a result where the mean value of each pixel will be unchanged. For each pixel, however, the standard deviation will decrease from σ to σ/\sqrt{P} .

If temporal averaging is not possible, then spatial averaging can be used to decrease the noise. This generally occurs, however, at a cost to image sharpness. Four obvious choices for spatial averaging are the smoothing algorithms that have been described in section 51.9.4 — Gaussian filtering [Eq. (51.93)], median filtering, Kuwahara filtering, and morphological smoothing [Eq. (51.180)].

Within the class of linear filters, the optimal filter for restoration in the presence of noise is given by the *Wiener filter*. The word “optimal” is used here in the sense of minimum mean-square error (*mse*). Because the square root operation is monotonic increasing, the optimal filter also minimizes

the root mean-square error (*rms*). The Wiener filter is characterized in the Fourier domain, and for additive noise that is independent of the signal it is given by:

$$H_W(u, v) = \frac{S_{aa}(u, v)}{S_{aa}(u, v) + S_{nn}(u, v)} \quad (51.193)$$

where $S_{aa}(u, v)$ is the power spectral density of an ensemble of random images $\{a[m, n]\}$ and $S_{nn}(u, v)$ is the power spectral density of the random noise. If we have a single image, then $S_{aa}(u, v) = |A(u, v)|^2$. In practice it is unlikely that the power spectral density of the uncontaminated image will be available. Because many images have a similar power spectral density that can be modeled by Table 51.4-T.8, that model can be used as an estimate of $S_{aa}(u, v)$.

A comparison of the five different techniques described above is shown in Fig. 51.49. The Wiener filter was constructed directly from Eq. (51.193) because the image spectrum and the noise spectrum were known. The parameters for the other filters were determined choosing that value (either σ or window size) that led to the minimum *rms*.

FIGURE 51.49: Noise suppression using various filtering techniques. (a) Noisy image ($SNR = 20$ dB) $rms = 25.7$; (b) Wiener filter $rms = 20.2$; (c) Gauss filter ($\sigma = 1.0$) $rms = 21.1$; (d) Kuwahara filter (5×5) $rms = 22.4$; (e) median filter 3×3 $rms = 22.6$; and (f) morphological smoothing (3×3) $rms = 26.2$.

The root mean-square errors (*rms*) associated with the various filters are shown in Fig. 51.49. For this specific comparison, the Wiener filter generates a lower error than any of the other procedures that are examined here. The two linear procedures, Wiener filtering and Gaussian filtering, performed slightly better than the three nonlinear alternatives.

Distortion Suppression

The model presented above — an image distorted solely by noise — is not, in general, sophisticated enough to describe the true nature of distortion in a digital image. A more realistic model includes not only the noise but also a model for the distortion induced by lenses, finite apertures, possible motion of the camera and/or an object, and so forth. One frequently used model is of an image $a[m, n]$ distorted by a linear, shift-invariant system $h_o[m, n]$ (such as a lens) and then contaminated by noise $\kappa[m, n]$. Various aspects of $h_o[m, n]$ and $\kappa[m, n]$ have been discussed in earlier sections. The most common combination of these is the additive model:

$$c[m, n] = (a[m, n] \otimes h_o[m, n]) + \kappa[m, n] \quad (51.194)$$

The restoration procedure that is based on linear filtering coupled to a minimum mean-square error criterion again produces a Wiener filter:

$$\begin{aligned} H_W(u, v) &= \frac{H_o^*(u, v) S_{aa}(u, v)}{|H_o(u, v)|^2 S_{aa}(u, v) + S_{nn}(u, v)} \\ &= \frac{H_o^*(u, v)}{|H_o(u, v)|^2 + (S_{nn}(u, v)/S_{aa}(u, v))} \end{aligned} \quad (51.195)$$

Once again $S_{aa}(u, v)$ is the power spectral density of an image, $S_{nn}(u, v)$ is the power spectral density of the noise, and $H_o(u, v) = \mathcal{F}\{h_o[m, n]\}$. Examination of this formula for some extreme cases can be useful. For those frequencies where $S_{aa}(u, v) \gg S_{nn}(u, v)$, where the signal spectrum dominates the noise spectrum, the Wiener filter is given by $1/H_o(u, v)$, the *inverse filter* solution. For those frequencies where $S_{aa}(u, v) \ll S_{nn}(u, v)$, where the noise spectrum dominates the signal spectrum, the Wiener filter is proportional to $H_o^*(u, v)$, the *matched filter* solution. For those frequencies where $H_o(u, v) = 0$, the Wiener filter $H_W(u, v) = 0$ preventing overflow.

The Wiener filter is a solution to the restoration problem based on the hypothesized use of a linear filter and the minimum mean-square (or *rms*) error criterion. In the example below, the image $a[m, n]$ was distorted by a bandpass filter and then white noise was added to achieve an $SNR = 30 \text{ dB}$. The results are shown in Fig. 51.50.

FIGURE 51.50: Noise and distortion suppression using the Wiener filter, Eq.(51.195) and the median filter. (a) Distorted, noisy image; (b) Wiener filter, $rms = 108.4$; (c) Median filter (3×3), $rms = 40.9$.

The *rms* after Wiener filtering but before contrast stretching was 108.4; after contrast stretching with Eq. (51.77), the final result as shown in Fig. 51.50(b) has a mean-square error of 27.8. Using a 3×3 median filter as shown in Fig. 51.50(c) leads to a *rms* error of 40.9 before contrast stretching and

35.1 after contrast stretching. Although the Wiener filter gives the minimum *rms* error over the set of all *linear* filters, the *nonlinear* median filter gives a lower *rms* error. The operation *contrast stretching* is itself a nonlinear operation. The “visual quality” of the median filtering result is comparable to the Wiener filtering result. This is due in part to periodic artifacts introduced by the linear filter which are visible in Fig. 51.50(b).

51.10.3 Segmentation

In the analysis of the objects in images, it is essential that we can distinguish between the objects of interest and “the rest”. This latter group is also referred to as the background. The techniques that are used to find the objects of interest are usually referred to as *segmentation techniques* — segmenting the foreground from background. In this section we will discuss two of the most common techniques — *thresholding* and *edge finding* — and we will present techniques for improving the quality of the segmentation result. It is important to understand that:

- there is no universally applicable segmentation technique that will work for all images, and,
- no segmentation technique is perfect.

Thresholding

This technique is based on a simple concept. A parameter θ called the *brightness threshold* is chosen and applied to the image $a[m, n]$ as follows:

$$\begin{array}{ll} \text{If } a[m, n] \geq \theta & a[m, n] = \text{object} = 1 \\ \text{Else} & a[m, n] = \text{background} = 0 \end{array} \quad (51.196)$$

This version of the algorithm assumes that we are interested in light objects on a dark background. For dark objects on a light background we would use:

$$\begin{array}{ll} \text{If } a[m, n] < \theta & a[m, n] = \text{object} = 1 \\ \text{Else} & a[m, n] = \text{background} = 0 \end{array} \quad (51.197)$$

The output is the label “object” or “background” which, due to its dichotomous nature, can be represented as a Boolean variable “1” or “0”. In principle, the test condition could be based on some property other than simple brightness [for example, *If (Redness $\{a[m, n]\} \geq \theta_{\text{red}})$], but the concept is clear.*

The central question in thresholding then becomes: How do we choose the threshold θ ? While there is no universal procedure for threshold selection that is guaranteed to work on all images, there is a variety of alternatives.

Fixed threshold – One alternative is to use a threshold that is chosen independently of the image data. If it is known that one is dealing with very high-contrast images where the objects are very dark and the background is homogeneous (section 51.10.1) and very light, then a constant threshold of 128 on a scale of 0 to 255 might be sufficiently accurate. By accuracy we mean that the number of falsely classified pixels should be kept to a minimum.

Histogram-derived thresholds – In most cases, the threshold is chosen from the brightness histogram of the region or image that we wish to segment (see sections 51.3.5 and 51.9.1). An image and its associated brightness histogram are shown in Fig. 51.51.

A variety of techniques has been devised to automatically choose a threshold starting from the gray-value histogram, $\{h[b] | b = 0, 1, \dots, 2^B - 1\}$. Some of the most common ones are presented below. Many of these algorithms can benefit from a smoothing of the raw histogram data to remove

FIGURE 51.51: Pixels below the threshold ($a[m, n] < \theta$) will be labeled as object pixels: those above the threshold will be labeled as background pixels. (a) Image to be *thresholded* and (b) brightness histogram of the image.

small fluctuations, but the smoothing algorithm must not shift the peak positions. This translates into a zero-phase smoothing algorithm given below where typical values for W are 3 or 5:

$$h_{smooth}[b] = \frac{1}{W} \sum_{w=-(W-1)/2}^{(W-1)/2} h_{raw}[b-w] \quad W \text{ odd} \quad (51.198)$$

Isodata algorithm – This iterative technique for choosing a threshold was developed by Ridler and Calvard. The histogram is initially segmented into two parts using a starting threshold value such as $\theta_0 = 2^{B-1}$, half the maximum dynamic range. The sample mean ($m_{f,0}$) of the gray values associated with the foreground pixels and the sample mean ($m_{b,0}$) of the gray values associated with the background pixels are computed. A new threshold value θ_1 is now computed as the average of these two sample means. The process is repeated, based on the new threshold, until the threshold value does not change any more. In formula:

$$\theta_k = (m_{f,k-1} + m_{b,k-1}) / 2 \quad \text{until } \theta_k = \theta_{k-1} \quad (51.199)$$

Background-symmetry algorithm – This technique assumes a distinct and dominant peak for the background that is symmetric about its maximum. The technique can benefit from smoothing as described above [Eq. (51.198)]. The maximum peak (*maxp*) is found by searching for the maximum value in the histogram. The algorithm then searches on the *nonobject pixel side* of that maximum to find a $p\%$ point as in Eq. (51.39).

In Fig. 51.51(b), where the object pixels are located to the *left* of the background peak at brightness 183, this means searching to the right of that peak to locate, as an example, the 95% value. At this brightness value, 5% of the pixels lie to the *right* of (are above) that value. This occurs at brightness 216 in Fig. 51.51(b). Because of the assumed symmetry, we use as a threshold a displacement to the *left* of the maximum that is equal to the displacement to the right where the $p\%$ is found. For Fig. 51.51(b) this means a threshold value given by $183 - (216 - 183) = 150$. In formula:

$$\theta = maxp - (p\% - maxp) \quad (51.200)$$

This technique can be adapted easily to the case where we have light objects on a dark, dominant background. Further, it can be used if the object peak dominates and we have reason to assume that the brightness distribution around the object peak is symmetric. An additional variation on this symmetry theme is to use an estimate of the sample standard deviation [s in Eq. (51.37)] based on one side of the dominant peak and then use a threshold based on $\theta = maxp \pm 1.96s$ (at the

5% level) or $\theta = \max p \pm 2.57s$ (at the 1% level). The choice of “+” or “−” depends on which direction from $\max p$ is being defined as the object/background threshold. Should the distributions be approximately Gaussian around $\max p$, then the values 1.96 and 2.57 will, in fact, correspond to the 5% and 1% level.

Triangle algorithm – This technique due to Zack is illustrated in Fig. 51.52. A line is constructed between the maximum of the histogram at brightness b_{\max} and the lowest value $b_{\min} = (p = 0)\%$ in the image. The distance d between the line and the histogram $h[b]$ is computed for all values of b from $b = b_{\min}$ to $b = b_{\max}$. The brightness value b_o where the distance between $h[b_o]$ and the line is maximal is the threshold value, that is, $\theta = b_o$. This technique is particularly effective when the object pixels produce a weak peak in the histogram.

FIGURE 51.52: The triangle algorithm is based on finding the value of b that gives the maximum distance d .

The three procedures described above give the values $\theta = 139$ for the Isodata algorithm, $\theta = 150$ for the background symmetry algorithm at the 5% level, and $\theta = 152$ for the triangle algorithm for the image in Fig. 51.51(a).

Thresholding does not have to be applied to entire images but can be used on a region-by-region basis. Chow and Kaneko developed a variation in which the $M \times N$ image is divided into nonoverlapping regions. In each region, a threshold is calculated and the resulting threshold values are put together (interpolated) to form a thresholding surface for the entire image. The regions should be of “reasonable” size so that there are a sufficient number of pixels in each region to make an estimate of the histogram and the threshold. The utility of this procedure — like so many others — depends on the application at hand.

Edge Finding

Thresholding produces a segmentation that yields all the pixels that, in principle, belong to the object or objects of interest in an image. An alternative to this is to find those pixels that belong to the borders of the objects. Techniques that are directed to this goal are termed *edge finding techniques*. From our discussion in section 51.9.6 on mathematical morphology, specifically Eqs. (51.162), (51.163), and (51.170), we see that there is an intimate relationship between edges and regions.

Gradient-based procedure – The central challenge to edge finding techniques is to find procedures that produce *closed* contours around the objects of interest. For objects of particularly high *SNR*, this can be achieved by calculating the gradient and then using a suitable threshold. This is illustrated in Fig. 51.53.

While the technique works well for the 30-dB image in Fig. 51.53(a), it fails to provide an accurate determination of those pixels associated with the object edges for the 20-dB image in Fig. 51.53(b).

FIGURE 51.53: Edge finding based on the Sobel gradient, Eq. (51.110), combined with the Isodata thresholding algorithm Eq. (51.199). (a) $SNR = 30$ dB and (b) $SNR = 20$ dB.

A variety of smoothing techniques as described in section 51.9.4 and in Eq. (51.180) can be used to reduce the noise effects before the gradient operator is applied.

Zero-crossing based procedure – A more modern view to handling the problem of edges in noisy images is to use the zero crossings generated in the Laplacian of an image (section 51.9.5). The rationale starts from the model of an ideal edge, a step function, that has been blurred by an *OTF* such as Table 51.4.T.3 (out-of-focus), T.5 (diffraction-limited), or T.6 (general model) to produce the result shown in Fig. 51.54.

FIGURE 51.54: Edge finding based on the zero crossing as determined by the second derivative, the Laplacian. The curves are not to scale.

The edge location is, according to the model, at that place in the image where the Laplacian changes sign, the zero crossing. As the Laplacian operation involves a second derivative, this means a potential

enhancement of noise in the image at high spatial frequencies; see Eq. (51.114). To prevent enhanced noise from dominating the search for zero crossings, a smoothing is necessary.

The appropriate smoothing filter from among the many possibilities described in section 51.9.4 should have, according to Canny, the following properties:

- In the frequency domain, (u, v) or (Ω, Ψ) , the filter should be as narrow as possible to provide suppression of high frequency noise, and;
- In the spatial domain, (x, y) or $[m, n]$, the filter should be as narrow as possible to provide good localization of the edge. A too wide filter generates uncertainty as to precisely where, within the filter width, the edge is located.

The smoothing filter that simultaneously satisfies both these properties — minimum bandwidth and minimum spatial width — is the Gaussian filter described in section 51.9.4. This means that the image should be smoothed with a Gaussian of an appropriate σ followed by application of the Laplacian. In formula:

$$\text{ZeroCrossing}\{a(x, y)\} = \{(x, y) | \nabla^2 \{g_{2D}(x, y) \otimes a(x, y)\} = 0\} \quad (51.201)$$

where $g_{2D}(x, y)$ is defined in Eq. (51.93). The derivative operation is linear and shift-invariant as defined in Eqs. (51.85) and (51.86). This means that the order of the operators can be exchanged [Eq. (51.4)] or combined into one single filter [Eq. (51.5)]. This second approach leads to the Marr-Hildreth formulation of the “Laplacian-of-Gaussians” (LoG) filter:

$$\text{ZeroCrossing}\{a(x, y)\} = \{(x, y) | LoG(x, y) \otimes a(x, y) = 0\} \quad (51.202)$$

where

$$LoG(x, y) = \frac{x^2 + y^2}{\sigma^4} g_{2D}(x, y) - \frac{2}{\sigma^2} g_{2D}(x, y) \quad (51.203)$$

Given the circular symmetry, this can also be written as:

$$LoG(r) = \left(\frac{r^2 - 2\sigma^2}{2\pi\sigma^6} \right) e^{-(r^2/2\sigma^2)} \quad (51.204)$$

This two-dimensional convolution kernel, which is sometimes referred to as a “Mexican hat filter”, is illustrated in Fig. 51.55.

FIGURE 51.55: LoG filter with $\sigma = 1.0$. (a) $-LoG(x, y)$ and (b) $LoG(r)$.

PLUS-based procedure – Among the zero crossing procedures for edge detection, perhaps the most accurate is the *PLUS* filter as developed by Verbeek and Van Vliet. The filter is defined, using Eqs. (51.121) and (51.122) as:

$$\begin{aligned} PLUS(a) &= SDGD(a) + Laplace(a) \\ &= \left(\frac{A_{xx}A_x^2 + 2A_{xy}A_xA_y + A_{yy}A_y^2}{A_x^2 + A_y^2} \right) + (A_{xx} + A_{yy}) \end{aligned} \quad (51.205)$$

Neither the derivation of the *PLUS*'s properties nor an evaluation of its accuracy are within the scope of this section. Suffice it to say that, for positively curved edges in gray value images, the Laplacian-based zero crossing procedure *overestimates* the position of the edge and the *SDGD*-based procedure *underestimates* the position. This is true in both two-dimensional and three-dimensional images with an error on the order of $(\sigma/R)^2$ where R is the radius of curvature of the edge. The *PLUS* operator has an error on the order of $(\sigma/R)^4$ if the image is sampled at, at least, $3 \times$ the usual Nyquist sampling frequency as in Eq. (51.56) or if we choose $\sigma \geq 2.7$ and sample at the usual Nyquist frequency.

All of the methods based on zero crossings in the Laplacian must be able to distinguish between zero *crossings* and zero *values*. While the former represent edge positions, the latter can be generated by regions that are no more complex than bilinear surfaces, that is, $a(x, y) = a_0 + a_1 \bullet x + a_2 \bullet y + a_3 \bullet x \bullet y$. To distinguish between these two situations, we first find the zero crossing positions and label them as “1” and all other pixels as “0”. We then multiply the resulting image by a measure of the *edge strength* at each pixel. There are various measures for the edge strength that are all based on the gradient as described in section 51.9.5 and Eq. (51.181). This last possibility, use of a morphological gradient as an edge strength measure, was first described by Lee, Haralick, and Shapiro and is particularly effective. After multiplication the image is then thresholded (as above) to produce the final result. The procedure is shown in Fig. 51.56.

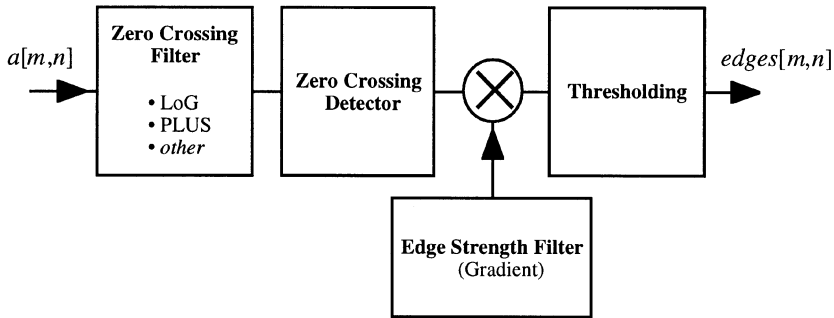

FIGURE 51.56: General strategy for edges based on zero crossings.

The results of these two edge finding techniques based on zero crossings, *LoG* filtering and *PLUS* filtering, are shown in Fig. 51.57 for images with a 20-dB *SNR*.

Edge finding techniques provide, as the name suggests, an image that contains a collection of edge pixels. Should the edge pixels correspond to objects, as opposed to say simple lines in the image, then a region-filling technique such as Eq. (51.170) may be required to provide the complete objects.

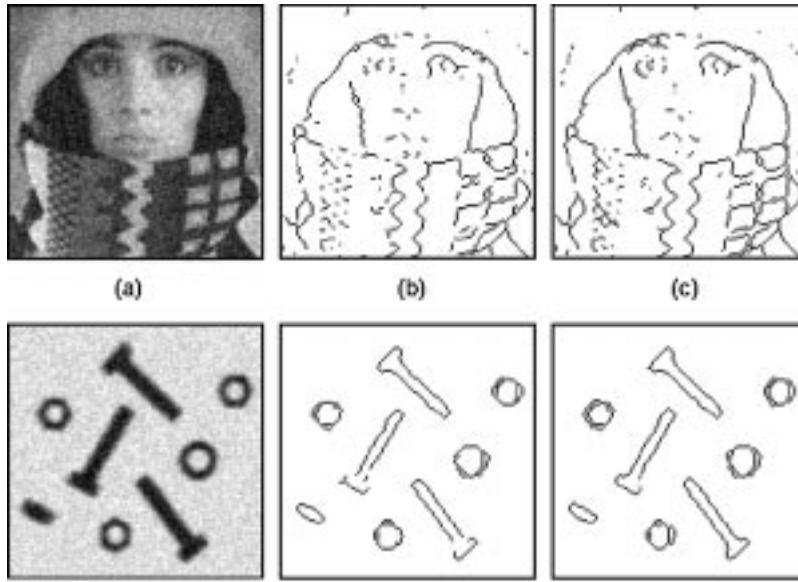

FIGURE 51.57: Edge finding using zero crossing algorithms *LoG* and *PLUS*. In both algorithms $\sigma = 1.5$. (a) Image $SNR = 20$ dB; (b) *LoG* filter; and (c) *PLUS* filter.

Binary Mathematical Morphology

The various algorithms that we have described for mathematical morphology in section 51.9.6 can be put together to form powerful techniques for the processing of binary images and gray level images. As binary images frequently result from segmentation processes on gray level images, the morphological processing of the binary result permits the improvement of the segmentation result.

Salt-or-pepper filtering – Segmentation procedures frequently result in isolated “1” pixels in a “0” neighborhood (salt) or isolated “0” pixels in a “1” neighborhood (pepper). The appropriate neighborhood definition must be chosen such as in Fig. 51.3. Using the lookup table formulation for Boolean operations in a 3×3 neighborhood that was described in association with Fig. 51.43, *salt filtering* and *pepper filtering* are straightforward to implement. We weight the different positions in the 3×3 neighborhood as follows:

$$\text{Weights} = \begin{bmatrix} w_4 = 16 & w_3 = 8 & w_2 = 4 \\ w_5 = 32 & w_0 = 1 & w_1 = 2 \\ w_6 = 64 & w_7 = 128 & w_8 = 256 \end{bmatrix} \quad (51.206)$$

For a 3×3 window in $a[m, n]$ with values “0” or “1” we then compute:

$$\begin{aligned} \text{sum} &= w_0 a[m, n] + w_1 a[m + 1, n] + w_2 a[m + 1, n - 1] + \\ &w_3 a[m, n - 1] + w_4 a[m - 1, n - 1] + w_5 a[m - 1, n] + \\ &w_6 a[m - 1, n + 1] + w_7 a[m, n + 1] + w_8 a[m + 1, n - 1] \end{aligned} \quad (51.207)$$

The result, *sum*, is a number bounded by $0 \leq \text{sum} \leq 511$.

Salt filter – The 4-connected and 8-connected versions of this filter are the same and are given by the following procedure:

$$\begin{aligned} (i) & \text{ Compute } \text{sum} \\ (ii) & \text{ If } ((\text{sum} == 1)) \quad c[m, n] = 0 \\ & \text{ Else } \quad c[m, n] = a[m, n] \end{aligned} \quad (51.208)$$

Pepper filter – The 4-connected and 8-connected versions of this filter are the following procedures:

<i>4-connected</i>	<i>8-connected</i>	
(i) Compute <i>sum</i>	(i) Compute <i>sum</i>	
(ii) If ((<i>sum</i> == 170)	(ii) If ((<i>sum</i> == 510)	(51.209)
<i>c</i> [<i>m</i> , <i>n</i>] = 1	<i>c</i> [<i>m</i> , <i>n</i>] = 1	
Else	Else	
<i>c</i> [<i>m</i> , <i>n</i>] = <i>a</i> [<i>m</i> , <i>n</i>]	<i>c</i> [<i>m</i> , <i>n</i>] = <i>a</i> [<i>m</i> , <i>n</i>]	

Isolate objects with holes – To find objects with holes, we can use the following procedure which is illustrated in Fig. 51.58.

- (i) *Segment* image to produce binary mask representation
- (ii) Compute *skeleton* without end pixels — Eq. (51.169)
- (iii) Use *salt* filter to remove single skeleton pixels
- (iv) *Propagate* remaining skeleton pixels into original binary mask — Eq. (51.170)

The binary objects are shown in gray and the skeletons, after application of the salt filter, are shown as a black overlay on the binary objects. Note that this procedure uses no parameters other than the fundamental choice of connectivity; it is free from “magic numbers”. In the example shown in Fig. 51.58, the 8-connected definition was used as well as the structuring elements $B = N_8$.

FIGURE 51.58: Isolation of objects with holes using morphological operations. (a) Binary image; (b) skeleton after salt filter; and (c) objects with holes.

Filling holes in objects – To fill holes in objects, we use the following procedure which is illustrated in Fig. 51.59.

- (i) *Segment* image to produce binary representation of objects
- (ii) Compute *complement* of binary image as a *mask image*
- (iii) Generate a *seed image* as the border of the image
- (iv) *Propagate* the *seed* into the *mask* — Eq. (51.170)
- (v) *Complement* result of propagation to produce final result.

The *mask image* is illustrated in gray in Fig. 51.59(a) and the *seed image* is shown in black in that same illustration. When the object pixels are specified with a connectivity of $C = 8$, then the propagation into the mask (background) image should be performed with a connectivity of $C = 4$, that is, dilations with the structuring element $B = N_4$. This procedure is also free of “magic numbers”.

FIGURE 51.59: Filling holes in objects. (a) Mask and seed images and (b) objects with holes filled.

Removing border-touching objects – Objects that are connected to the image border are not suitable for analysis. To eliminate them we can use a series of morphological operations that are illustrated in Fig. 51.60.

- (i) Segment image to produce binary *mask image* of objects
- (ii) Generate a *seed image* as the border of the image (51.212)
- (iii) Propagate the *seed* into the *mask* — Eq. (51.170)
- (iv) Compute *XOR* of the propagation result and the *mask image* as final result.

The *mask image* is illustrated in gray in Fig. 51.60(a) and the *seed image* is shown in black in that same illustration. If the structuring element used in the propagation is $B = N_4$, then objects are removed that are 4-connected with the image boundary. If $B = N_8$ is used, then objects that 8-connected with the boundary are removed.

FIGURE 51.60: Removing objects touching borders. (a) Mask and seed images and (b) remaining objects.

Exo-skeleton – The *exo-skeleton* of a set of objects is the skeleton of the background that contains the objects. The *exo-skeleton* produces a partition of the image into regions each of which contains one object. The actual skeletonization [Eq. (51.169)] is performed without the preservation of end pixels and with the border set to “0”. The procedure is described below and the result is illustrated in Fig. 51.61.

FIGURE 51.61: Exo-skeleton.

- (i) *Segment* image to produce binary image
- (ii) Compute *complement* of binary image
- (iii) Compute *skeleton* using Eq. (51.169) $i + ii$ with border set to “0”.

(51.213)

Touching objects – Segmentation procedures frequently have difficulty separating slightly touching, yet distinct, objects. The following procedure provides a mechanism to separate these objects and makes minimal use of “magic numbers”. The exo-skeleton produces a partition of the image into regions each of which contains one object. The actual skeletonization is performed without the preservation of end pixels and with the border set to “0”. The procedure is illustrated in Fig. 51.62.

- (i) *Segment* image to produce binary image
- (ii) Compute a “small number” of *erosions* with $B = N_4$
- (iii) Compute *exo-skeleton* of eroded result
- (iv) Complement *exo-skeleton* result
- (v) Compute *AND* of original binary image and the complemented exo-skeleton.

(51.214)

The *eroded binary image* is illustrated in gray in Fig. 51.62(a) and the *exo-skeleton image* is shown in black in that same illustration. An enlarged section of the final result is shown in Fig. 51.62(b) and the separation is easily seen. This procedure involves choosing a small, minimum number of erosions, but the number is not critical as long as it initiates a coarse separation of the desired objects. The actual separation is performed by the exo-skeleton which, itself, is free of “magic numbers”. If the exo-skeleton is 8-connected, then the background separating the objects will be 8-connected. The objects themselves will be disconnected according to the 4-connected criterion. (See section 51.9.6 and Fig. 51.36.)

Gray-Value Mathematical Morphology

As we have seen in section 51.10.1, gray-value morphological processing techniques can be used for practical problems such as shading correction. In this section, several other techniques will be presented.

Top-hat transform – The isolation of gray-value objects that are convex can be accomplished with the *top-hat transform* as developed by Meyer. Depending on whether we are dealing with light objects on a dark background or dark objects on a light background, the transform is defined as:

$$\text{Light objects - TopHat}(A, B) = A - (A \circ B) = A - \max_B \left(\min_B(A) \right) \quad (51.215)$$

FIGURE 51.62: Separation of touching objects. (a) Eroded and exo-skeleton images and (b) objects separated (detail).

$$\text{Dark objects - TopHat}(A, B) = (A \bullet B) - A = \min_B \left(\max_B(A) \right) - A \quad (51.216)$$

where the structuring element B is chosen to be bigger than the objects in question and, if possible, to have a convex shape. Because of the properties given in Eqs. (51.155) and (51.158), $\text{TopHat}(A, B) \geq 0$. An example of this technique is shown in Fig. 51.63.

The original image including shading is processed by a 15×1 structuring element as described in Eqs. (51.215) and (51.216) to produce the desired result. Note that the transform for dark objects has been defined in such a way as to yield “positive” objects as opposed to “negative” objects. Other definitions are, of course, possible.

Thresholding – A simple estimate of a locally varying threshold surface can be derived from morphological processing as follows:

$$\text{Threshold surface - } \theta[m, n] = \frac{1}{2}(\max(A) + \min(A)) \quad (51.217)$$

Once again, we suppress the notation for the structuring element B under the \max and \min operations to keep the notation simple. Its use, however, is understood.

Local contrast stretching – Using morphological operations, we can implement a technique for *local contrast stretching*. That is, the amount of stretching that will be applied in a neighborhood will be controlled by the original contrast in that neighborhood. The morphological gradient defined in Eq. (51.181) may also be seen as related to a measure of the local contrast in the window defined by the structuring element B :

$$\text{LocalContrast}(A, B) = \max(A) - \min(A) \quad (51.218)$$

The procedure for local contrast stretching is given by:

$$c[m, n] = \text{scale} \bullet \frac{A - \min(A)}{\max(A) - \min(A)} \quad (51.219)$$

The \max and \min operations are taken over the structuring element B . The effect of this procedure is illustrated in Fig. 51.64. It is clear that this *local* operation is an extended version of the *point* operation for contrast stretching presented in Eq. (51.77).

Using standard test images (as we have seen in so many examples in this chapter) illustrates the power of this local morphological filtering approach.

52.1 Introduction

Digital representation of images is important for digital transmission and storage on different media such as magnetic or laser disks. However, pictorial material requires vast amounts of bits if represented through direct quantization. As an example, an SVGA color image requires $3 \times 600 \times 800 \text{ bytes} = 1,44 \text{ Mbytes}$ when each color component is quantized using 1 byte per pixel, the amount of bytes that can be stored on one standard 3.5-inch diskette. It is therefore evident that *compression* (often called *coding*) is necessary for reducing the amount of data [33].

In this chapter we address three fundamental questions concerning image compression:

- Why is image compression possible?
- What are the theoretical coding limits?
- Which practical compression methods can be devised?

The first two questions concern statistical and structural properties of the image material and human visual perception. Even if we were able to answer these questions accurately, the methodol-

¹Parts of this manuscript are based on Ramstad, T.A., Aase, S.O., and Husøy, J.H., *Subband Compression of Images — Principles and Examples*, Elsevier Science Publishers BV, North Holland, 1995. Permission to use the material is given by ELSEVIER Science Publishers BV.

ogy for image compression (third question) does not follow thereof. That is, the practical coding algorithms must be found otherwise. The bulk of the chapter will review image coding principles and present some of the best proposed still image coding methods.

The prevailing technique for image coding is *transform coding*. This is part of the JPEG (Joint Picture Expert Group) standard [14] as well as a part of all the existing video coding standards (H.261, H.263, MPEG-1, MPEG-2) [15, 16, 17, 18]. Another closely related technique, *subband coding*, is in some respects better, but has not yet been recognized by the standardization bodies. A third technique, *differential coding*, has not been successful for still image coding, but is often used to code the lowpass-lowpass band in subband coders, and is an integral part of hybrid video coders for removal of temporal redundancy. *Vector quantization* (VQ) is the ultimate technique if there were no complexity constraints. Because all practical systems must have limited complexity, VQ is usually used as a component in a multi-component coding scheme. Finally, *fractal* or *attractor coding* is based on an idea far from other methods, but it is, nevertheless, strongly related to vector quantization.

For natural images, no exact digital representation exists because the quantization, which is an integral part of digital representations, is a lossy technique. Lossy techniques will always add noise, but the noise level and its characteristics can be controlled and depend on the number of bits per pixel as well as the performance of the method employed. *Lossless* techniques will be discussed as a component in other coding methods.

52.1.1 Signal Chain

We assume a model where the input signal is properly bandlimited and digitized by an appropriate *analog-to-digital converter*. All subsequent processing in the encoder will be digital. The decoder is also digital up to the digital-to-analog converter, which is followed by a lowpass reconstruction filter.

Under idealized conditions, the interconnection of the signal chain excluding the compression unit will be assumed to be noise-free. (In reality, the analog-to-digital conversion will render a noise power which can be approximated by $\Delta^2/12$, where Δ is the quantizer interval. This interval depends on the number of bits, and we assume that it is so high that the contribution to the overall noise from this process is negligible). The performance of the coding chain can then be assessed from the difference between the input and output of the digital compression unit disregarding the analog part.

Still images must be sampled on some two-dimensional grid. Several schemes are viable choices, and there are good reasons for selecting nonrectangular grids. However, to simplify, rectangular sampling will be considered only, and all filtering will be based on separable operations, first performed on the rows and subsequently on the columns of the image. The theory is therefore presented for one-dimensional models, only.

52.1.2 Compressibility of Images

There are two reasons why images can be compressed:

- All meaningful images exhibit some form of internal structure, often expressed through statistical dependencies between pixels. We call this property *signal redundancy*.
- The human visual system is not perfect. This means that certain degradations cannot be perceived by human observers. The degree of allowable noise is called *irrelevancy* or *visual redundancy*. If we furthermore accept visual degradation, we can exploit what might be termed *tolerance*.

In this section we make some speculations about the compression potential resulting from redundancy and irrelevancy.

The two fundamental concepts in evaluating a coding scheme are *distortion*, which measures quality in the compressed signal, and *rate*, which measures how costly it is to transmit or store a signal.

Distortion is a measure of the deviation between the encoded/decoded signal and the original signal. Usually, distortion is measured by a single number for a given coder and bit rate. There are numerous ways of mapping an error signal onto a single number. Moreover, it is hard to conceive that a single number could mimic the quality assessment performed by a human observer. An easy-to-use and well-known error measure is the *mean square error (mse)*. The visual correctness of this measure is poor. The human visual system is sensitive to errors in shapes and deterministic patterns, but not so much in stochastic textures. The *mse* defined over the entire image can, therefore, be entirely erroneous in the visual sense. Still, *mse* is the prevailing error measure, and it can be argued that it reflects well small changes due to optimization in a given coder structure, but poor as for the comparison between different models that create different noise characteristics.

Rate is defined as *bits per pixel* and is connected to the information content in a signal, which can be measured by *entropy*.

A Lower Bound for Lossless Coding

To define image entropy, we introduce the set \mathbf{S} containing all possible images of a certain size and call the number of images in the set N_S . To exemplify, assume the image set under consideration has dimension 512×512 pixels and each pixel is represented by 8 bits. The number of different images that exist in this set is $2^{512 \times 512 \times 8}$, an overwhelming number!

Given the probability P_i of each image in the set \mathbf{S} , where $i \in N_S$ is the index pointing to the different images, the source entropy is given by

$$H = - \sum_{i \in N_S} P_i \log_2 P_i . \quad (52.1)$$

The entropy is a lower bound for the rate in lossless coding of the digital images.

A Lower Bound for Visually Lossless Coding

In order to incorporate perceptual redundancies, it is observed that all the images in the given set cannot be distinguished visually. We therefore introduce *visual entropy* as an abstract measure which incorporates distortion.

We now partition the image set into disjoint subsets, S_i , in which all the different images have similar appearance. One image from each subset is chosen as the *representation* image. The collection of these $N_{\mathcal{R}}$ representation images constitutes a subset \mathcal{R} , that is a set spanning all distinguishable images in the original set.

Assume that image $i \in \mathcal{R}$ appears with probability \hat{P}_i . Then the *visual entropy* is defined by

$$H_V = - \sum_{i \in N_{\mathcal{R}}} \hat{P}_i \log_2 \hat{P}_i . \quad (52.2)$$

The minimum attainable bit rate is lower bounded by this number for image coders without visual degradation.

52.1.3 The Ideal Coding System

Theoretically, we can approach the visual entropy limit using an unrealistic *vector quantizer (VQ)*, in conjunction with an ideal *entropy coder*. The principle of such an optimal coding scheme is described next.

The set of representation images is stored in what is usually called a *codebook*. The encoder and decoder have similar copies of this codebook. In the encoding process, the image to be coded is compared to all the vectors in the codebook applying the visually correct distortion measure.

The codebook member with the closest resemblance to the sample image is used as the *coding approximation*. The corresponding codebook index (address) is entropy coded and transmitted to the decoder. The decoder looks up the image located at the address given by the transmitted index.

Obviously, the above method is unrealistic. The complexity is beyond any practical limit both in terms of storage and computational requirement. Also, the correct visual distortion measure is not presently known. We should therefore only view the indicated coding strategy as the limit for any coding scheme.

52.1.4 Coding with Reduced Complexity

In practical coding methods, there are basically two ways of avoiding the extreme complexity of ideal VQ. In the first method, the encoder operates on small image blocks rather than on the complete image. This is obviously suboptimal because the method cannot profit from the redundancy offered by large structures in an image. But the larger the blocks, the better the method. The second strategy is very different and applies some preprocessing on the image prior to quantization. The aim is to remove statistical dependencies among the image pixels, thus avoiding representation of the same information more than once. Both techniques are exploited in practical coders, either separately or in combination.

A typical image encoder incorporating preprocessing is shown in Fig. 52.1.

FIGURE 52.1: Generic encoder structure block diagram. D = decomposition unit, Q = quantizer, B = coder for minimum bit-representation.

The first block (D) decomposes the signal into a set of coefficients. The coefficients are subsequently quantized (in Q), and are finally coded to a minimum bit representation (in B). This model is correct for frequency domain coders, but in *closed loop differential coders (DPCM)*, the decomposition and quantization is performed in the same block, as will be demonstrated later. Usually the decomposition is exact. In *fractal coding*, the decomposition is replaced by approximate modeling.

Let us consider the *decoder* and introduce a *series expansion* as a unifying description of the different image representation methods:

$$\hat{x}(l) = \sum_k \hat{a}_k \phi_k(l) . \quad (52.3)$$

The formula represents the recombination of signal components. Here $\{\hat{a}_k\}$ are the coefficients (the parameters in the representation), and $\{\phi_k(l)\}$ are the *basis functions*. A major distinction between coding methods is their set of basis functions, as will be demonstrated in the next section.

The complete decoder consists of three major parts as shown in Fig. 52.2. The first block (I) receives the bit representation which it partitions into entities representing the different coder parameters and decodes them. The second block (Q^{-1}) is a dequantizer which maps the code to the parametric approximation. The third block (R) reconstructs the signal from the parameters using the series representation.

FIGURE 52.2: Block diagram of generic decoder structure. I = bit-representation decoder, Q^{-1} = inverse quantizer, R = signal reconstruction unit.

The second important distinction between compression structures is the coding of the series expansion coefficients in terms of bits. This is dealt with in section 52.3.

52.2 Signal Decomposition

As introduced in the previous section, series expansion can be viewed as a common tool to describe signal decomposition. The choice of basis functions will distinguish different coders and influence such features as *coding gain* and the types of distortions present in the decoded image for low bit rate coding. Possible classes of basis functions are:

1. Block-oriented basis functions.

- The basis functions can cover the whole signal length L . L linearly independent basis functions will make a complete representation.
- Blocks of size $N \leq L$ can be decomposed individually. *Transform coders* operate in this way. If the blocks are small, the decomposition can catch fast transients. On the other hand, regions with constant features, such as smooth areas or textures, require long basis functions to fully exploit the correlation.

2. Overlapping basis functions:

The length of the basis functions and the degree of overlap are important parameters. The issue of reversibility of the system becomes nontrivial.

- In *differential coding*, one basis function is used over and over again, shifted by one sample relative to the previous function. In this case, the basis function usually varies slowly according to some adaptation criterion with respect to the local signal statistics.
- In subband coding using a uniform filter bank, N distinct basis functions are used. These are repeated over and over with a shift between each group by N samples. The length of the basis functions is usually several times larger than the shifts accommodating for handling fast transients as well as long-term correlations if the basis functions taper off at both ends.
- The basis functions may be finite (FIR filters) or semi-infinite (IIR filters).

Both time domain and frequency domain properties of the basis functions are indicators of the coder performance. It can be argued that decomposition, whether it is performed by a transform or a filter bank, represents a spectral decomposition. Coding gain is obtained if the different output channels are *decorrelated*. It is therefore desirable that the frequency responses of the different basis functions are localized and separate in frequency. At the same time, they must cover the whole frequency band in order to make a complete representation.

The desire to have highly localized basis functions to handle transients, with localized Fourier transforms to obtain good coding gain, are contradictory requirements due to the *Heisenberg uncertainty relation* [33] between a function and its Fourier transform. The selection of the basis functions must be a compromise between these conflicting requirements.

52.2.1 Decomposition by Transforms

When nonoverlapping block transforms are used, the Karhunen-Loève transform decorrelates, in a statistical sense, the signal within each block completely. It is composed of the eigenvectors of the correlation matrix of the signal. This means that one either has to know the signal statistics in advance or estimate the correlation matrix from the image itself.

Mathematically the eigenvalue equation is given by

$$\mathbf{R}_{xx} \mathbf{h}_n = \lambda_n \mathbf{h}_n . \quad (52.4)$$

If the eigenvectors are column vectors, the KLT matrix is composed of the eigenvectors \mathbf{h}_n , $n = 0, 1, \dots, N - 1$, as its rows:

$$\mathbf{K} = [\mathbf{h}_0 \mathbf{h}_1 \dots \mathbf{h}_{N-1}]^T . \quad (52.5)$$

The decomposition is performed as

$$\mathbf{y} = \mathbf{Kx} . \quad (52.6)$$

The *eigenvalues* are equal to the power of each transform coefficient.

In practice, the so-called *Cosine Transform* (of type II) is usually used because it is a fixed transform and it is close to the KLT when the signal can be described as a first-order autoregressive process with correlation coefficient close to 1.

The cosine transform of length N in one dimension is given by:

$$y(k) = \sqrt{\frac{2}{N}} \alpha(k) \sum_{n=0}^{N-1} x(n) \cos \frac{(2n+1)k\pi}{2N}, \quad k = 0, 1, \dots, N-1, \quad (52.7)$$

where

$$\alpha(0) = \frac{1}{\sqrt{2}} \quad \text{and} \quad \alpha(k) = 1 \quad \text{for} \quad k \neq 0 . \quad (52.8)$$

The inverse transform is similar except that the scaling factor $\alpha(k)$ is inside the summation.

Many other transforms have been suggested in the literature (DFT, Hadamard Transform, Sine Transform, etc.), but none of these seem to have any significance today.

52.2.2 Decomposition by Filter Banks

Uniform analysis and synthesis filter banks are shown in Fig. 52.3.

In the analysis filter bank the input signal is split in contiguous and slightly overlapping frequency bands denoted *subbands*. An ideal frequency partitioning is shown in Fig. 52.4.

If the analysis filter bank was able to *decorrelate* the signal completely, the output signal would be white. For all practical signals, complete decorrelation requires an infinite number of channels.

In the encoder the symbol $\downarrow N$ indicates decimation by a factor of N . By performing this decimation in each of the N channels, the total number of samples is conserved from the system input to decimator outputs. With the channel arrangement in Fig. 52.4, the decimation also serves as a *demodulator*. All channels will have a baseband representation in the frequency range $[0, \pi/N]$ after decimation.

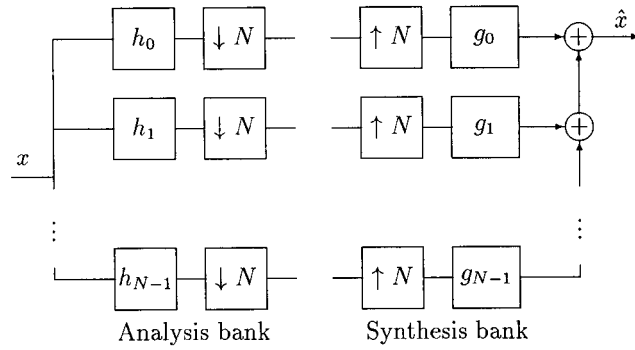

FIGURE 52.3: Subband coder system.

FIGURE 52.4: Ideal frequency partitioning in the analysis channel filters in a subband coder.

The synthesis filter bank, as shown in Fig. 52.3, consists of N branches with interpolators indicated by $\uparrow N$ and bandpass filters arranged as the filters in Fig. 52.4.

The reconstruction formula constitutes the following series expansion of the output signal:

$$\hat{x}(l) = \sum_{n=0}^{N-1} \sum_{k=-\infty}^{\infty} e_n(k) g_n(l - kN), \quad (52.9)$$

where $\{e_n(k), n = 0, 1, \dots, N-1, k = -\infty, \dots, -1, 0, 1, \dots, \infty\}$ are the expansion coefficients representing the quantized subband signals and $\{g_n(k), n = 0, 1, \dots, N\}$ are the basis functions, which are implemented as unit sample responses of bandpass filters.

Filter Bank Structures

Through the last two decades, an extensive literature on filter banks and filter bank structures has evolved. Perfect reconstruction (PR) is often considered desirable in subband coding systems. It is not a trivial task to design such systems due to the downsampling required to maintain a minimum sampling rate. PR filter banks are often called identity systems. Certain filter bank structures inherently guarantee PR.

It is beyond the scope of this chapter to give a comprehensive treatment of filter banks. We shall only present different alternative solutions at an overview level, and in detail discuss an important two-channel system with inherent perfect reconstruction properties.

We can distinguish between different filter banks based on several properties. In the following, five classifications are discussed.

1. FIR vs. IIR filters — Although IIR filters have an attractive complexity, their inherent long unit sample response and nonlinear phase are obstacles in image coding. The unit sample response length influences the *ringing problem*, which is a main source of

objectionable distortion in subband coders. The nonlinear phase makes the *edge mirroring technique* [30] for efficient coding of images near their borders impossible.

2. Uniform vs. nonuniform filter banks — This issue concerns the spectrum partitioning in frequency subbands. Currently it is the general conception that nonuniform filter banks perform better than uniform filter banks. There are two reasons for that. The first reason is that our visual system also performs a nonuniform partitioning, and the coder should mimic the type of receptor for which it is designed. The second reason is that the filter bank should be able to cope with slowly varying signals (correlation over a large region) as well as transients that are short and represent high frequency signals. Ideally, the filter banks should be adaptive (and good examples of adaptive filter banks have been demonstrated in the literature [2, 11]), but without adaptivity one filter bank has to be a good compromise between the two extreme cases cited above. Nonuniform filter banks can give the best tradeoff in terms of space-frequency resolution.
3. Parallel vs. tree-structured filter banks — The parallel filter banks are the most general, but tree-structured filter banks enjoy a large popularity, especially for octave band (dyadic frequency partitioning) filter banks as they are easily constructed and implemented. The popular subclass of filter banks denoted *wavelet filter banks* or *wavelet transforms* belong to this class. For octave band partitioning, the tree-structured filter banks are as general as the parallel filter banks when perfect reconstruction is required [4].
4. Linear phase vs. nonlinear phase filters — There is no general consensus about the optimality of linear phase. In fact, the traditional wavelet transforms cannot be made linear phase. There are, however, three indications that linear phase should be chosen. (1) The noise in the reconstructed image will be antisymmetrical around edges with nonlinear phase filters. This does not appear to be visually pleasing. (2) The mirror extension technique [30] cannot be used for nonlinear phase filters. (3) Practical coding gain optimizations have given better results for linear than nonlinear phase filters.
5. Unitary vs. nonunitary systems — A unitary filter bank has the same analysis and synthesis filters (except for a reversal of the unit sample responses in the synthesis filters with respect to the analysis filters to make the overall phase linear). Because the analysis and synthesis filters play different roles, it seems plausible that they, in fact, should not be equal. Also, the gain can be larger, as demonstrated in section 52.2.3, for nonunitary filter banks as long as straightforward scalar quantization is performed on the subbands.

Several other issues could be taken into consideration when optimizing a filter bank. These are, among others, the actual frequency partitioning including the number of bands, the length of the individual filters, and other design criteria than coding gain to alleviate coding artifacts, especially at low rates. As an example of the last requirement, it is important that the different phases in the reconstruction process generate the same noise; in other words, the noise should be stationary rather than cyclo-stationary. This may be guaranteed through requirements on the norms of the unit sample responses of the polyphase components [4].

The Two-Channel Lattice Structure

A versatile perfect reconstruction system can be built from two-channel substructures based on lattice filters [36]. The analysis filter bank is shown in Fig. 52.5. It consists of delay-free blocks given in matrix forms as

$$\eta = \begin{bmatrix} a & b \\ c & d \end{bmatrix}, \quad (52.10)$$

and single delays in the lower branch between each block. At the input, the signal is multiplexed into the two branches, which also constitutes the decimation in the analysis system.

FIGURE 52.5: Multistage two-channel lattice analysis lattice filter bank.

FIGURE 52.6: Multistage two-channel polyphase synthesis lattice filter bank.

A similar synthesis filter structure is shown in Fig. 52.6. In this case, the lattices are given by the inverse of the matrix in Eq. 52.10:

$$\eta^{-1} = \frac{1}{ad - bc} \begin{bmatrix} d & -b \\ -c & a \end{bmatrix}, \quad (52.11)$$

and the delays are in the upper branches. It is not hard to realize that the two systems are inverse systems provided $ad - bc \neq 0$, except for a system delay.

As the structure can be extended as much as wanted, the flexibility is good. The filters can be made unitary or they can have a linear phase. In the unitary case, the coefficients are related through $a = d = \cos \phi$ and $b = -c = \sin \phi$, whereas in the linear phase case, the coefficients are $a = d = 1$ and $b = c$. In the linear phase case, the last block (η_L) must be a *Hadamard* transform.

Tree Structured Filter Banks

In tree-structured filter banks, the signal is first split in two channels. The resulting outputs are input to a second stage with further separation. This process can go on as indicated in Fig. 52.7 for a system where at every stage the outputs are split further until the required resolution has been obtained.

Tree-structured systems have a rather high flexibility. Nonuniform filter banks are obtained by splitting only some of the outputs at each stage. To guarantee perfect reconstruction, each stage in the synthesis filter bank (Fig. 52.7) must reconstruct the input signal to the corresponding analysis filter.

52.2.3 Optimal Transforms/Filter Banks

The *gain* in subband and transform coders depends on the detailed construction of the filter bank as well as the quantization scheme.

Assume that the analysis filter bank unit sample responses are given by $\{h_n(k), n = 0, 1, \dots, N-1\}$. The corresponding unit sample responses of the synthesis filters are required to have unit norm:

$$\sum_{k=0}^{L-1} g_n^2(k) = 1.$$

FIGURE 52.7: Left: Tree structured analysis filter bank consisting of filter blocks where the signal is split in two and decimated by a factor of two to obtain critical sampling. Right: Corresponding synthesis filter bank for recombination and interpolation of the signals.

The coding gain of a subband coder is defined as the ratio between the noise using scalar quantization (PCM) and the subband coder noise incorporating optimal bit-allocation as explained in section 52.3:

$$G_{SBC} = \left[\prod_{n=0}^{N-1} \frac{\sigma_{x_n}^2}{\sigma_x^2} \right]^{-1/N} \quad (52.12)$$

Here σ_x^2 is the variance of the input signal while $\{\sigma_{x_n}^2, n = 0, 1, \dots, N-1\}$ are the subband variances given by

$$\sigma_{x_n}^2 = \sum_{l=-\infty}^{\infty} R_{xx}(l) \sum_{j=-\infty}^{\infty} h_n(j) h_n(l+j) \quad (52.13)$$

$$= \int_{-\pi}^{\pi} S_{xx}(e^{j\omega}) |H_n(e^{j\omega})|^2 \frac{d\omega}{2\pi} . \quad (52.14)$$

The subband variances depend both on the filters and the second order spectral information of the input signal.

For images, the gain is often estimated assuming that the image can be modeled as a first order Markov source (also called an AR(1) process) characterized by

$$R_{xx}(l) = \sigma_x^2 0.95^{|l|} . \quad (52.15)$$

(Strictly speaking, the model is valid only after removal of the image average).

We consider the maximum gain using this model for three special cases. The first is the transform coder performance, which is an important reference as all image and video coding standards are based on transform coding. The second is for unitary filter banks, for which optimality is reached by using ideal brick-wall filters. The third case is for nonunitary filter banks, often denoted *biorthogonal* when the perfect reconstruction property is guaranteed. In the nonunitary case, *halfwhitening* is obtained within each band. Mathematically this can be seen from the optimal magnitude response for the filter in channel n :

$$|H_n(e^{j\omega})| = \begin{cases} c_2 \left[\frac{S_{xx}(e^{j\omega})}{\sigma_x^2} \right]^{-1/4} & \text{for } \omega \in \left[\pm \frac{\pi n}{N}, \frac{\pi(n+1)}{N} \right] \\ 0 & \text{otherwise,} \end{cases} \quad (52.16)$$

where c_2 is a constant that can be selected for correct gain in each band.

The inverse operation must be performed in the synthesis filter to make completely flat responses within each band.

In Fig. 52.8, we give optimal coding gains as a function of the number of channels.

FIGURE 52.8: Maximum coding gain as function of the number of channels for different one-dimensional coders operating on a first order Markov source with one-delay correlation $\rho = 0.95$. Lower curve: Cosine transform. Middle curve: Unitary filter bank. Upper curve: Unconstrained filter bank. Nonunitary case.

52.2.4 Decomposition by Differential Coding

In *closed-loop differential* coding, the generic encoder structure (Fig. 52.1) is not valid as the quantizer is placed inside a feedback loop. The decoder, however, behaves according to the generic decoder structure. Basic block diagrams of a closed-loop differential encoder and the corresponding decoder are shown in Figs. 52.9(a) and (b), respectively.

In the encoder, the input signal x is represented by the bit-stream b . Q is the quantizer and Q^{-1} the dequantizer, but $Q Q^{-1} \neq 1$, except for the case of infinite resolution in the quantizer. The signal d , which is quantized and transmitted by some binary code, is the difference between the input signal and a predicted value of the input signal based on previous outputs and a prediction filter with transfer function $G(z) = 1/(1 - P(z))$. Notice that the decoder is a substructure of the encoder, and that $\tilde{x} = x$ in the limiting case of infinite quantizer resolution. The last property guarantees exact representation when discarding quantization.

Introducing the inverse z -transform of $G(z)$ as $g(l)$, the reconstruction is performed on the dequantized values as

$$\tilde{x}(l) = \sum_{k=0}^{\infty} e(k)g(l-k). \quad (52.17)$$

The output is thus a linear combination of unit sample responses excited by the sample amplitudes at different times and, can be viewed as a series expansion of the output signal. In this case, the basis

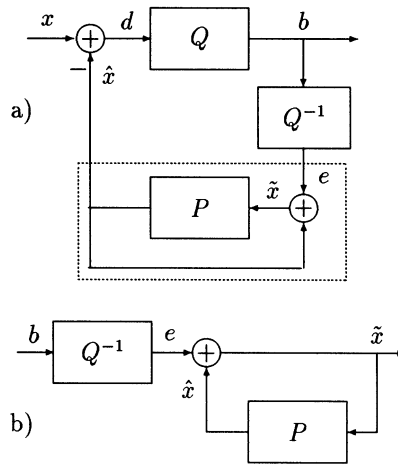

FIGURE 52.9: (a) DPCM encoder. (b) DPCM decoder.

functions are generated by shifts of a single basis function [the unit sample response $g(l)$] and the coefficients represent the coded difference signal $e(n)$.

With an adaptive filter the basis function will vary slowly, depending on some spectral modification derived from the incoming samples.

52.3 Quantization and Coding Strategies

Quantization is the means of providing approximations to signals and signal parameters by a finite number of representation levels. This process is nonreversible and thus always introduces noise. The representation levels constitute a finite alphabet which is usually represented by binary symbols, or *bits*. The mapping from symbols in a finite alphabet to bits is not unique. Some important techniques for quantization and coding will be reviewed next.

52.3.1 Scalar Quantization

The simplest quantizer is the *scalar* quantizer. It can be optimized to match the *probability density function* (*pdf*) of the input signal.

A *scalar* quantizer maps a continuous variable x to a finite set according to the rule

$$x \in R_i \quad \implies \quad Q[x] = y_i, \quad (52.18)$$

where $R_i = (x_i, x_{i+1})$, $i = 1, \dots, L$, are nonoverlapping, contiguous intervals covering the real line, and (\cdot, \cdot) denotes open, half open, or closed intervals. $\{y_i, i = 1, 2, \dots, L\}$ are referred to as *representation levels* or *reconstruction values*. The associated values $\{x_i\}$ defining the partition are referred to as *decision levels* or *decision thresholds*. Fig. 52.10 depicts the representation and decision levels.

FIGURE 52.10: Quantization notation.

In a *uniform* quantizer, all intervals are of the same length and the representation levels are the midpoints in each interval. Furthermore, in a *uniform threshold* quantizer, the decision levels form a uniform partitioning of the real line, while the representation levels are the *centroids* (see below) in each decision interval. Strictly speaking, uniform quantizers consist of an infinite number of intervals. In practice, the number of intervals is adapted to the dynamic range of the signal. All other quantizers are *non-uniform*.

The optimization task is to minimize the average *distortion* between the original samples and the appropriate representation levels given the number of levels. This is the so-called *pdf-optimized* quantizer. Allowing for variable rate per symbol, the *entropy constrained* quantizer can be used. These schemes are described in the following two subsections.

The Lloyd-Max Quantizer

The Lloyd-Max quantizer is a scalar quantizer where the 1st order signal pdf is exploited to increase the quantizer performance. It is therefore often referred to as a *pdf-optimized quantizer*. Each signal sample is quantized using the same number of bits. The optimization is done by minimizing the total distortion of a quantizer with a given number L of representation levels. For an input signal X with pdf $p_X(x)$, the average mean square distortion is

$$D = \sum_{i=1}^L \int_{x_i}^{x_{i+1}} (x - y_i)^2 p_X(x) dx . \quad (52.19)$$

Minimization of D leads to the following implicit expressions connecting the decision and representation levels:

$$x_{k,opt} = \frac{1}{2}(y_{k,opt} + y_{k-1,opt}), \quad k = 1, \dots, L-1 \quad (52.20)$$

$$x_{0,opt} = -\infty \quad (52.21)$$

$$x_{L,opt} = \infty \quad (52.22)$$

$$y_{k,opt} = \frac{\int_{x_{k,opt}}^{x_{k+1,opt}} x p_X(x) dx}{\int_{x_{k,opt}}^{x_{k+1,opt}} p_X(x) dx}, \quad k = 0, \dots, L-1 . \quad (52.23)$$

Equation 52.20 indicates that the decision levels should be the midpoints between neighboring representation levels, while Eq. 52.23 requires that the optimal representation levels are the *centroids* of the pdf in the appropriate interval.

The equations can be solved iteratively [21]. For high bit rates it is possible to derive approximate formulas assuming that the signal pdf is flat within each quantization interval [21].

In most practical situations the pdf is not known, and the optimization is based on a training set. This will be discussed in section 52.3.2.

Entropy Constrained Quantization

When minimizing the total distortion for a fixed number of possible representation levels, we have tacitly assumed that every signal sample is coded using the same number of bits: $\log_2 L$ bits/sample. If we allow for a variable number of bits for coding each sample, a further rate-distortion advantage is gained. The Lloyd-Max solution is then no longer optimal. A new optimization is needed, leading to the *entropy constrained quantizer*.

At high bit rates, the optimum is reached when using a uniform quantizer with an infinite number of levels. At low bit rates, uniform quantizers perform close to optimum provided the representation levels are selected as the centroids according to Eq. 52.23. The performance of the entropy constrained quantizer is significantly better than the performance of the Lloyd-Max quantizer [21].

A standard algorithm for assigning codewords of variable length to the representation levels was given by Huffman [12]. The Huffman code will minimize the average rate for a given set of probabilities and the resulting average bit rate will be close to the entropy bound. Even closer performance to the bound is obtained by *arithmetic coders* [32].

At high bit rates, scalar quantization on *statistically independent* samples renders a bit rate which is at least 0.255 bits/sample higher than the *rate distortion bound* irrespective of the signal pdf. Huffman coding of the quantizer output typically gives a somewhat higher rate.

52.3.2 Vector Quantization

Simultaneous quantization of several samples is referred to as *vector quantization* (VQ) [9], as mentioned in the introductory section. VQ is a generalization of scalar quantization:

A vector quantizer maps a continuous N -dimensional vector \mathbf{x} to a discrete-valued N -dimensional vector according to the rule

$$\mathbf{x} \in C_i \implies Q[\mathbf{x}] = \mathbf{y}_i, \quad (52.24)$$

where C_i is an N -dimensional cell. The L possible cells are nonoverlapping and contiguous and fill the entire geometric space. The vectors $\{\mathbf{y}_i\}$ correspond to the representation levels in a scalar quantizer. In a VQ setting the collection of representation levels is referred to as the *codebook*. The cells C_i , also called *Voronoi regions*, correspond to the decision regions, and can be thought of as solid polygons in the N -dimensional space.

In the scalar case, it is trivial to test if a signal sample belongs to a given interval. In VQ an indirect approach is utilized via a *fidelity criterion or distortion measure* $d(\cdot, \cdot)$:

$$Q[\mathbf{x}] = \mathbf{y}_i \iff d(\mathbf{x}, \mathbf{y}_i) \leq d(\mathbf{x}, \mathbf{y}_j), \quad j = 0, \dots, L-1. \quad (52.25)$$

When the best match, \mathbf{y}_i , has been found, the *index* i identifies that vector and is therefore coded as an efficient representation of the vector. The receiver can then reconstruct the vector \mathbf{y}_i by looking up the contents of cell number i in a copy of the codebook. Thus, the bit rate in bits per sample in this scheme is $\log_2 L/N$ when using straightforward bit-representation for i . A block diagram of vector quantization is shown in Fig. 52.11.

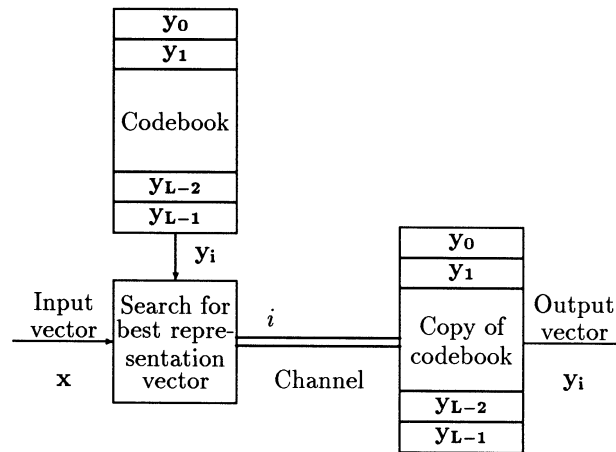

FIGURE 52.11: Vector quantization procedure.

In the previous section we stated that scalar entropy coding was sub-optimal, even for sources producing independent samples. The reason for the sub-optimal performance of the entropy constrained quantizer is a phenomenon called *sphere packing*. In addition to obtaining good sphere packing, a VQ scheme also exploits both correlation and higher order statistical dependencies of a signal. The higher order statistical dependency can be thought of as “a preference for certain vectors”. Excellent examples of sphere packing and higher order statistical dependencies can be found in [28].

In principle, the codebook design is based on the N -dimensional pdf. But as the pdf is usually not known, the codebook is optimized from a training data set. This set consists of a large number of vectors that are representative for the signal source. A sub-optimal codebook can then be designed using an iterative algorithm, for example the *K-means* or *LBG* algorithm [25].

Multistage Vector Quantization

To alleviate the complexity problems of vector quantization, several methods have been suggested. They all introduce some structure into the codebook which makes fast search possible. Some systems also reduce storage requirements, like the one we present in this subsection. The obtainable performance is always reduced, but the performance in an implementable coder can be improved.

Fig. 52.12 illustrates the encoder structure.

FIGURE 52.12: K -stage VQ encoder structure showing the successive approximation of the signal vector.

The first block in the encoder makes a rough approximation to the input vector by selecting the codebook vector which, upon scaling by e_1 , is closest in some distortion measure. Then this approximation is subtracted from the input signal. In the second stage, the difference signal is approximated by a vector from the second codebook scaled by e_2 . This procedure continues in K stages, and can be thought of as a successive approximation to the input vector. The indices $\{i(k), k = 1, 2, \dots, K\}$ are transmitted as part of the code for the particular vector under consideration.

Compared to unstructured VQ, this method is suboptimal but has a much lower complexity than the optimal case due to the small codebooks that can be used.

A special case is the *mean-gain-shape VQ* [9], where one stage only is kept, but in addition the mean is represented separately.

In all multistage VQs, the code consists of the codebook address and codes for the quantized versions of the scaling coefficients.

52.3.3 Efficient Use of Bit-Resources

Assume we have a signal that can be split in classes with different statistics. As an example, after applying signal decomposition, the different transform coefficients typically have different variances. Assume also that we have a pool of bits to be used for representing a collection of signal vectors from the different classes, or we try to minimize the number of bits to be used after all signals have been quantized. These two situations are described below.

Bit Allocation

Assume that a signal consists of N components $\{x_i, i = 1, 2, \dots, N\}$ forming a vector \mathbf{x} where the variance of component number i is equal to $\sigma_{x_i}^2$ and all components are zero mean.

We want to quantize the vector \mathbf{x} using scalar quantization on each of the components and minimize the total distortion with the only constraint that the total number of bits to be used for the whole vector be fixed and equal to B . Denoting the quantized signal components $Q_i(x_i)$, the average distortion per component can be written as

$$D_{DS} = \frac{1}{N} \sum_{i=1}^N E[x_i - Q_i(x_i)]^2 = \frac{1}{N} \sum_{i=1}^N D_i, \quad (52.26)$$

where $E[\cdot]$ is the expectation operator, and the subscript DS stands for *decomposed source*.

The bit-constraint is given by

$$B = \sum_{i=1}^N b_i, \quad (52.27)$$

where b_i is the number of bits used to quantize component number i .

Minimizing D_{DS} with Eq. 52.27 as a constraint, we obtain the following bit assignment

$$b_j = \frac{B}{N} + \frac{1}{2} \log_2 \frac{\sigma_{x_j}^2}{\left[\prod_{n=1}^N \sigma_{x_n}^2 \right]^{1/N}}. \quad (52.28)$$

This formula will in general render noninteger and even negative values of the bit count. So-called “greedy” algorithms can be used to avoid this problem.

To evaluate the coder performance, we use *coding gain*. It is defined as the distortion advantage of the component-wise quantization over a direct scalar quantization at the same rate. For the example at hand, the coding gain is found to be

$$G_{DS} = \frac{\frac{1}{N} \sum_{j=1}^N \sigma_{x_j}^2}{\left(\prod_{j=1}^N \sigma_{x_j}^2 \right)^{1/N}}. \quad (52.29)$$

The gain is equal to the ratio between the arithmetic mean and the geometric mean of the component variances. The minimum value of the variance ratio is equal to 1 when all the component variances are equal. Otherwise, the gain is larger than one. Using the optimal bit allocation, the noise contribution is equal in all components.

If we assume that the different components are obtained by passing the signal through a bank of bandpass filters, then the variance from one band is given by the integral of the power spectral density over that band. If the process is non-white, the variances are more different the more colored the original spectrum is. The maximum possible gain is obtained when the number of bands tends to infinity [21]. Then the gain is equal to the maximum gain of a differential coder which again is inversely proportional to the *spectral flatness measure* [21] given by

$$\gamma_x^2 = \frac{\exp\left[\int_{-\pi}^{\pi} \ln S_{xx}(e^{j\omega}) \frac{d\omega}{2\pi}\right]}{\int_{-\pi}^{\pi} S_{xx}(e^{j\omega}) \frac{d\omega}{2\pi}}, \quad (52.30)$$

where $S_{xx}(e^{j\omega})$ is the spectral density of the input signal. In both subband coding and differential coding, the complexity of the systems must approach infinity to reach the coding gain limit.

To be able to apply bit allocation dynamically to non-stationary sources, the decoder must receive information about the local bit allocation. This can be done either by transmitting the bit allocation

table, or the variances from which the bit allocation was derived. For real images where the statistics vary rapidly, the cost of transmitting the side information may become costly, especially for low rate coders.

Rate Allocation

Assume we have the same signal collection as above. This time we want to minimize the number of bits to be used after the signal components have been quantized. The first order entropy of the decomposed source will be selected as the measure for the obtainable minimum bit-rate when scalar representation is specified.

To simplify, assume all signal components are Gaussian. The entropy of a Gaussian source with zero mean and variance σ_x^2 and statistically independent samples quantized by a uniform quantizer with quantization interval Δ can, for high rates, be approximated by

$$H_G(X) = \frac{1}{2} \log_2(2\pi e(\sigma_x/\Delta)^2) . \quad (52.31)$$

The rate difference [24] between direct scalar quantization of the signal collection using one entropy coder and the rate when using an adapted entropy coder for each component is

$$\Delta H = H_{PCM} - H_{DS} = \frac{1}{2} \log_2 \frac{\sigma_x^2}{[\prod_{i=1}^N \sigma_{x_i}^2]^{1/N}} , \quad (52.32)$$

provided the decomposition is power conserving, meaning that

$$\sigma_x^2 = \sum_{i=1}^N \sigma_{x_i}^2 . \quad (52.33)$$

The coding gain in Eq. 52.29 and the rate gain in Eq. 52.32 are equivalent for Gaussian sources.

In order to exploit this result in conjunction with signal decomposition, we can view each output component as a stationary source, each with different signal statistics. The variances will depend on the spectrum of the input signal. From Eq. 52.32 and Eq. 52.33 we see that the rate difference is larger the more different the channel variances are.

To obtain the rate gain indicated by Eq. 52.32, different *Huffman* or *arithmetic* coders [9] adapted to the rate given in Eq. 52.31 must be employed. In practice, a pool of such coders should be generated and stored. During encoding, the closest fitting coder is chosen for each block of components. An index indicating which coder was used is transmitted as side information to enable the decoder to reinterpret the received code.

52.4 Frequency Domain Coders

In this section we present the JPEG standard and some of the best subband coders that have been presented in the literature.

52.4.1 The JPEG Standard

The JPEG coder [37] is the only internationally standardized still image coding method. Presently there is an international effort to bring forth a new, improved standard under the title JPEG2000.

The principle can be sketched as follows: First, the image is decomposed using a two-dimensional cosine transform of size 8×8 . Then, the transform coefficients are arranged in an 8×8 matrix as given in Fig. 52.13, where i and j are the horizontal and vertical frequency indices, respectively.

A vector is formed by a scanning sequence which is chosen to make large amplitudes, on average, appear first, and smaller amplitudes at the end of the scan. In this arrangement, the samples at the end of the scan string approach zero. The scan vector is quantized in a non-uniform scalar quantizer with characteristics as depicted in Fig. 52.14.

FIGURE 52.13: Zig-zag scanning of the coefficient matrix.

FIGURE 52.14: Non-uniform quantizer characteristic obtained by combining a midtread uniform quantizer and a thresholder. Δ is the quantization interval and T is the threshold.

Due to the thresholder, many of the trailing coefficients in the scan vector are set to zero. Often the zero values appear in clusters. This property is exploited by using *runlength coding*, which basically amounts to finding zero-runs. After runlength coding, each run is represented by a *number pair* (a, r) where the number a is the amplitude and r is the length of the run. Finally, the number pair is entropy coded using the Huffman method, or arithmetic coding.

The thresholding will increase the distortion and lower the entropy both with and without decom-

position, although not necessarily with the same amounts.

As can be observed from Fig. 52.13, the coefficient in position (0,0) is not part of the string. This coefficient represents the block average. After collecting all block averages in one image, this image is coded using a DPCM scheme [37].

Coding results for three images are given in Fig. 52.16.

52.4.2 Improved Coders: State-of-the-Art

Many coders that outperform JPEG have been presented in the scientific literature. Most of these are based on subband decomposition (or the special case: wavelet decomposition). Subband coders have a higher potential coding gain by using filter banks rather than transforms, and thus exploiting correlations over larger image areas. Figure 52.8 shows the theoretical gain for a stochastic image model. Visually, subband coders can avoid the blocking-effects experienced in transform coders at low bit-rates. This property is due to the overlap in basis functions in subband coders. On the other hand, Gibb's phenomenon is more prevalent in subband coders and can cause severe ringing in homogeneous areas close to edges. The detailed choice and optimization of the filter bank will strongly influence the visual performance of subband coders. The other factor which decides the coding quality is the detailed quantization of the subband signals. The final bit-representation method does not effect the quality, only the rate for a given quality.

Depending on the bit-representation, the total rate can be preset for some coders, and will depend on some quality factor specified for other coders. Even though it would be desirable to preset the visual quality in a coder, this is a challenging task, which has not yet been satisfactorily solved.

In the following we present four subband coders with different coding schemes and different filter banks.

Subband Coder Based on Entropy Coder Allocation [24]

This coder uses an 8×8 uniform filter bank optimized for reducing blocking and ringing artifacts, plus maximizing the coding gain [1]. The lowpass-lowpass band is quantized using a fixed rate DPCM coder with a third-order two-dimensional predictor. The other subband signals are segmented into blocks of size 4×4 , and each block is classified based on the block power. Depending on the block power, each block is allocated a corresponding entropy coder (implemented as an arithmetic coder). The entropy coders have been preoptimized by minimizing the first-order entropy given the number of available entropy coders (See section 52.3.3). This number is selected to balance the amount of side information necessary in the decoder to identify the correct entropy decoder and the gain by using more entropy coders. Depending on the bit-rate, the number of entropy coders is typically 3 to 5. In the presented results, three arithmetic coders are used. Conditional arithmetic coding has been used to represent the side information efficiently.

Coding results are presented in Fig. 52.16 under the name "Lervik".

Zero-Tree Coding

Shapiro [35] introduced a method that exploits some dependency between pixels in corresponding location in the bands of an octave band filter bank. The basic assumed dependencies are illustrated in Fig. 52.15. The low-pass band is coded separately. Starting in any location in any of the other three bands of same size, any pixel will have an increasing number of *descendants* as one passes down the tree representing information from the same location in the original image. The number of corresponding pixels increases by a factor of four from one level to the next. When used in a coding context, the tree is terminated at any zero-valued pixel (obtained after quantization using some threshold) after which all subsequent pixels are assumed to be zero as well. Due to the growth by a factor of four between levels, many samples can be discarded this way.

FIGURE 52.15: Zero-tree arrangement in an octave-band decomposed image.

What is the underlying mechanism that makes this technique work so well? On one hand, the image spectrum falls off rapidly as a function of frequency for most images. This means that there is a tendency to have many zeros when approaching the leaves of the tree. Our visual system is furthermore more tolerant to high frequency errors. This should be compared to the zig-zag scan in the JPEG coder. On the other hand, viewed from a pure statistical angle, the subbands are uncorrelated if the filter bank has done what is required from it! However, the statistical argument is based on the assumption of “local ergodicity”, which means that statistical parameters derived locally from the data have the same mean values everywhere. With real images composed of objects with edges, textures, etc. these assumptions do not hold. The “activity” in the subbands tends to appear in the same locations. This is typical at edges. One can look at these connections as energy correlations among the subbands. The zero-tree method will efficiently cope with these types of phenomena.

Shapiro furthermore combined the zero-tree representation with bit-plane coding. Said [34] went one step further and introduced what he calls *set partitioning*. The resulting algorithm is simple and fast, and is embedded in the sense that the bit-stream can be cut off at any point in time in the decoder, and the obtained approximation is optimal using that number of bits. The subbands are obtained using the 9/7 biorthogonal spline filters [38].

Coding results from Said’s coder are shown in Fig. 52.16 and marked “Said”.

Pyramid VQ and Improved Filter Bank

This coder is based on bit-allocation, or rather, allocation of vector quantizers of different sizes. This implies that the coder is fixed rate, that is, we can preset the total number of bits for an image. It is assumed that the subband signals have a Laplacian distribution, which makes it possible to apply *pyramid* vector quantizers [6]. These are suboptimal compared to trained codebook vector quantizers, but significantly better than scalar quantizers without increasing the complexity too much.

The signal decomposition in the encoder is performed using an 8×8 channel uniform filter bank [1], followed by an octave-band filter bank of three stages operating on the resulting lowpass-lowpass band. The uniform filter bank is nonunitary and optimized for coding gain. The building blocks of the octave band filter bank have been carefully selected from all available perfect reconstruction, two-channel filter systems with limited FIR filter orders.

Coding results from this coder are shown in Figs. 52.16 and are marked “Balasingham”.

Trellis Coded Quantization

Joshi [22] has presented what is presently the “state-of-the-art” coder. Being based on trellis coded quantization [29], the encoder is more complex than the other coders presented. Furthermore, it does not have the embedded character of Said’s coder.

The filter bank employed has 22 subbands. This is obtained by first employing a 4×4 uniform filter bank, followed by a further split of the resulting lowpass-lowpass band using a two-stage octave band filter bank. All filters in the curves shown in the next section are 9/7 biorthogonal spline filters [38].

The encoding of the subbands is performed in several stages:

- Separate classification of signal blocks in each band.
- Rate allocation among all blocks.
- Individual arithmetic coding of the trellis-coded quantized signals in each class.

The trellis coded quantization [7] is a method that can reach the rate distortion bound in the same way as vector quantization. It uses search methods in the encoder, which adds to its complexity. The decoder is much simpler.

Coding results from this coder are shown in Fig. 52.16 and are marked “Joshi”.

Frequency Domain Coding Results

The five coders presented above are compared in this section. All of them are simulated using the three images “Lenna”, “Barbara”, and “Goldhill” of size 512×512 . These three images have quite different contents in terms of spectrum, textures, edges, and so on. Fig. 52.16 shows the PSNR as a function of bit-rate for the five coders. The PSNR is defined as

$$\text{PSNR} = 10 \log_{10} \left(\frac{255^2}{\frac{1}{NM} \sum_{n=1}^N \sum_{m=1}^M (x(n, m) - \hat{x}(n, m))^2} \right). \quad (52.34)$$

As is observed, the coding quality among the coders varies when exposed to such different stimuli. The exception is that all subband coders are superior to JPEG, which was expected from the use of better decomposition as well as more clever quantization and coding strategies. Joshi’s coder is best for “Lenna” and “Goldhill” at high rates. Balasingham’s coder is, however, better for “Barbara” and for “Goldhill” at low rates. These results are interpreted as follows. The Joshi coder uses the most elaborate quantization/coding scheme, but the Balasingham coder applies a better filter bank in two respects. First, it has better high frequency resolution, which explains that the “Barbara” image, with a relatively high frequency content, gives a better result for the latter coder. Second, the improved low frequency resolution of this filter bank also implies better coding at low rates for “Goldhill”.

From the results above, it is also observed that the Joshi coder performs well for images with a lowpass character such as the “Lenna” image, especially at low rates. In these cases there are many “zeros” to be represented, and the zero-tree coding can typically cope well with zero-representations.

A combination of several of the aforementioned coders, picking up their best components, would probably render an improved system.

52.5 Fractal Coding

This section is placed towards the end of the chapter because fractal coding deviates in many respects from the generic coder on the one hand, but on the other hand can be compared to vector quantization.

FIGURE 52.16: Coding results. Top: “Lenna”, middle: “Barbara”, bottom: “Goldhill”.

A good overview of the field can be found in [8].

Fractal coding (also called attractor coding) is based on *Banach's fixed point theorem* and exploits *self-similarity* or *partial self-similarity* among different scales of a given image. A nonlinear transform gives the fractal image representation. Iterative operations using this transform starting from any initial image will converge to the image approximation, called the *attractor*. The success of such a scheme will rest upon the compactness, in terms of bits, of the description of the nonlinear transform. A classical example of self-similarity is Michael Barnsley's fern, where each branch is a small copy of the complete fern. Even the branches are composed of small copies of itself. A very compact description can be found for the class of images exhibiting self similarity. In fact, the fern can be described by 24 numbers, according to Barnsley.

Self-similarity is a dependency among image elements (possibly objects) that is not described by correlation, but can be called affine correlation.

There is an enormous potential for image compression if images really have the self-similarity property. However, there seems to be no reason to believe that global self-similarity exists in any complex image created, e.g., by photographing natural or man-made scenes. The less requiring notion of partial self-similarity among image blocks of different scales has proven to be fruitful [19].

In this section we will, in fact, present a practical fractal coder exploiting partial self-similarity among different scales, which can be directly compared to mean-gain-shape vector quantization (MGSVQ). The difference between the two systems is that the vector quantizer uses an optimized codebook based on data from a large collection of different images, whereas the fractal coder uses a *self codebook*, in the sense that the codebook is generated from the image itself and implicitly and approximately transmitted to the receiver as part of the image code. The question is then, "Is the 'adaptive' nature of the fractal codebook better than the statistically optimized codebook of standard vector quantization?"

We will also comment on other models and give a brief status of fractal compression techniques.

52.5.1 Mathematical Background

The code of an image in the language of fractal coding is given as the bit-representation of a nonlinear transform T . The transform defines what is called the *collage* x_c of the image. The collage is found by

$$x_c = Tx ,$$

where x is the original image.

The collage is the object we try to make resemble the image as closely as possible in the encoder through minimization of the distortion function

$$D = d(x, x_c) . \quad (52.35)$$

Usually the distortion function is chosen as the Euclidean distance between the two vectors. The decoder cannot reconstruct the collage as it depends on the knowledge of the original image, and not only the transform T . We therefore have to accept reconstruction of the image with less accuracy.

The reconstruction algorithm is based on *Banach's fixed point theorem*: If a transform T is *contractive* or *eventually contractive* [26], the fixed point theorem states that the transform then has a unique *attractor* or *fixed point* given by

$$x_T = Tx_T , \quad (52.36)$$

and that the fixed point can be approached by iteration from any starting vector according to

$$x_T = \lim_{n \rightarrow \infty} T^n y; \quad \forall y \in X , \quad (52.37)$$

where X is a normed linear space.

The similarity between the collage and the attractor is indicated from an extended version of the collage theorem [27]:

Given an original image x and its collage Tx where $\|x - Tx\| \leq \epsilon$, then

$$\|x - x_T\| \leq \frac{1 - s_1^K}{(1 - s_1)(1 - s_K)} \epsilon \quad (52.38)$$

where s_1 and s_K are the Lipschitz constants of T and T^K , respectively, provided $|s_1| < 1$ and $|s_K| < 1$.

Provided the collage is a good approximation of the original image and the Lipschitz constants are small enough, there will also be similarity between the original image and the attractor.

In the special case of *fractal block coding*, a given image block (usually called a *domain block*) is supposed to resemble another block (usually called a *range block*) after some *affine transformation*. The transformation that is most commonly used moves the image block to a different position while shrinking the block, rotating it or shuffling the pixels, and adding what we denote a *fixed term*, which could be some predefined function with possible parameters to be decided in the encoding process. In most natural images it is not difficult to find affine similarity, e.g., in the form of objects situated at different distances and positions in relation to the camera. In standard block coding methods, only local statistical dependencies can be utilized. The inclusion of *affine redundancies* should therefore offer some extra advantage.

In this formalism we do not see much resemblance with VQ. However, the similarities and differences between fractal coding and VQ were pointed out already in the original work by Jacquin [20]. We shall, in the following section, present a specific model that enforces further similarity to VQ.

52.5.2 Mean-Gain-Shape Attractor Coding

It has been proven [31] that in all cases where each domain block is a union of range blocks, the decoding algorithms for sampled images where the nonlinear part (fixed term) of the transform is orthogonal to the image transformed by the linear part, full convergence is reached after a finite and small number of iterations. In one special case there are no iterations at all [31], and then $x_T = Tx$. We shall discuss only this important case here because it has an important application potential due to its simplicity in the decoder, but, more importantly, we can more clearly demonstrate the similarity to VQ.

Codebook Formation

In the encoder two tasks have to be performed, the codebook formation and the codebook search, to find the best representation of the transform T with as few bits as possible.

First the image is split in non-overlapping blocks of size $L \times L$ so that the complete image is covered.

The codebook construction goes as follows:

- Calculate the mean value m in each block.
- Quantize the mean values, resulting in the approximation \hat{m} , and transmit their code to the receiver.

These values will serve two purposes:

1. They are the additive, nonlinear terms in the block transform.
2. They are the building elements for the codebook.

All the following steps must be performed both in the encoder and the decoder.

- Organize the quantized mean values as an image so that it becomes a block averaged and downsampled version of the original image.
- Pick blocks of size $L \times L$ in the obtained image. Overlap between blocks is possible.
- Remove the mean values from each block. The resulting blocks constitute part of the codebook.
- Generate new codebook vectors by a predetermined set of mathematical operations (mainly pixel shuffling).

With the procedure given, the codebook is explicitly known in the decoder, because the mean values also act as the nonlinear part of the affine transforms. The codebook vectors are orthogonal to the nonlinear term due to the mean value removal.

Observe also that the block decimation in the encoder must now be chosen as $L \times L$, which is also the size of the blocks to be coded.

The Encoder

The actual encoding is similar to traditional product code VQ.

In our particular case, the image block in position (k, l) is modeled as

$$\hat{x}_{k,l} = \hat{m}_{k,l} + \hat{\alpha}_{k,l} \rho^{(i)} , \quad (52.39)$$

where $\hat{m}_{k,l}$ is the quantized mean value of the block, $\rho^{(i)}$ is codebook vector number i , and $\hat{\alpha}_{k,l}$ is a quantized scaling factor.

To optimize the parameters, we minimize the Euclidean distance between the image block and the given approximation,

$$d = \|x_{k,l} - \hat{x}_{k,l}\| . \quad (52.40)$$

This minimization is equivalent to the maximization of

$$P^{(i)} = \frac{\langle x_{k,l}, \rho^{(i)} \rangle^2}{\|\rho^{(i)}\|^2} , \quad (52.41)$$

where $\langle u, v \rangle$ denotes the inner product between u and v over one block. If vector number j maximizes P , then the scaling factor can be calculated as

$$\alpha_{k,l} = \frac{\langle x_{k,l}, \rho^{(j)} \rangle}{\|\rho^{(j)}\|^2} . \quad (52.42)$$

The Decoder

In the decoder, the codebook can be regenerated, as previously described, from the mean values. The decoder reconstructs each block according to Eq. 52.39 using the transmitted, quantized parameters. In the particular case given above, the following procedure is followed:

Denote by c an image composed of subblocks of size $L \times L$ which contains the correct mean values. The decoding is then performed by

$$x_1 = Tc = Ac + c , \quad (52.43)$$

where A is the linear part of the transform. The operation of A can be described blockwise.

- It takes a block from c of size $L^2 \times L^2$,
- shrinks it to size $L \times L$ after averaging over subblocks of size $L \times L$,
- subtracts from the resulting block its mean value,

- performs the prescribed pixel shuffling,
- multiplies by the scaling coefficient,
- and finally inserts the resulting block in the correct position.

Notice that x_1 has the correct mean value due to c , and because Ac does not contribute to the block mean values. Another observation is that each block of size $L \times L$ is mapped to one pixel.

The algorithm just described is equivalent to the VQ decoding given earlier.

The iterative algorithm indicated by Banach's fixed point theorem can be used also in this case. The above described algorithm is the first iteration. In the next iteration we get

$$x_2 = Ax_1 + c = A(Ac) + Ac + c. \quad (52.44)$$

But $A(Ac) = 0$ because A and Ac are orthogonal, therefore $x_2 = x_1$. The iteration can, of course, be continued without changing the result. Note also that $Ac = Ax$, where x is the original image!

We will stress the important fact that as the attractor and the collage are equivalent in the noniterative case, we have direct control of the attractor, unlike any other fractal coding method.

Experimental Comparisons with the Performance of MSGVQ

It is difficult to conclude from theory alone as to the performance of the attractor coder model. Experiments indicate, however, that for this particular fractal coder the performance is always worse than for the VQ with optimized codebook for all images tested [23]. The adaptivity of the *self codebook*, does not seem to outcompete the VQ codebook which is optimal in a statistical sense.

52.5.3 Discussion

The above model is severely constrained through the required relation between the block size ($L \times L$) and the decimation factor (also $L \times L$). Better coding results are obtained by using smaller decimation factors, typically 2×2 .

Even with small decimation factors, no pure fractal coding technique has, in general, been shown to outperform vector quantization of similar complexity.

However, fractal methods have potential in hybrid block coding. It can efficiently represent edges and other deterministic structures where a shrunk version of another block is likely to resemble the block we are trying to represent. For instance, edges tend to be edges also after decimation. On the other hand, many textures can be hard to represent, as the decimation process requires that another texture with different frequency contents be present in the image to make a good approximation.

Using several block coding methods, where for each block the best method in a distortion-rate sense is selected, has been proven to give good coding performance [5, 10].

On the practical side, the fractal encoders have a very high complexity. Several methods have been suggested to alleviate this problem. These methods include limited search regions in the vicinity of the block to be coded, clustering of codebook vectors, and hierarchical search at different resolutions.

The iteration-free decoder is one of the fastest decoders obtainable for any coding method.

52.6 Color Coding

Any color image can be split in three color components and thereafter coded individually for each component. If this is done on the RGB (Red, Green, Blue) components, the bit rate tends to be approximately three times as high as for black and white images.

However, there are many other ways of decomposing the colors. The most used representations split the image in a *luminance* component and two *chrominance* components. Examples are so-called YUV and YIQ representations. One rationale for doing this kind of splitting is that the human visual

system has different resolution for luminance and chrominance. The chrominance sampling can therefore be performed at a lower resolution, from two to eight times lower resolution depending on the desired quality and the interpolation method used to reconstruct the image. A second rationale is that the RGB components in most images are strongly correlated and therefore direct coding of the RGB components results in repeated coding of the same information. The luminance/chrominance representations try to decorrelate the components.

The transform between RGB and the luminance and chrominance components (YIQ) used in NTSC is given by

$$\begin{bmatrix} Y \\ I \\ Q \end{bmatrix} = \begin{bmatrix} 0.299 & 0.587 & 0.114 \\ 0.596 & -0.274 & -0.322 \\ 0.058 & -0.523 & 0.896 \end{bmatrix} \begin{bmatrix} R \\ G \\ B \end{bmatrix}. \quad (52.45)$$

There are only minor differences between the suggested color transforms. It is also possible to design the optimal decomposition based on the Karhunen-Loève transform. The method could be made adaptive by deriving a new transform for each image based on an estimated color correlation matrix.

We shall not go further into the color coding problem, but state that it is possible to represent color by adding 10 to 20% to the luminance component bit rate.

53.1 Introduction

Digital images and video, acquired by still cameras, consumer camcorders, or even broadcast-quality video cameras, are usually degraded by some amount of blur and noise. In addition, most electronic cameras have limited spatial resolution determined by the characteristics of the sensor array. Common causes of blur are out-of-focus, relative motion, and atmospheric turbulence. Noise sources include film grain, thermal, electronic, and quantization noise. Further, many image sensors and media have known nonlinear input-output characteristics which can be represented as point nonlinearities. The goal of image and video (image sequence) restoration is to estimate each image (frame or field) as it would appear without any degradations, by first modeling the degradation process, and then applying an inverse procedure. This is distinct from image enhancement techniques which are designed to manipulate an image in order to produce more pleasing results to an observer without making use of particular degradation models. On the other hand, superresolution refers to estimating an image at a resolution higher than that of the imaging sensor. Image sequence filtering (restoration and superresolution) becomes especially important when still images from video are desired. This is because the blur and noise can become rather objectionable when observing a “freeze-frame”, although they may not be visible to the human eye at the usual frame rates. Since many video signals encountered in practice are interlaced, we address the cases of both progressive and interlaced video.

The problem of image restoration has sparked widespread interest in the signal processing community over the past 20 or 30 years. Because image restoration is essentially an ill-posed inverse problem which is also frequently encountered in various other disciplines such as geophysics, astronomy, medical imaging, and computer vision, the literature that is related to image restoration is abundant. A concise discussion of early results can be found in the books by Andrews and Hunt [1] and Gonzalez and Woods [2]. More recent developments are summarized in the book by Katsaggelos [3], and review papers by Meinel [4], Demoment [5], Sezan and Tekalp [6], and Kaufman and Tekalp [7]. Most recently, printing high-quality still images from video sources has become an important application for multi-frame restoration and superresolution methods. An in-depth coverage of video filtering methods can be found in the book *Digital Video Processing* by Tekalp [8]. This chapter summarizes key results in digital image and video restoration.

53.2 Modeling

Every image restoration/superresolution algorithm is based on an observation model, which relates the observed degraded image(s) to the desired “ideal” image, and possibly a regularization model, which conveys the available *a priori* information about the ideal image. The success of image restoration and/or superresolution depends on how good the assumed mathematical models fit the actual application.

53.2.1 Intra-Frame Observation Model

Let the observed and ideal images be sampled on the same 2-D lattice Λ . Then, the observed blurred and noisy image can be modeled as

$$\mathbf{g} = s(\mathbf{D}\mathbf{f}) + \mathbf{v} \quad (53.1)$$

where \mathbf{g} , \mathbf{f} , and \mathbf{v} denote vectors representing lexicographical ordering of the samples of the observed image, ideal image, and a particular realization of the additive (random) noise process, respectively. The operator \mathbf{D} is called the blur operator. The response of the image sensor to light intensity is represented by the memoryless mapping $s(\cdot)$, which is, in general, nonlinear. (This nonlinearity has often been ignored in the literature for algorithm development.)

The blur may be space-invariant or space-variant. For space-invariant blurs, \mathbf{D} becomes a convolution operator, which has block-Toeplitz structure; and Eq. (53.1) can be expressed, in scalar form, as

$$g(n_1, n_2) = s \left(\sum_{(m_1, m_2) \in \mathcal{S}_d} d(m_1, m_2) f(n_1 - m_1, n_2 - m_2) \right) + v(n_1, n_2) \quad (53.2)$$

where $d(m_1, m_2)$ and \mathcal{S}_d denote the kernel and support of the operator \mathbf{D} , respectively. The kernel $d(m_1, m_2)$ is the impulse response of the blurring system, often called the point spread function (PSF). In case of space-variant blurs, the operator \mathbf{D} does not have a particular structure; and the observation equation can be expressed as a superposition summation

$$g(n_1, n_2) = s \left(\sum_{(m_1, m_2) \in \mathcal{S}_d(n_1, n_2)} d(n_1, n_2; m_1, m_2) f(m_1, m_2) \right) + v(n_1, n_2) \quad (53.3)$$

where $\mathcal{S}_d(n_1, n_2)$ denotes the support of the PSF at the pixel location (n_1, n_2) .

The noise is usually approximated by a zero-mean, white Gaussian random field which is additive and independent of the image signal. In fact, it has been generally accepted that more sophisticated noise models do not, in general, lead to significantly improved restorations.

53.2.2 Multispectral Observation Model

Multispectral images refer to image data with multiple spectral bands that exhibit inter-band correlations. An important class of multispectral images are color images with three spectral bands. Suppose we have K spectral bands, each blurred by possibly a different PSF. Then, the vector-matrix model (53.1) can be extended to multispectral modeling as

$$\mathbf{g} = \mathcal{D}\mathbf{f} + \mathbf{v} \quad (53.4)$$

where

$$\mathbf{g} \doteq \begin{bmatrix} \mathbf{g}_1 \\ \vdots \\ \mathbf{g}_K \end{bmatrix}, \quad \mathbf{f} \doteq \begin{bmatrix} \mathbf{f}_1 \\ \vdots \\ \mathbf{f}_K \end{bmatrix}, \quad \mathbf{v} \doteq \begin{bmatrix} \mathbf{v}_1 \\ \vdots \\ \mathbf{v}_K \end{bmatrix}$$

denote $N^2K \times 1$ vectors representing the multispectral observed, ideal, and noise data, respectively, stacked as composite vectors, and

$$\mathcal{D} \doteq \begin{bmatrix} \mathbf{D}_{11} & \cdots & \mathbf{D}_{1K} \\ \vdots & \ddots & \vdots \\ \mathbf{D}_{K1} & \cdots & \mathbf{D}_{KK} \end{bmatrix}$$

is an $N^2K \times N^2K$ matrix representing the multispectral blur operator. In most applications, \mathcal{D} is block diagonal, indicating no inter-band blurring.

53.2.3 Multiframe Observation Model

Suppose a sequence of blurred and noisy images $g_k(n_1, n_2)$, $k = 1, \dots, L$, corresponding to multiple shots (from different angles) of a static scene sampled on a 2-D lattice or frames (fields) of video sampled (at different times) on a 3-D progressive (interlaced) lattice, is available. Then, we may be able to estimate a higher-resolution “ideal” still image $f(m_1, m_2)$ (corresponding to one of the observed frames) sampled on a lattice, which has a higher sampling density than that of the input lattice. The main distinction between the multispectral and multiframe observation models is that here the observed images are subject to sub-pixel shifts (motion), possibly space-varying, which makes high-resolution reconstruction possible. In the case of video, we may also model blurring due to motion within the aperture time to further sharpen images.

To this effect, each observed image (frame or field) can be related to the desired high-resolution ideal still-image through the superposition summation [8]

$$g_k(n_1, n_2) = s \left(\sum_{(m_1, m_2) \in \mathcal{S}_d(n_1, n_2; k)} d_k(n_1, n_2; m_1, m_2) f(m_1, m_2) \right) + v_k(n_1, n_2) \quad (53.5)$$

where the support of the summation over the high-resolution grid (m_1, m_2) at a particular observed pixel $(n_1, n_2; k)$ depends on the motion trajectory connecting the pixel $(n_1, n_2; k)$ to the ideal image, the size of the support of the low-resolution sensor PSF $h_d(x_1, x_2)$ with respect to the high resolution grid, and whether there is additional optical (out-of-focus, motion, etc.) blur. Because the relative positions of low- and high-resolution pixels in general vary by spatial coordinates, the discrete sensor PSF is space-varying. The support of the space-varying PSF is indicated by the shaded area in Fig. 53.1, where the rectangle depicted by solid lines shows the support of a low-resolution pixel over the high-resolution sensor array. The shaded region corresponds to the area swept by the low-resolution pixel due to motion during the aperture time [8].

FIGURE 53.1: Illustration of the discrete system PSF.

Note that the model (53.5) is invalid in case of occlusion. That is, each observed pixel $(n_1, n_2; k)$ can be expressed as a linear combination of several desired high-resolution pixels (m_1, m_2) , provided that $(n_1, n_2; k)$ is connected to (m_1, m_2) by a motion trajectory. We assume that occlusion regions can be detected *a priori* using a proper motion estimation/segmentation algorithm.

53.2.4 Regularization Models

Restoration is an ill-posed problem which can be regularized by modeling certain aspects of the desired “ideal” image. Images can be modeled as either 2-D deterministic sequences or random fields. A *priori* information about the ideal image can then be used to define hard or soft constraints on the solution. In the deterministic case, images are usually assumed to be members of an appropriate Hilbert space, such as a Euclidean space with the usual inner product and norm. For example, in the context of set theoretic restoration, the solution can be restricted to be a member of a set consisting of all images satisfying a certain smoothness criterion [9]. On the other hand, constrained least squares (CLS) and Tikhonov-Miller regularization use quadratic functionals to impose smoothness constraints in an optimization framework.

In the random case, models have been developed for the pdf of the ideal image in the context of maximum *a posteriori* (MAP) image restoration. For example, Trussell and Hunt [10] have proposed a Gaussian distribution with space-varying mean and stationary covariance as a model for the pdf of the image. Geman and Geman [11] proposed a Gibbs distribution to model the pdf of the image. Alternatively, if the image is assumed to be a realization of a homogeneous Gauss-Markov random process, then it can be statistically modeled through an autoregressive (AR) difference equation [12]

$$f(n_1, n_2) = \sum_{(m_1, m_2) \in \mathcal{S}_c} c(m_1, m_2) f(n_1 - m_1, n_2 - m_2) + w(n_1, n_2) \quad (53.6)$$

where $\{c(m_1, m_2) : (m_1, m_2) \in \mathcal{S}_c\}$ denote the model coefficients, \mathcal{S}_c is the model support (which may be causal, semi-causal, or non-causal), and $w(n_1, n_2)$ represents the modeling error which is Gaussian distributed. The model coefficients can be determined such that the modeling error has minimum variance [12]. Extensions of (53.6) to inhomogeneous Gauss-Markov fields was proposed by Jeng and Woods [13].

53.3 Model Parameter Estimation

In this section, we discuss methods for estimating the parameters that are involved in the observation and regularization models for subsequent use in the restoration algorithms.

53.3.1 Blur Identification

Blur identification refers to estimation of both the support and parameters of the PSF $\{d(n_1, n_2) : (n_1, n_2) \in S_d\}$. It is a crucial element of image restoration because the quality of restored images is highly sensitive to errors in the PSF [14]. An early approach to blur identification has been based on the assumption that the original scene contains an ideal point source, and that its spread (hence the PSF) can be determined from the observed image. Rosenfeld and Kak [15] show that the PSF can also be determined from an ideal line source. These approaches are of limited use in practice because a scene, in general, does not contain an ideal point or line source and the observation noise may not allow the measurement of a useful spread.

Models for certain types of PSF can be derived using principles of optics, if the source of the blur is known [7]. For example, out-of-focus and motion blur PSF can be parameterized with a few parameters. Further, they are completely characterized by their zeros in the frequency-domain. Power spectrum and cepstrum (Fourier transform of the logarithm of the power spectrum) analysis methods have been successfully applied in many cases to identify the location of these zero-crossings [16, 17]. Alternatively, Chang et al. [18] proposed a bispectrum analysis method, which is motivated by the fact that bispectrum is not affected, in principle, by the observation noise. However, the bispectral method requires much more data than the method based on the power spectrum. Note that PSFs, which do not have zero crossings in the frequency domain (e.g., Gaussian PSF modeling atmospheric turbulence), cannot be identified by these techniques.

Yet another approach for blur identification is the maximum likelihood (ML) estimation approach. The ML approach aims to find those parameter values (including, in principle, the observation noise variance) that have most likely resulted in the observed image(s). Different implementations of the ML image and blur identification are discussed under a unifying framework [19]. Pavlović and Tekalp [20] propose a practical method to find the ML estimates of the parameters of a PSF based on a continuous domain image formation model.

In multi-frame image restoration, blur identification using more than one frame at a time becomes possible. For example, the PSF of a possibly space-varying motion blur can be computed at each pixel from an estimate of the frame-to-frame motion vector at that pixel, provided that the shutter speed of the camera is known [21].

53.3.2 Estimation of Regularization Parameters

Regularization model parameters aim to strike a balance between the fidelity of the restored image to the observed data and its smoothness. Various methods exist to identify regularization parameters, such as parametric pdf models, parametric smoothness constraints, and AR image models. Some restoration methods require the knowledge of the power spectrum of the ideal image, which can be estimated, for example, from an AR model of the image. The AR parameters can, in turn, be estimated from the observed image by a least squares [22] or an ML technique [63]. On the other hand, non-parametric spectral estimation is also possible through the application of periodogram-based methods to a prototype image [69, 23]. In the context of maximum *a posteriori* (MAP) methods, the *a priori* pdf is often modeled by a parametric pdf, such as a Gaussian [10] or a Gibbsian [11]. Standard methods for estimating these parameters do not exist. Methods for estimating the regularization parameter in the CLS, Tikhonov-Miller, and related formulations are discussed in [24].

53.3.3 Estimation of the Noise Variance

Almost all restoration algorithms assume that the observation noise is a zero-mean, white random process that is uncorrelated with the image. Then, the noise field is completely characterized by its variance, which is commonly estimated by the sample variance computed over a low-contrast local

region of the observed image. As we will see in the following section, the noise variance plays an important role in defining constraints used in some of the restoration algorithms.

53.4 Intra-Frame Restoration

We start by first looking at some basic regularized restoration strategies, in the case of an LSI blur model with no pointwise nonlinearity. The effect of the nonlinear mapping $s(\cdot)$ is discussed in Section 53.4.2. Methods that allow PSFs with a random components are summarized in Section 53.4.3. Adaptive restoration for ringing suppression and blind restoration are covered in Sections 53.4.4 and 53.4.5, respectively. Restoration of multispectral images and space-varying blurred images are addressed in Sections 53.4.6 and 53.4.7, respectively.

53.4.1 Basic Regularized Restoration Methods

When the mapping $s(\cdot)$ is ignored, it is evident from Eq. (53.1) that image restoration reduces to solving a set of simultaneous linear equations. If the matrix D is nonsingular (i.e., D^{-1} exists) and the vector g lies in the column space of D (i.e., there is no observation noise), then there exists a unique solution which can be found by direct inversion (also known as inverse filtering). In practice, however, we almost always have an underdetermined (due to boundary truncation problem [14]) and inconsistent (due to observation noise) set of equations. In this case, we resort to a minimum-norm least-squares solution. A least squares (LS) solution (not unique when the columns of D are linearly dependent) minimizes the norm-square of the residual

$$J_{LS}(f) \doteq ||g - Df||^2 \quad (53.7)$$

LS solution(s) with the minimum norm (energy) is (are) generally known as pseudo-inverse solution(s) (PIS).

Restoration by pseudo-inversion is often ill-posed owing to the presence of observation noise [14]. This follows because the pseudo-inverse operator usually has some very large eigenvalues. For example, a typical blur transfer function has zeros; and thus, its pseudo-inverse attains very large magnitudes near these singularities as well as at high frequencies. This results in excessive amplification at these frequencies in the sensor noise. Regularized inversion techniques attempt to roll-off the transfer function of the pseudo-inverse filter at these frequencies to limit noise amplification. It follows that the regularized inverse deviates from the pseudo-inverse at these frequencies which leads to other types of artifacts, generally known as regularization artifacts [14]. Various strategies for regularized inversion (and how to achieve the right amount of regularization) are discussed in the following.

Singular-Value Decomposition Method

The pseudo-inverse D^+ can be computed using the singular value decomposition (SVD) [1]

$$D^+ = \sum_{i=0}^R \lambda_i^{-1/2} z_i u_i^T \quad (53.8)$$

where λ_i denote the singular values, z_i and u_i are the eigenvectors of $D^T D$ and $D D^T$, respectively, and R is the rank of D . Clearly, reciprocation of zero singular-values is avoided since the summation runs to R , the rank of D . Under the assumption that D is block-circulant (corresponding to a circular convolution), the PIS computed through Eq. (53.8) is equivalent to the frequency domain

pseudo-inverse filtering

$$D^+(u, v) = \begin{cases} 1/D(u, v) & \text{if } D(u, v) \neq 0 \\ 0 & \text{if } D(u, v) = 0 \end{cases} \quad (53.9)$$

where $D(u, v)$ denotes the frequency response of the blur. This is because a block-circulant matrix can be diagonalized by a 2-D discrete Fourier transformation (DFT) [2].

Regularization of the PIS can then be achieved by truncating the singular value expansion (53.8) to eliminate all terms corresponding to small λ_i (which are responsible for the noise amplification) at the expense of reduced resolution. Truncation strategies are generally ad-hoc in the absence of additional information.

Iterative Methods (Landweber Iterations)

Several image restoration algorithms are based on variations of the so-called Landweber iterations [25, 26, 27, 28, 31, 32]

$$f_{k+1} = f_k + \mathbf{R} \mathbf{D}^T (\mathbf{g} - \mathbf{D} f_k) \quad (53.10)$$

where \mathbf{R} is a matrix that controls the rate of convergence of the iterations. There is no general way to select the best \mathbf{C} matrix. If the system (53.1) is nonsingular and consistent (hardly ever the case), the iterations (53.10) will converge to the solution. If, on the other hand, (53.1) is underdetermined and/or inconsistent, then (53.10) converges to a minimum-norm least squares solution (PIS). The theory of this and other closely related algorithms are discussed by Sanz and Huang [26] and Tom et al. [27]. Kawata and Ichioka [28] are among the first to apply the Landweber-type iterations to image restoration, which they refer to as “reblurring” method.

Landweber-type iterative restoration methods can be regularized by appropriately terminating the iterations before convergence, since the closer we are to the pseudo-inverse, the more noise amplification we have. A termination rule can be defined on the basis of the norm of the residual image signal [29]. Alternatively, soft and/or hard constraints can be incorporated into iterations to achieve regularization. The constrained iterations can be written as [30, 31]

$$f_{k+1} = \mathbf{C} \left[f_k + \mathbf{R} \mathbf{D}^T (\mathbf{g} - \mathbf{D} f_k) \right] \quad (53.11)$$

where \mathbf{C} is a nonexpansive constraint operator, i.e., $\|\mathbf{C}(f_1) - \mathbf{C}(f_2)\| \leq \|f_1 - f_2\|$, to guarantee the convergence of the iterations. Application of Eq. (53.11) to image restoration has been extensively studied (see [31, 32] and the references therein).

Constrained Least Squares Method

Regularized image restoration can be formulated as a constrained optimization problem, where a functional $\|\mathbf{Q}(f)\|^2$ of the image is minimized subject to the constraint $\|\mathbf{g} - \mathbf{D}f\|^2 = \sigma^2$. Here σ^2 is a constant, which is usually set equal to the variance of the observation noise. The constrained least squares (CLS) estimate minimizes the Lagrangian [34]

$$J_{CLS}(f) = \|\mathbf{Q}(f)\|^2 + \alpha \left(\|\mathbf{g} - \mathbf{D}f\|^2 - \sigma^2 \right) \quad (53.12)$$

where α is the Lagrange multiplier. The operator \mathbf{Q} is chosen such that the minimization of Eq. (53.12) enforces some desired property of the ideal image. For instance, if \mathbf{Q} is selected as the Laplacian operator, smoothness of the restored image is enforced. The CLS estimate can be expressed, by taking the derivative of Eq. (53.12) and setting it equal to zero, as [1]

$$\hat{f} = \left(\mathbf{D}^H \mathbf{D} + \gamma \mathbf{Q}^H \mathbf{Q} \right)^{-1} \mathbf{D}^H \mathbf{g} \quad (53.13)$$

where H stands for Hermitian (i.e., complex-conjugate and transpose). The parameter $\gamma = \frac{1}{\alpha}$ (the regularization parameter) must be such that the constraint $\|g - Df\|^2 = \sigma^2$ is satisfied. It is often computed iteratively [2]. A sufficient condition for the uniqueness of the CLS solution is that Q^{-1} exists. For space-invariant blurs, the CLS solution can be expressed in the frequency domain as [34]

$$\hat{F}(u, v) = \frac{D^*(u, v)}{|D(u, v)|^2 + \gamma |L(u, v)|^2} G(u, v) \quad (53.14)$$

where $*$ denotes complex conjugation. A closely related regularization method is the Tikhonov-Miller (T-M) regularization [33, 35]. T-M regularization has been applied to image restoration [31, 32, 36]. Recently, neural network structures implementing the CLS or T-M image restoration have also been proposed [37, 38].

Linear Minimum Mean Square Error Method

The linear minimum mean square error (LMMSE) method finds the linear estimate which minimizes the mean square error between the estimate and ideal image, using up to second order statistics of the ideal image. Assuming that the ideal image can be modeled by a zero-mean homogeneous random field and the blur is space-invariant, the LMMSE (Wiener) estimate, in the frequency domain, is given by [8]

$$\hat{F}(u, v) = \frac{D^*(u, v)}{|D(u, v)|^2 + \sigma_v^2 / |P(u, v)|^2} G(u, v) \quad (53.15)$$

where σ_v^2 is the variance of the observation noise (assumed white) and $|P(u, v)|^2$ stands for the power spectrum of the ideal image. The power spectrum of the ideal image is usually estimated from a prototype. It can be easily seen that the CLS estimate (53.14) reduces to the Wiener estimate by setting $|L(u, v)|^2 = \sigma_v^2 / |P(u, v)|^2$ and $\gamma = 1$.

A Kalman filter determines the causal (up to a fixed lag) LMMSE estimate recursively. It is based on a state-space representation of the image and observation models. In the first step of Kalman filtering, a prediction of the present state is formed using an autoregressive (AR) image model and the previous state of the system. In the second step, the predictions are updated on the basis of the observed image data to form the estimate of the present state. Woods and Ingle [39] applied 2-D reduced-update Kalman filter (RUKF) to image restoration, where the update is limited to only those state variables in a neighborhood of the present pixel. The main assumption here is that a pixel is insignificantly correlated with pixels outside a certain neighborhood about itself. More recently, a reduced-order model Kalman filtering (ROMKF), where the state vector is truncated to a size that is on the order of the image model support has been proposed [40]. Other Kalman filtering formulations, including higher-dimensional state-space models to reduce the effective size of the state vector, have been reviewed in [7]. The complexity of higher-dimensional state-space model based formulations, however, limits their practical use.

Maximum *A posteriori* Probability Method

The maximum *a posteriori* probability (MAP) restoration maximizes the *a posteriori* probability density function (pdf) $p(f|g)$, i.e., the likelihood of a realization of f being the ideal image given the observed data g . Through the application of the Bayes rule, we have

$$p(f|g) \propto p(g|f)p(f) \quad (53.16)$$

where $p(g|f)$ is the conditional pdf of g given f (related to the pdf of the noise process) and $p(f)$ is the *a priori* pdf of the ideal image. We usually assume that the observation noise is Gaussian, leading

to

$$p(\mathbf{g}|\mathbf{f}) = \frac{1}{(2\pi)^{N/2} |\mathbf{R}_v|^{1/2}} \exp \left\{ -1/2 (\mathbf{g} - \mathbf{D}\mathbf{f})^T \mathbf{R}_v^{-1} (\mathbf{g} - \mathbf{D}\mathbf{f}) \right\} \quad (53.17)$$

where \mathbf{R}_v denotes the covariance matrix of the noise process. Unlike the LMMSE method, the MAP method uses complete pdf information. However, if both the image and noise are assumed to be homogeneous Gaussian random fields, the MAP estimate reduces to the LMMSE estimate, under a linear observation model.

Trussell and Hunt [10] used non-stationary *a priori* pdf models, and proposed a modified form of the Picard iteration to solve the nonlinear maximization problem. They suggested using the variance of the residual signal as a criterion for convergence. Geman and Geman [11] proposed using a Gibbs random field model for the *a priori* pdf of the ideal image. They used simulated annealing procedures to maximize Eq. (53.16). It should be noted that the MAP procedures usually require significantly more computation compared to, for example, the CLS or Wiener solutions.

Maximum Entropy Method

A number of maximum entropy (ME) approaches have been discussed in the literature, which vary in the way that the ME principle is implemented. A common feature of all these approaches, however, is their computational complexity. Maximizing the entropy enforces smoothness of the restored image. (In the absence of constraints, the entropy is highest for a constant-valued image). One important aspect of the ME approach is that the nonnegativity constraint is implicitly imposed on the solution because the entropy is defined in terms of the logarithm of the intensity.

Frieden was the first to apply the ME principle to image restoration [41]. In his formulation, the sum of the entropy of the image and noise, given by

$$J_{ME1}(\mathbf{f}) = - \sum_i f(i) \ln f(i) - \sum_i n(i) \ln n(i) \quad (53.18)$$

is maximized subject to the constraints

$$\mathbf{n} = \mathbf{g} - \mathbf{D}\mathbf{f} \quad (53.19)$$

$$\sum_i f(i) = K \doteq \sum_i g(i) \quad (53.20)$$

which enforce fidelity to the data and a constant sum of pixel intensities. This approach requires the solution of a system of nonlinear equations. The number of equations and unknowns are on the order of the number of pixels in the image. The formulation proposed by Gull and Daniell [42] can be viewed as another form of Tikhonov regularization (or constrained least squares formulation), where the entropy of the image

$$J_{ME2}(\mathbf{f}) = - \sum_i f(i) \ln f(i) \quad (53.21)$$

is the regularization functional. It is maximized subject to the following usual constraints

$$\|\mathbf{g} - \mathbf{D}\mathbf{f}\|^2 = \sigma_v^2 \quad (53.22)$$

$$\sum_i f(i) = K \doteq \sum_i g(i) \quad (53.23)$$

on the restored image. The optimization problem is solved using an ascent algorithm. Trussell [43] showed that in the case of a prior distribution defined in terms of the image entropy, the MAP solution is identical to the solution obtained by this ME formulation. Other ME formulations were also proposed [44, 45]. Note that all ME methods are nonlinear in nature.

Set-Theoretic Methods

In set-theoretic methods, first a number of “constraint sets” are defined such that their members are consistent with the observations and/or some *a priori* information about the ideal image. A set-theoretic estimate of the ideal image is then defined as a feasible solution satisfying all constraints, i.e., any member of the intersection of the constraint sets. Note that set-theoretic methods are, in general, nonlinear.

Set-theoretic methods vary according to the mathematical properties of the constraint sets. In the method of projections onto convex sets (POCS), the constraint sets C_i are closed and convex in an appropriate Hilbert space \mathcal{H} . Given the sets C_i , $i = 1, \dots, M$, and their respective projection operators \mathbf{P}_i , a feasible solution is found by performing successive projections as

$$\mathbf{f}_{k+1} = \mathbf{P}_M \mathbf{P}_{M-1} \dots \mathbf{P}_1 \mathbf{f}_k; \quad k = 0, 1, \dots \quad (53.24)$$

where \mathbf{f}_0 is the initial estimate (a point in \mathcal{H}). The projection operators are usually found by solving constrained optimization problems. In finite-dimensional problems (which is the case for digital image restoration), the iterations converge to a feasible solution in the intersection set [46, 47, 48]. It should be noted that the convergence point is affected by the choice of the initialization. However, as the size of the intersection set becomes smaller, the differences between the convergence points obtained by different initializations become smaller. Trussell and Civanlar [49] applied POCS to image restoration. For examples of convex constraint sets that are used in image restoration, see [23]. A relationship between the POCS and Landweber iterations were developed in [10].

A special case of POCS is the Gerchberg-Papoulis type algorithms where the constraint sets are either linear subspaces or linear varieties [50]. Extensions of POCS to the case of nonintersecting sets [51] and nonconvex sets [52] have been discussed in the literature. Another extension is the method of fuzzy sets (FS), where the constraints are defined in terms of FS. More precisely, the constraints are reflected in the membership functions defining the FS. In this case, a feasible solution is defined as one that has a high grade of membership (e.g., above a certain threshold) in the intersection set. The method of FS has also been applied to image restoration [53].

53.4.2 Restoration of Images Recorded by Nonlinear Sensors

Image sensors and media may have nonlinear characteristics that can be modeled by a pointwise (memoryless) nonlinearity $s(\cdot)$. Common examples are photographic film and paper, where the nonlinear relationship between the exposure (intensity) and the silver density deposited on the film or paper is specified by a “ $d - \log e$ ” curve. The modeling of sensor nonlinearities was first addressed by Andrews and Hunt [1]. However, it was not generally recognized that results obtained by taking the sensor nonlinearity into account may be far more superior to those obtained by ignoring the sensor nonlinearity, until the experimental work of Tekalp and Pavlović [54, 55].

Except for the MAP approach, none of the algorithms discussed above are equipped to handle sensor nonlinearity in a straightforward fashion. A simple approach would be to expand the observation model with $s(\cdot)$ into its Taylor series about the mean of the observed image and obtain an approximate (linearized) model, which can be used with any of the above methods [1]. However, the results do not show significant improvement over those obtained by ignoring the nonlinearity. The MAP method is capable of taking the sensor nonlinearity into account directly. A modified Picard iteration was proposed in [10], assuming both the image and noise are Gaussian distributed, which is given by

$$\hat{\mathbf{f}}_{k+1} = \bar{\mathbf{f}}_k + \mathbf{R}_f \mathbf{D}^T \mathbf{S}_b \mathbf{R}_n^{-1} [\mathbf{g} - s(\mathbf{D} \mathbf{f}_k)] \quad (53.25)$$

where $\bar{\mathbf{f}}$ denotes non-stationary image mean, \mathbf{R}_f and \mathbf{R}_n are the correlation matrices of the ideal image and noise, respectively, and \mathbf{S}_b is a diagonal matrix consisting of the derivatives of $s(\cdot)$ evaluated

at $\mathbf{b} = \mathbf{D}\mathbf{f}$. It is the matrix \mathbf{S}_b that maps the difference $[\mathbf{g} - s(\mathbf{D}\mathbf{f}_k)]$ from the observation domain to the intensity domain.

An alternative approach, which is computationally less demanding, transforms the observed density domain image to the exposure domain [54]. There is a convolutional relationship between the ideal and blurred images in the exposure domain. However, the additive noise in the density domain manifests itself as multiplicative noise in the exposure domain. To this effect, Tekalp and Pavlović [54] derive an LMMSE deconvolution filter in the presence of multiplicative noise under certain assumptions. Their results show that accounting for the sensor nonlinearity may dramatically improve restoration results [54, 55].

53.4.3 Restoration of Images Degraded by Random Blurs

Basic regularized restoration methods (reviewed in Section 53.4.1) assume that the blur PSF is a deterministic function. A more realistic model may be

$$\mathbf{D} = \bar{\mathbf{D}} + \Delta\mathbf{D} \quad (53.26)$$

where $\bar{\mathbf{D}}$ is the deterministic part (known or estimated) of the blur operator and $\Delta\mathbf{D}$ stands for the random component. Random component may represent inherent random fluctuations in the PSF, for instance due to atmospheric turbulence or random relative motion, or it may model the PSF estimation error.

A naive approach would be to employ the expected value of the blur operator in one of the restoration algorithms discussed above. The resulting restoration, however, may be unsatisfactory. Slepian [56] derived the LMMSE estimate, which explicitly incorporated the random component of the PSF. The resulting Wiener filter requires the *a priori* knowledge of the second order statistics of the blur process. Ward et al. [57, 58] also proposed LMMSE estimators. Combettes and Trussell [59] addressed restoration of random blurs within the framework of POCS, where fluctuations in the PSF are reflected in the bounds defining the residual constraint sets. The method of total least squares (TLS) has been used in the mathematics literature to solve a set of linear equations with uncertainties in the system matrix. The TLS method amounts to finding the minimum perturbations on \mathbf{D} and \mathbf{g} to make the system of equations consistent. A variation of this principle has been applied to image restoration with random PSF by Mesarovic et al. [60]. Various authors have shown that modeling the uncertainty in the PSF (by means of a random component) reduces ringing artifacts that are due to using erroneous PSF estimates.

53.4.4 Adaptive Restoration for Ringing Reduction

Linear space-invariant (LSI) restoration methods introduce disturbing ringing artifacts which originate around sharp edges and image borders [36]. A quantitative analysis of the origins and characteristics of ringing and other restoration artifacts was given by Tekalp and Sezan [14]. Suppression of ringing may be possible by means of adaptive filtering, which tracks edges or image statistics such as local mean and variance.

Iterative and set-theoretic methods are well-suited for adaptive image restoration with ringing reduction. Lagendijk et al. [36] have extended Miller regularization to adaptive restoration by defining the solution in a weighted Hilbert space, in terms of norms weighted by space-variant weights. Later, Sezan and Tekalp [9] extended the method of POCS to the space-variant case by introducing a region-based bound on the signal energy. In both methods, the weights and/or the regions were identified from the degraded image. Recently, Sezan and Trussell [23] have developed constraints based on prototype images for set-theoretic image restoration with artifact reduction.

Kalman filtering can also be extended to adaptive image restoration. For a typical image, the homogeneity assumption will hold only over small regions. Rajala and de Figueiredo [61] used an

off-line visibility function to segment the image according to the local spatial activity of the picture being restored. Later, a rapid edge adaptive filter based on multiple image models to account for edges with various orientations was developed by Tekalp et al. [62]. Jeng and Woods [13] developed inhomogeneous Gauss-Markov field models for adaptive filtering, and maximum entropy methods were used for ringing reduction [45]. Results show a significant reduction in ringing artifacts in comparison to LSI restoration.

53.4.5 Blind Restoration (Deconvolution)

Blind restoration refers to methods that do not require prior identification of the blur and regularization model parameters. Two examples are simultaneous identification and restoration of noisy blurred images [63] and image recovery from Fourier phase information [64]. Lagendijk et al. [63] applied the E-M algorithm to blind image restoration, which alternates between ML parameter identification and minimum mean square error image restoration. Chen et al. [64] employed the POCS method to estimate the Fourier magnitude of the ideal image from the Fourier phase of the observed blurred image by assuming a zero-phase blur PSF so that the Fourier phase of the observed image is undistorted. Both methods require the PSF to be real and symmetric.

53.4.6 Restoration of Multispectral Images

A trivial solution to multispectral image restoration, when there is no inter-band blurring, may be to ignore the spectral correlations among different bands and restore each band independently, using one of the algorithms discussed above. However, algorithms that are optimal for single-band imagery may no longer be so when applied to individual spectral bands. For example, restoration of the red, green, and blue bands of a color image independently usually results in objectionable color shift artifacts.

To this effect, Hunt and Kubler [65] proposed employing the Karhunen-Loeve (KL) transform to decorrelate the spectral bands so that an independent-band processing approach can be applied. However, because the KL transform is image dependent, they then recommended using the NTSC YIQ transformation as a suboptimum but easy-to-use alternative. Experimental evidence shows that the visual quality of restorations obtained in the KL, YIQ, or another luminance-chrominance domain are quite similar [65]. In fact, restoration of only the luminance channel suffices in most cases. This method applies only when there is no inter-band blurring. Further, one should realize that the observation noise becomes correlated with the image under a non-orthogonal transformation. Thus, filtering based on the assumption that the image and noise are uncorrelated is not theoretically founded in the YIQ domain.

Recent efforts in multispectral image restoration are concentrated on making total use of the inherent correlations between the bands [66, 67]. Applying the CLS filter expression (53.13) to the observation model (53.4) with $\mathbf{Q}^H \mathbf{Q} = \mathcal{R}_f^{-1} \mathcal{R}_v$, we obtain the multispectral Wiener estimate $\hat{\mathbf{f}}$, given by [68]

$$\hat{\mathbf{f}} = \left(\mathcal{D}^T \mathcal{D} + \mathcal{R}_f^{-1} \mathcal{R}_v \right)^{-1} \mathcal{D}^T \mathbf{g} \quad (53.27)$$

where

$$\mathcal{R}_f \doteq \begin{bmatrix} \mathbf{R}_{f;11} & \cdots & \mathbf{R}_{f;1K} \\ \vdots & \ddots & \vdots \\ \mathbf{R}_{f;K1} & \cdots & \mathbf{R}_{f;KK} \end{bmatrix}, \text{ and } \mathcal{R}_v \doteq \begin{bmatrix} \mathbf{R}_{v;11} & \cdots & \mathbf{R}_{v;1K} \\ \vdots & \ddots & \vdots \\ \mathbf{R}_{v;K1} & \cdots & \mathbf{R}_{v;KK} \end{bmatrix}$$

Here $\mathbf{R}_{f;ij} \doteq \mathcal{E}\{\mathbf{f}_i \mathbf{f}_j^T\}$ and $\mathbf{R}_{v;ij} \doteq \mathcal{E}\{\mathbf{v}_i \mathbf{v}_j^T\}$, $i, j = 1, 2, \dots, K$ denote the inter-band, cross-correlation matrices. Note that if $\mathbf{R}_{f;ij} = \mathbf{0}$ for $i \neq j$, $i, j = 1, 2, \dots, K$, then the multiframe

estimate becomes equivalent to stacking the K single-frame estimates obtained independently.

Direct computation of \hat{f} through Eq. (53.27) requires inversion of a $N^2 L \times N^2 L$ matrix. Because the blur PSF is not necessarily the same in each band and the inter-band correlations are not shift-invariant, the matrices \mathcal{D} , \mathcal{R}_f , and \mathcal{R}_v are not block-Toeplitz; thus, a 3-D DFT would not diagonalize them. However, assuming LSI blurs, each \mathbf{D}_k is block-Toeplitz. Furthermore, assuming each image and noise band are wide-sense stationary, $\mathbf{R}_{f;ij}$ and $\mathbf{R}_{v;ij}$ are also block-Toeplitz. Approximating the block-Toeplitz submatrices \mathbf{D}_i , $\mathbf{R}_{f;ij}$, and $\mathbf{R}_{v;ij}$ by block-circulant ones, each submatrix can be diagonalized by a separate 2-D DFT operation so that we only need to invert a block matrix with diagonal sub-blocks. Galatsanos and Chin [66] proposed a method that successively partitions the matrix to be inverted and recursively computes the inverse of these partitions. Later Ozkan et al. [68] has shown that the desired inverse can be computed by inverting N^2 submatrices, each $K \times K$, in parallel. The resulting numerically stable filter was called the cross-correlated multiframe (CCMF) Wiener filter.

The multispectral Wiener filter requires the knowledge of the correlation matrices \mathcal{R}_f and \mathcal{R}_v . If we assume that the noise is white and spectrally uncorrelated, the matrix \mathcal{R}_v is diagonal with all diagonal entries equal to σ_v^2 . Estimation of the multispectral correlation matrix \mathcal{R}_f can be performed by either the periodogram method or 3-D AR modeling [68]. Sezan and Trussell [69] show that the multispectral Wiener filter is highly sensitive to the cross-power spectral estimates, which contain phase information. Other multispectral restoration methods include Kalman filtering approach of Tekalp and Pavlović [67], least squares approaches of Ohyama et al. [70] and Galatsanos et al. [71], and set-theoretic approach of Sezan and Trussell [23, 69] who proposed multispectral image constraints.

53.4.7 Restoration of Space-Varying Blurred Images

In principle, all basic regularization methods apply to the restoration of space-varying blurred images. However, because Fourier transforms cannot be utilized to simplify large matrix operations (such as inversion or singular value decomposition) when the blur is space-varying, implementation of some of these algorithms may be computationally formidable. There exist three distinct approaches to attack the space-variant restoration problem: (1) sectioning, (2) coordinate transformation, and (3) direct approaches.

The main assumption in sectioning is that the blur is approximately space-invariant over small regions. Therefore, a space-varying blurred image can be restored by applying the well-known space-invariant techniques to local image regions. Trussell and Hunt [73] propose using iterative MAP restoration within rectangular, overlapping regions. Later, Trussell and Fogel proposed using a modified Landweber iteration [21]. A major drawback of sectioning methods is generation of artifacts at the region boundaries. Overlapping the contiguous regions somewhat reduces these artifacts, but does not completely suppress them.

Most space-varying PSF vary continuously from pixel to pixel (e.g., relative motion with acceleration) violating the basic premise of the sectioning methods. To this effect, Robbins et al. [74] and then Sawchuk [75] proposed a coordinate transformation (CTR) method such that the blur PSF in the transformed coordinates is space-invariant. Then, the transformed image can be restored by a space-invariant filter and then transformed back to obtain the final restored image. However, the statistical properties of the image and noise processes are affected by the CTR, which should be taken into account in restoration filter design. The results reported in [74] and [75] have been obtained by inverse filtering; and thus, this statistical issue was of no concern. Also note that the CTR method is applicable to a limited class of space-varying blurs. For instance, blurring due to depth of field is not amenable to CTR.

The lack of generality of sectioning and CTR methods motivates direct approaches. Iterative schemes, Kalman filtering, and set-theoretic methods can be applied to restoration of space-varying

blurs in a computationally feasible manner. Angel and Jain [76] propose solving the superposition Eq. (53.3) iteratively using a conjugate gradient method. Application of constrained iterative methods was discussed in [30]. More recently, Ozkan et al. [72] developed a robust POCS algorithm for space-varying image restoration, where they defined a closed, convex constraint set for each observed blurred image pixel (n_1, n_2) , given by:

$$C_{n_1, n_2} = \left\{ \mathbf{y} : |r^{(\mathbf{y})}(n_1, n_2)| \leq \delta_0 \right\} \quad (53.28)$$

and

$$r^{(\mathbf{y})}(n_1, n_2) \doteq g(n_1, n_2) - \sum_{(m_1, m_2) \in \mathcal{S}_d(n_1, n_2)} d(n_1, n_2; m_1, m_2) y(m_1, m_2) \quad (53.29)$$

is the residual at pixel (n_1, n_2) associated with \mathbf{y} , which denotes an arbitrary member of the set. The quantity δ_0 is an *a priori* bound reflecting the statistical confidence with which the actual image is a member of the set C_{n_1, n_2} . Since $r^{(\mathbf{f})}(n_1, n_2) = v(n_1, n_2)$, the bound δ_0 is determined from the statistics of the noise process so that the ideal image is a member of the set within a certain statistical confidence. The collection of bounded residual constraints over all pixels (n_1, n_2) enforces the estimate to be consistent with the observed image.

The projection of an arbitrary $x(i_1, i_2)$ onto each C_{n_1, n_2} is defined as:

$$\mathbf{P}_{n_1, n_2} [x(i_1, i_2)] = \begin{cases} x(i_1, i_2) + \frac{r^{(\mathbf{x})}(n_1, n_2) - \delta_0}{\sum_{o_1} \sum_{o_2} h^2(n_1, n_2; o_1, o_2)} h(n_1, n_2; i_1, i_2) & \text{if } r^{(\mathbf{x})}(n_1, n_2) > \delta_0 \\ x(i_1, i_2) & \text{if } -\delta_0 \leq r^{(\mathbf{x})}(n_1, n_2) \leq \delta_0 \\ x(i_1, i_2) + \frac{r^{(\mathbf{x})}(n_1, n_2) + \delta_0}{\sum_{o_1} \sum_{o_2} h^2(n_1, n_2; o_1, o_2)} h(n_1, n_2; i_1, i_2) & \text{if } r^{(\mathbf{x})}(n_1, n_2) < -\delta_0 \end{cases} \quad (53.30)$$

The algorithm starts with an arbitrary $x(i_1, i_2)$, and successively projects onto each C_{n_1, n_2} . This is repeated until convergence [72]. Additional constraints, such as bounded energy, amplitude, and limited support, can be utilized to improve the results.

53.5 Multiframe Restoration and Superresolution

Multiframe restoration refers to estimating the ideal image on a lattice that is identical with the observation lattice, whereas superresolution refers to estimating it on a lattice that has a higher sampling density than the observation lattice. They both employ the multiframe observation model (53.5), which establishes a relation between the ideal image and observations at more than one instance. Several authors eluded that the sequential nature of video sources can be statistically modeled by means of temporal correlations [68, 71]. Multichannel filters similar to those described for multispectral restoration were thus proposed for multiframe restoration. Here, we only review motion-compensated (MC) restoration and superresolution methods, because they are more effective.

53.5.1 Multiframe Restoration

The sequential nature of images in a video source can be used to better estimate the PSF parameters, regularization terms, and the restored image. For example, the extent of a motion blur can be estimated from interframe motion vectors, provided that the aperture time is known. The first MC approach was the motion-compensated multiframe Wiener filter (MCMF) proposed by Ozkan et al. [68] who considered the case of frame-to-frame global translations. Then, the auto power spectra

of all frames are the same and the cross spectra are related by a phase factor which can be estimated from the motion information. Given the motion vectors (one for each frame) and the auto power spectrum of the reference frame, they derived a closed-form solution, given by

$$\hat{F}_k(u, v) = \frac{S_{f;k}(u, v) \sum_{i=1}^N S_{f;i}^*(u, v) D_i^*(u, v) G_i(u, v)}{\sum_{i=1}^N |S_{f;i}(u, v) D_i(u, v)|^2 + \sigma_v^2}, \quad (53.31)$$

where k is the index of the ideal frame to be restored, N is the number of available frames, and $P_{f;ki}(u, v) = S_{f;k}(u, v) S_{f;i}^*(u, v)$ denotes the cross power spectrum between the frames k and i in factored form. The fact that such a factorization exists was shown in [68] for the case of global translational motion. The MCMF yields the biggest improvement when the blur PSF changes from frame-to-frame. This is because the summation in the denominator may not be zero at any frequency, even though each term $D_i(u, v)$ may have zeros at certain frequencies. The case of space-varying blurs may be considered as a special case of the last section which covers superresolution with space-varying restoration.

53.5.2 Superresolution

When the interframe motion is subpixel, each frame, in fact, contains some “new” information that can be utilized to achieve superresolution. Superresolution refers to high-resolution image expansion, which aims to remove aliasing artifacts, blurring due to sensor PSF, and optical blurring given the observation model (53.5). Provided that enough frames with subpixel motion are available, the observation model becomes invertible. It can be easily seen, however, that superresolution from a single observed image is ill-posed because we have more unknowns than equations, and there exist infinitely many expanded images that are consistent with the model (53.5). Therefore, single-frame nonlinear interpolation (also called image expansion and digital zooming) methods for improved definition image expansion employ additional regularization criteria, such as edge-preserving smoothness constraints [77, 78]. (It is well-known that no new high-frequency information can be generated by LSI interpolation techniques, including ideal band-limited interpolation, hence the need for nonlinear methods.)

Several early motion-compensated methods are in the form of two-stage interpolation-restoration algorithms [79, 80]. They are based on the premise that pixels from all observed frames can be mapped back onto a desired frame, based on estimated motion trajectories, to obtain an upsampled reference frame. However, unless we assume global translational motion, the upsampled reference frame is nonuniformly sampled. In order to obtain a uniformly spaced upsampled image, interpolation onto a uniform sampling grid needs to be performed. Image restoration is subsequently applied to the upsampled image to remove the effect of the sensor blur. However, these methods do not use an accurate image formation model, and cannot remove aliasing artifacts.

Motion-compensated (multiframe) superresolution methods that are based on the model (53.5) can be classified as those that aim to eliminate (1) aliasing only, (2) aliasing and LSI blurs, and (3) aliasing and space-varying blurs. In addition, some of these methods are designed for global translational motion only, while others can handle space-varying motion fields with occlusion. Multiframe superresolution was first introduced by Tsai and Huang [81] who exploited the relationship between the continuous and discrete Fourier transforms of the undersampled frames to remove aliasing errors, in the special case of global motion. Their formulation has been extended by Kim et. al. [82] to take into account noise and blur in the low-resolution images, by posing the problem in the least squares sense. A further refinement by Kim and Su [83] allowed blurs that are different for each frame of

low-resolution data, by using a Tikhonov regularization. However, the resulting algorithm did not treat the formation of blur due to motion or sensor size, and suffers from convergence problems.

Inspection of the model (53.5) suggests that the superresolution problem can be stated in the spatio-temporal domain as the solution of a set of simultaneous linear equations. Suppose that the desired high-resolution frames are $M \times M$, and we have L low-resolution observations, each $N \times N$. Then, from Eq. (53.5), we can set up at most $L \times N \times N$ equations in M^2 unknowns to reconstruct a particular high-resolution frame. These equations are linearly independent provided that all displacements between the successive frames are at subpixel amounts. (Clearly, the number of equations will be reduced by the number of occlusion labels encountered along the respective motion trajectories.) In general, it is desirable to set up an overdetermined system of equations, i.e., $L > R^2 = M^2/N^2$, to obtain a more robust solution in the presence of observation noise. Because the impulse response coefficients $h_{ik}(n_1, n_2; m_1, m_2)$ are spatially varying, and hence the system matrix is not block-Toeplitz, fast methods to solve them are not available. Stark and Oskui [86] proposed a POCS method to compute a high resolution image from observations obtained by translating and/or rotating an image with respect to a CCD array. Irani and Peleg [84, 85] employed iterative methods. Patti et al. [87] extended the POCS formulation to include sensor noise and space-varying blurs. Bayesian approaches were also employed for superresolution [88]. The extension of the POCS method with space-varying blurs is explained in the following.

53.5.3 Superresolution with Space-Varying Restoration

The POCS method described here addresses the most general form of the superresolution problem based on the model (53.5). The formulation is quite similar to the POCS approach presented for intraframe restoration of space-varying blurred images. In this case, we define a different closed, convex set for each observed low-resolution pixel (n_1, n_2, k) (which can be connected to the desired frame i by a motion trajectory) as

$$C_{n_1, n_2; i, k} = \left\{ x_i(m_1, m_2) : |r_k^{(\mathbf{x}_i)}(n_1, n_2)| \leq \delta_0 \right\}, \quad 0 \leq n_1, n_2 \leq N-1, \quad k = 1, \dots, L \quad (53.32)$$

where

$$r_k^{(\mathbf{x}_i)}(n_1, n_2) \doteq g_k(n_1, n_2) - \sum_{m_1=0}^{M-1} \sum_{m_2=0}^{M-1} x_i(m_1, m_2) h_{ik}(m_1, m_2; n_1, n_2)$$

and δ_0 represents the confidence that we have in the observation and is set equal to $c\sigma_v$, where σ_v is the standard deviation of the noise and $c \geq 0$ is determined by an appropriate statistical confidence bound. These sets define high-resolution images that are consistent with the observed low-resolution frames within a confidence bound that is proportional to the variance of the observation noise. The projection operator which projects onto $C_{n_1, n_2; i, k}$ can be deduced from Eq. (53.30) [8]. Additional constraints, such as amplitude and/or finite support constraints, can be utilized to improve the results. Excellent reconstructions have been reported using this procedure [68, 87].

A few observations about the POCS method are in order: (1) While certain similarities exist between the POCS iterations and the Landweber-type iterations [79, 84, 85], the POCS method can adapt to the amount of the observation noise, while the latter generally cannot. (2) The POCS method finds a feasible solution, that is, a solution consistent with all available low-resolution observations. Clearly, the more observations (more frames with reliable motion estimation) we have, the better the high-resolution reconstructed image $\hat{s}_i(m_1, m_2)$ will be. In general, it is desirable that $L > M^2/N^2$. Note, however, that the POCS method generates a reconstructed image with any number L of available frames. The number L is just an indicator of how large the feasible set of solutions will be. Of course, the size of the feasible set can be further reduced by employing other closed, convex constraints in the form of statistical or structural image models.

53.6 Conclusion

At present, factors that limit the success of digital image restoration technology include lack of reliable (1) methods for blur identification, especially identification of space-variant blurs, (2) methods to identify imaging system nonlinearities, and (3) methods to deal with the presence of artifacts in restored images. Our experience with the restoration of real-life blurred images indicates that the choice of a particular regularization strategy (filter) has a small effect on the quality of the restored images as long as the parameters of the degradation model, i.e., the blur PSF and the SNR, and any imaging system nonlinearity is properly compensated. Proper compensation of system nonlinearities also plays a significant role in blur identification.

54.1 Introduction

The scanning format of a video signal is a major determinant of general picture quality. Specifically, it determines such aspects as stationary and dynamic resolution, motion portrayal, aliasing, scanning structure visibility, and flicker. Various formats have been designed and standardized to strike a particular balance between quality, cost, transmission capacity, and compatibility with other standards.

The field of video scanning format conversion is concerned with the translation of video signals from one format into another. It consists of two basic parts: temporal interpolation and spatial interpolation. A particular case is de-interlacing, which poses an inseparable spatio-temporal interpolation problem.

Vertical and temporal interpolation cause practical and fundamental difficulties in achieving high-quality scanning format conversion. This is because the conditions of the sampling theorem are generally not met in video signals. If they were satisfied, standard conversions of arbitrary accuracy would be possible using suitable linear filters.

The earlier conversion methods neglected the fundamental problems and, consequently, negatively influenced the resolution and the motion portrayal. More recent algorithms apply motion vectors to predict the position of moving objects at unregistered temporal instances to improve the quality of the picture at the output format. A so-called *motion estimator* extracts these vectors from the input

signal. The motion vectors partly solve the fundamental problems, but the demands on the motion estimator for scanning format conversion are severe.

In this section we shall first briefly indicate why we can expect that the importance of scanning format conversion will grow. Then we discuss in more detail the fundamental problems of temporal interpolation of video signals. Next we provide a concise overview of the basic methods in scanning format conversion, focused on temporal sampling rate conversion and de-interlacing. Finally, we give an overview of motion estimation algorithms, which are crucial in the more advanced scanning format converters.

54.2 Conversion vs. Standardization

Scanning formats have been designed in the past to strike a particular compromise between quality, cost, transmission capacity, and compatibility with other standards. There were three main formats in use a decade ago: 50 Hz interlaced, 60 Hz interlaced, and 24 (or 25) Hz progressive (film). With the arrival of video-conferencing, HDTV, workstations, and PCs, many new video formats have appeared. These include low end formats such as CIF and QCIF with smaller picture size and lower frame rates, progressive and interlaced HDTV formats at 50 Hz and 60 Hz, and other video formats used on computer workstations and enhanced television displays with field rates up to 100 Hz. It will be clear that the problem of scanning format conversion is of a growing importance, despite many attempts to globally standardize video formats.

54.3 Problems with Linear Sampling Rate Conversion Applied to Video Signals

High-quality scanning format conversion is difficult to achieve, as the conditions of the sampling theorem are generally not met in video signals. The solution of Sample Rate Conversion (SRC) for systems satisfying the conditions of the sampling theory is well known for arbitrary sampling ratios [1].

Figure 54.1 illustrates the procedure for a ratio of 2. To arrive at the double output sampling rate, in a first step, zero-valued samples are inserted between every input pair of samples. In a second step, a low-pass filter (LPF) at the output rate is applied to remove the first repeat spectrum from the input data. In case of a temporal SRC, the interpolating LPF has to be a temporal LPF, i.e., a filter including picture delays. Though feasible, this makes it a fairly expensive filter.

A more complicated, though still not fundamental, problem occurs at the signal acquisition stage. Since scenes do occur with almost unlimited spatial and/or temporal bandwidth, the sampling theorem requires that this signal be low-pass filtered prior to the scanning process. Interlaced scanning, as commonly applied, even demands two-dimensional prefiltering in the vertical-temporal frequency plane. In a video system, it is the camera that samples the scene in a vertical and temporal sense; therefore, the prefilter has to be realized in the optical path. Although there are considerable practical problems achieving this filtering, it would apparently bring down the problem of temporal interpolation of video images to the common sampling rate conversion problem. The next section will show, however, that in addition to the practical problems there is a fundamental problem as well.

54.3.1 Temporal Interpolation

Considering the eye's sine-wave temporal frequency response for full brightness potential and full field display [2], as shown in Fig. 54.2, temporal prefiltering with a bandwidth of 75 Hz at first sight seems sufficient. The fundamental problem now is that the relation shown in Fig. 54.2 holds for

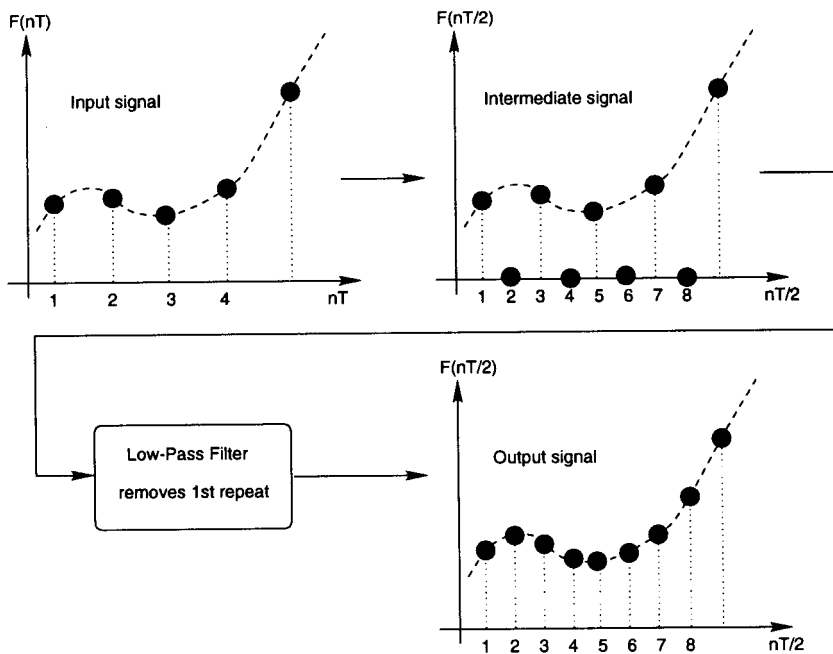

FIGURE 54.1: Consecutive steps in upsampling with a factor of two.

temporal frequencies as they occur at the retina of the observer. These frequencies, however, equal the frequencies at the display only if the eye is stationary with respect to this display. Particularly with the eye tracking objects moving on the screen, this assumption is no longer valid. For a tracking observer very high temporal frequencies on the screen can be transformed to much lower frequencies or even DC at the retina. Consequently, suppression of these frequencies, with an interpolating lowpass filter, results in excessive blurring of moving objects as will be discussed next.

Figure 54.3 shows, in a time-discrete representation, a simple object, a square, moving with a constant velocity. Again, in this example, we consider up-sampling with a factor of two. Therefore, the true position of the object is available at every second temporal position only (e.g., the odd numbered samples). The “tracking observer” views along the motion trajectory, represented with a line in the illustration, which results in a stationary image of the object on the retina. If the output field sampling frequency exceeds the cutoff temporal frequency of the human visual system,¹ the viewer will have the illusion that the object is continuously present.

Therefore, the object is actually seen at a position corresponding with the motion trajectory. If now, e.g., in the 6th output field, the object is interpolated according to SRC theory, weighted copies of the object from surrounding fields resulting from the interpolating LPF are displayed. Figure 54.3 illustrates the case of a symmetrical transversal lowpass filter. In this situation, the viewer sees the object at the correct position but also various attenuated and displaced copies (the impulse response of the interpolating temporal filter) of the object in a neighborhood. The attenuation depends on the coefficients of the interpolating filter, and the distance between the copies is related to the displacement

¹ Actually the picture update frequency may be even as low as 16 Hz, to guarantee smooth perceived motion (see, e.g., [3]). The higher display rates are merely necessary to prevent the annoying large area flicker.

FIGURE 54.2: The contrast sensitivity of the human observer (y-axis) for large areas of uniform brightness, as a function of the temporal frequency (x-axis).

FIGURE 54.3: The effect of temporal interpolation for an object tracking observer. The field numbers are counted at the output field rate.

of the moving object in a field period. For the object-tracking observer, therefore, the temporal LPF is transformed into a spatial LPF. For an object velocity of one pixel per field period (one pel/field), its frequency characteristic equals the temporal frequency characteristic of the interpolating LPF.² 1 pel/field is a slow motion, as in broadcast picture material; velocities in a range exceeding 16 pel/field do occur. Thus, the spatial blur caused by the SRC process becomes unacceptable even for moderate object velocities.

54.3.2 Vertical Interpolation and Interlaced Scanning

Much similar to the situation of field rate conversion, it may seem that sequential scan conversion is an up-sampling problem for which SRC-theory provides an adequate solution. However, straightforward, one-dimensional, up-sampling in the vertical frequency domain is incorrect as the data is clearly sub-Nyquist sampled due to interlace.

If, more correctly, the sequential scan conversion is considered as a two-dimensional up-sampling problem in the vertical-temporal frequency domain, we arrive at a discussion similar to the one

²It is assumed here that both filters are normalized to their respective sampling frequency.

in Section 54.3.1: the problem cannot be solved as we do not know the temporal frequency at the retina of a movement-tracking observer. It is possible to disregard this problem and to perform a two-dimensional SRC, implicitly assuming a stationary viewer and prefiltered information. Such systems were described and have been implemented for studio applications. With the older image pick-up tubes the results can be satisfactory, as these devices have a poor dynamic resolution. When modern (CCD-)cameras are used, however, the limitations of the assumptions become obvious.

54.4 Alternatives for Sampling Rate Conversion Theory

With the problem of linear interpolation of video signals clarified, we will discuss alternative algorithms developed over time. These algorithms fall into two categories. A first category simplifies the interpolation filter prescribed by SRC-theory, considering that a completely correct solution is impossible anyway. The resulting “**simple algorithms**” are more attractive for hardware realization than the method from which they are derived and under certain conditions can perform quite similarly. The second category includes the most “**advanced algorithms**” for scanning format conversion. These methods can be characterized by their common attempt to interpolate the 3-D image data in the direction in which the correlation is highest. The difference between the various options lies mainly in the number of possible directions, and dimensions, which are considered. The implementation can show various linear interpolation filters controlled by one or more detectors, or a multi-dimensional nonlinear filter that has an inherent edge adaptivity. As this description allows a large number of algorithms, we will illustrate it with some important examples.

54.4.1 Simple Algorithms

SRC-theory in the temporal and vertical frequency domain is not applicable due to the missing prefilter in common video systems. A sophisticated linear interpolation filter therefore makes little sense. Any interpolating (spatio-)temporal low-pass filter will suppress original temporal frequency components as well as aliased signal components, as they occupy, by definition, the same spectrum. As the first effect is desired and the second not, the transfer function of the filter strikes a compromise between alias and blurring. Repetition of the most recent sample in this sense is optimal for the dynamic resolution and worst for alias. A strong temporal low-pass filter suppresses much (not necessarily all) alias and yields a poor dynamic resolution. The annoyance of the temporal alias depends on the input and output picture frequency, and particularly their difference. In the easiest case, both frequencies are high and their difference 50 Hz or more. In the worst case, input and output picture rate are low and their difference in the order of 10 Hz. In case of an annoying beat frequency, an interpolating LPF usually improves picture quality, otherwise the best compromise is closer to repetition of the most recent sample.

54.4.2 Advanced Algorithms

As indicated before, these methods are characterized by their common attempt to interpolate the 3-D image data in the direction in which the correlation is highest. To this end they either have an explicit or implicit detector to find this direction. In case of (1-D) temporal interpolation the explicit detector is usually called a **motion detector**, for 2-D spatial interpolation it is called an **edge detector**, while the most advanced device estimating the optimal spatio-temporal (3-D) interpolation direction is usually called a **motion estimator**. The interpolation filter can be recursive or transversal, and can have any number of taps, but a transversal filter with one or two taps is the most common choice. For a two taps FIR approach we can write the interpolated video signal F_{int} , in picture n , at spatial

position $\underline{x} = (x, y)^T$ as a function of the input video signal $F(\underline{x}, n)$:

$$F_{\text{int}}(\underline{x}, n) = 0.5 \left[F \left(\underline{x} + \begin{pmatrix} \delta_1 \\ \delta_2 \end{pmatrix}, n + \delta_3 \right) + F \left(\underline{x} - \begin{pmatrix} \delta_1 \\ \delta_2 \end{pmatrix}, n - \delta_3 \right) \right] \quad (54.1)$$

In this terminology a motion detector controls δ_3 , an edge detector δ_1 , and δ_2 , while a motion estimator can be applied to determine δ_1 , δ_2 , and δ_3 .

Algorithms with a Motion Detector

To detect motion, the difference between two successive pictures is calculated. It is too simple, however, to expect this signal to become zero in a picture part without moving objects. The common problems with the detection are noise and alias. Additional problems occurring in some systems are color subcarriers causing non-stationarities in colored regions, interlace causing nonstationarities in vertically detailed picture parts, and timing jitter of the sampling clock which is particularly harmful in detailed areas.

All these problems imply that the output of the motion detector usually is not a binary, but rather a multi-level signal, indicating the probability of motion. Usual (but not always valid) assumptions made to improve the detector are:

1. Noise is small and signal is large.
2. The spectrum part around the color carrier carries no motion information.
3. Low-frequency energy in the signal is larger than in the noise and alias.
4. Moving objects are large compared to a pixel.

The general structure of the motion detector resulting from these assumptions is depicted in Figure 54.4. As can be seen, the difference signal is first low-pass (and carrier reject) filtered to profit

FIGURE 54.4: General structure of a motion detector.

from (54.2) and (54.3). It also makes the detector less “nervous” for timing jitter in detailed areas. After the rectification another low-pass filter improves the consistency of the motion signal, based on assumption (54.4). Finally, the nonlinear (but monotonous) transfer function in the last block translates the signal in a probability figure for the motion P_m , using (54.1). This last function may have to be adapted to the expected noise level. Low-pass filters are not necessarily linear. More than one detector can be used, working on more than just two pictures in the neighborhood of the current image, and a logical or linear combination of their outputs may lead to a more reliable indication of motion.

The motion detector (MD) is applied to switch or fade between two processing modes, one of which is optimal for stationary and the other for moving image parts. Examples are:

- De-interlacing. The MD fades between intra-field interpolation (line-averaging, or edge

dependent spatial interpolation) and inter-field interpolation (repetition of the previous field, averaging of neighboring fields, etc.).

- Field rate doubling on interlaced video: The MD fades between repetition of fields (best dynamic resolution without motion compensation for moving picture parts) and repetition of frames (best spatial resolution in stationary image parts).

To slightly elaborate on the first example of de-interlacing, we define the interpolated pixel $X_m(\underline{x}, n)$ in a moving picture part as:

$$X_m(\underline{x}, n) = 0.5 \left[F\left(\underline{x} - \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n\right) + F\left(\underline{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n\right) \right] \quad (54.2)$$

while for stationary picture parts the interpolated pixel $X_s(\underline{x}, n)$ is taken as:

$$X_s(\underline{x}, n) = F(\underline{x}, n - 1) \quad (54.3)$$

and taking the probability of motion P_m , from the motion detector into account, the output is given by:

$$F_{\text{int}}(\underline{x}, n) = P_m X_m(\underline{x}, n) + (1 - P(m)) X_s(\underline{x}, n) \quad (54.4)$$

In most practical cases the output P_m has a nonlinear relation with the actual probability.

Algorithms with an Edge Detector

To detect the orientation of a spatial edge, usually the differences between pairs of spatially neighboring pixels are calculated. Again it is a bit unrealistic to expect that a zero difference is a reliable indication of a spatial direction in which the signal is stationary. The same problems (noise, alias, carriers, timing-jitter) occur as with motion detection. The edge detector (ED) is applied to switch or fade between at least two but usually more processing modes, each of them optimal for interpolation of a certain orientation of the spatial edge. Examples are:

- De-interlacing. The ED fades between vertical line-averaging and diagonal averaging ($+/- 45^\circ$, or even more angles).
- Up-conversion to a higher resolution format. A simple bi-linear interpolation filter is applied with its coefficients adapted to the output of the edge detector.

FIGURE 54.5: Identification of pixels as applied for direction dependent spatial interpolation.

In Fig. 54.5, X is the pixel to be interpolated for the sequential scan conversion and the result applying pixels in a neighborhood (A, B, C, D, E and F) is either X_a, X_b , or X_c , where:

$$X_a = 0.5[A + F] = 0.5 \left[F \left(\underline{x} - \begin{pmatrix} 1 \\ 1 \end{pmatrix}, n \right) + F \left(\underline{x} + \begin{pmatrix} 1 \\ 1 \end{pmatrix}, n \right) \right] \quad (54.5)$$

and:

$$X_b = 0.5[B + E] = 0.5 \left[F \left(\underline{x} - \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n \right) + F \left(\underline{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n \right) \right] \quad (54.6)$$

and:

$$X_c = 0.5[C + D] = 0.5 \left[F \left(\underline{x} + \begin{pmatrix} +1 \\ -1 \end{pmatrix}, n \right) + F \left(\underline{x} + \begin{pmatrix} -1 \\ +1 \end{pmatrix}, n \right) \right] \quad (54.7)$$

The selection of X_a, X_b , or X_c to the interpolated output F_{int} is controlled by a luminance gradient indication calculated from the same neighborhood:

$$F_{\text{int}}(\underline{x}, n) = \begin{cases} X_a, & (|A - F| < |C - D| \wedge |A - F| < |B - E|) \\ X_b, & (|B - E| \leq |A - F| \wedge |B - E| \leq |C - D|) \\ X_c, & (|C - D| < |A - F| \wedge |C - D| < |B - E|) \end{cases} \quad (54.8)$$

In this example, the gradient is calculated on the same pixels that are used in the interpolation step. This is not necessarily the case. Similar to the earlier described motion detector, it is advantageous to filter the video signal prior to and/or after the rectification in Eq. (54.8). Also the decision, i.e., the optimal interpolation angle, can be low-pass filtered to improve the consistency of the interpolation angle. Finally, the edge dependent interpolation can be combined with (motion adaptive or motion compensated) temporal interpolation to improve the interpolation quality of near horizontal edges.

Implicit Detection in Nonlinear Interpolation Filters

Many nonlinear interpolation methods have been described. Most popular is the class of order statistical filters. Combinations with linear (bandsplitting) filters are known, optimizing the interpolation for individual spectrum parts. We will limit ourselves to some basic examples here.

An illustration of a basic inherently adapting filter is shown in Figure 54.6. The line to be inter-

FIGURE 54.6: Sequential scan conversion with three-tap vertical-temporal median filtering. The thin lines show which pixels are input for the median filter.

polated is found as the median of the spatially neighboring lines (a and b) and the corresponding line (c) from the previous field:

$$F_{\text{int}}(\underline{x}, n) = \text{median} [a, b, c] =$$

$$\text{median} \left[F \left(\underline{x} + \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n \right), F \left(\underline{x} - \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n \right), F(\underline{x}, n-1) \right] \quad (54.9)$$

with:

$$\text{median} (X, Y, Z) = \begin{cases} X, & (Y \leq X \leq Z \vee Z \leq X \leq Y) \\ Y, & (X < Y \leq Z \vee Z \leq Y < X) \\ Z, & (\text{otherwise}) \end{cases} \quad (54.10)$$

The inherent adaptation to edges is understood as follows: In case of a temporal edge (i.e., motion) larger than the spatial edge (i.e., vertical detail), the difference between a and b is relatively small compared to their difference with c. Therefore, an intra-field interpolation results (a or b is copied). In case of a non-moving vertical edge, the difference between a and b will be relatively large compared to the difference between c and a or b. In this case, the inter-field interpolation (c is copied) is most likely.

It is possible to combine edge detectors with non-linear filters, e.g., a so-called weighted median filter. In a weighted median filter, the (integer) weight given to a sample indicates the number of times its value is included in the input of the filter to the ranking stage. An increase of this weight increases the chance this sample value is selected as the median. It therefore provides a method, using the output of an edge detector with uncertainties, to statistically improve the performance of the interpolation.

We will again use Fig. 54.5 to identify the location of the pixels used in the interpolation. The output value for the pixel position indicated with X results as:

$$F_{\text{int}}(\underline{x}, n) = \text{median} \left[A, B, C, D, E, F, \alpha \cdot X^{-1}, \beta \cdot \frac{B+E}{2} \right], (\alpha, \beta \in \mathbb{N}) \quad (54.11)$$

with:

$$X^{-1} = F(\underline{x}, n-1), \quad A = F \left(\underline{x} - \begin{pmatrix} 1 \\ 1 \end{pmatrix}, n \right), \quad B = F \left(\underline{x} - \begin{pmatrix} 0 \\ 1 \end{pmatrix}, n \right), \dots \dots \dots \quad (54.12)$$

as illustrated in Fig. 54.5. The weighting (α and β) implies that an assumed “important” pixel is fed more than once to the median calculating circuit:

$$\alpha \cdot A = \frac{A, A, A, \dots, A, A}{\alpha \text{ times}} \quad (54.13)$$

The combination arises if a motion detector is used to control the weighting factors of the pixel from the previous field and that of the value found by line averaging. A large value of α increases the probability of field insertion, while a large β causes an increased probability of line averaging.

Although the examples in this section are limited to de-interlacing, it should be noted that proposals exist for field rate conversion as well.

Algorithms with a Motion Estimator

The idea to interpolate picture content in the direction in which it is most correlated can be extended to a three-dimensional case. This results in an interpolation along the motion trajectory. Figure 54.7 defines the motion trajectory as the line that connects identical picture parts in a sequence

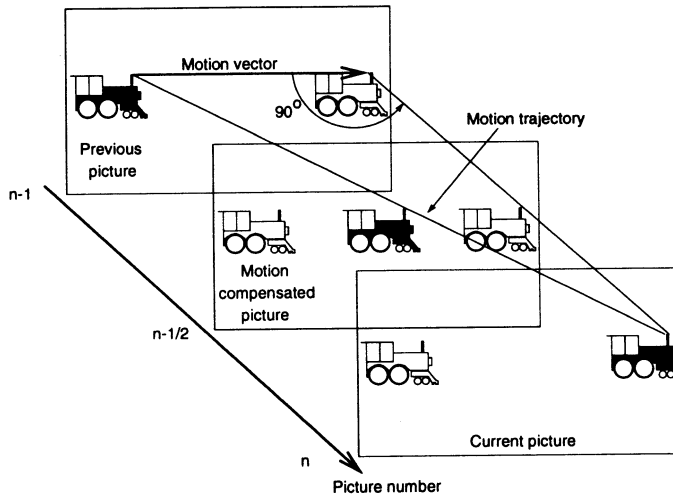

FIGURE 54.7: Identical picture parts of successive images lie on the *motion trajectory*. Its projection in the image plane is the *motion vector*.

of pictures. The projection of this motion trajectory between two successive pictures on the image plane, called the motion vector, is also shown in this figure. Not all temporal information changes can be described adequately as object velocities: e.g., fades and concealed or obscured background. Nevertheless, this method has the strongest physical background, as due to their inertia it always takes time for objects to completely disappear, or change geometry, resulting in a strong correlation of successive images after compensation for motion. This is in contrast to spatial (edge adaptive) interpolation for which there is a statistical but no physical background.

Knowledge of motion vectors allows us to interpolate image data at any temporal instance between two successive pictures. The most common form uses motion compensated averaging according to:

$$F_{\text{int}}(\underline{x}, n + \alpha) = 1/2 \cdot \left[F(\underline{x} - \alpha \underline{D}(\underline{x}, n), n) + F(\underline{x} + (1 - \alpha) \underline{D}(\underline{x}, n), n + 1) \right], \quad (0 \leq \alpha \leq 1) \quad (54.14)$$

where $\underline{D}(\underline{x}, n)$ is the object displacement at position $\underline{x} = (x, y)^T$ estimated between fields n and $n+1$, while α determines the temporal instance for which the interpolated data has to be valid. However, all previously mentioned interpolation methods that involve a temporal component can be used as a basis of a motion compensated interpolation. So linear, nonlinear, motion adaptive, edge adaptive, and inherently adapting interpolation methods can be upgraded toward their motion-compensated counterparts. Furthermore, bandsplitting can be used to sophisticate the interpolation.

We will not elaborate further on these methods as they follow straightforward from the earlier text. We will make an exception, however, for temporal interpolation on interlaced signals, as this poses non-trivial problems even with knowledge of local motion.

Motion Compensated De-Interlacing

In general, the pixels required for the motion compensated interpolation do not exist in the time discrete input signal, e.g., due to non-integer velocities. In the horizontal domain this problem can be solved with linear SRC-theory, but not in the vertical domain. Three solutions for this problem have been proposed:

1. Application of a generalized sampling theory (GST).

2. Straight extension of the motion vector into earlier pictures until it points (almost) to an existing pixel.
3. Recursive de-interlacing of the signal.

The implication of GST is that it is possible to perfectly reconstruct a signal sampled at $1/n$ times the Nyquist rate if n independent sets of samples describe the signal. The de-interlacing problem is a specific case for which $n = 2$. The required two sets are the current field and the motion compensated previous field, respectively. If the two do not coincide, i.e., the object does not have an odd integer vertical motion vector component, the independency constraint is fulfilled, and the problem can theoretically be solved. Practical problems are:

- a. The velocity can have an odd vertical component.
- b. Perfect reconstruction requires the use of pixels from many lines, for which the velocity need not be constant.
- c. For nearly odd integer valued vertical velocities, noise may be enhanced.

Solution 2 is valid only if we assume the velocity constant over a larger temporal interval. This is a rather severe limitation which makes the method practically useless. Solution 3 is based on the assumption that it is possible at some time to have a perfectly de-interlaced picture in a memory. Once this is true, the picture is used to de-interlace the next input field. With motion compensation, this solution can be perfect as the de-interlaced picture in the memory allows the use of SRC-theory also in the vertical domain. If this new de-interlaced field is written in the memory, it can be used to de-interlace the next incoming field. Limitations of this method are:

- a. Propagation of motion vector and interpolation errors.
- b. Even a perfectly de-interlaced picture can contain alias in the vertical domain in the common case of a camera without an optical prefilter.

In practice, problem a is the more serious one, particularly for nearly odd vertical velocities.

Although there are restrictions, motion compensated interpolation techniques for field rate up-conversion and de-interlacing provide the most advanced option. However, they require nontrivial algorithms to measure object displacements between consecutive images. These motion estimation methods therefore shall be discussed more extensively in the next section.

54.5 Motion Estimation

This section provides an overview of motion estimation algorithms developed over time. The estimators applicable for scanning format conversion require additional constraints which are discussed in the last part of this section.

54.5.1 Pel-Recursive Estimators

The category of pel-recursive motion estimators can be derived from iterative methods that use a previously calculated motion vector \underline{D}^{i-1} to find the result vector \underline{D}^i according to:

$$\underline{D}^i = \underline{D}^{i-1} + \text{update} \quad (54.15)$$

Several algorithms based on iteration can be found in the literature. A common form applies iterative minimization of the squared value of the displaced frame difference (DFD) along the steepest gradient of the luminance function:

$$\underline{D}^i = \underline{D}^{i-1} - \frac{1}{2} \cdot \alpha \cdot \begin{pmatrix} \delta/\delta D_x^{i-1} \\ \delta/\delta D_y^{i-1} \end{pmatrix} DFD^2 \left(\underline{x}, \underline{D}^{i-1}, n \right) \quad (54.16)$$

where the DFD is defined as:

$$DFD(\underline{x}, \underline{D}^{i-1}, n) = F(\underline{x}, n) - F(\underline{x} - \underline{D}^{i-1}, n-1) \quad (54.17)$$

and:

$$\underline{D}^i = \begin{pmatrix} D_x^i \\ D_y^i \end{pmatrix} \quad (54.18)$$

As before, n stands for the field or picture number. The constant α is positive and determines the speed of convergence and the accuracy of the estimate. The value of α is limited to a maximum, since instability or a noisy estimation result can occur for higher values. Equation (54.16) can be rewritten as:

$$\underline{D}^i = \underline{D}^{i-1} - \alpha \cdot DFD(\underline{x}, \underline{D}^{i-1}, n) \cdot \begin{pmatrix} \delta/\delta x \\ \delta/\delta y \end{pmatrix} F(\underline{x} - \underline{D}^{i-1}, n) \quad (54.19)$$

The method is known as “steepest descent algorithm”. The updating process can be stopped after a fixed number of iterations, at the moment the update term falls under a threshold, or in case slow convergence or even divergence is detected. Rather than iterating the estimation process in a fixed position of the picture, the estimated result from a previously scanned position in the same picture can be used as the prediction for the present location. We shall then speak of a spatial recursive process, and if for every pixel an update is calculated, the name “pel-recursive motion estimation” is commonly used. The spatial prediction can be based on either a single previously calculated result, in which case the convergence shall be one-dimensional, or on a number of earlier calculated vectors. In case more than one vector is used, the design can select the best according to a criterion before or after updating, e.g., the smallest DFD or a weighted average can be calculated. The coefficients that determine the weighting can be based on statistical properties of the vector field. Depending on the choice of the relative positions in the picture from which prediction vectors are taken, a one- or two-dimensional convergence can result. In the case of temporal recursion, a further refinement can be obtained by motion compensating the prediction values from the preceding field before weighting them with the values from the present field.

The algorithm can be improved by calculating the update term from a group of pixels rather than from only one pixel. This is then referred to as “gradient summed error algorithm”:

$$\underline{D}^i = \underline{D}^{i-1} - \alpha \cdot \sum_{\underline{x} \in \text{group}} \left[DFD(\underline{x}, \underline{D}^{i-1}, n) \cdot \begin{pmatrix} \delta/\delta x \\ \delta/\delta y \end{pmatrix} F(\underline{x} - \underline{D}^{i-1}, n) \right] \quad (54.20)$$

Again the group can extend into a one-, two-, or three-dimensional neighborhood. Weighted averaging is an option and weights can be adapted to image statistics. In case of gradients taken from a temporally neighboring position, motion compensation can be applied prior to weighting with the spatial neighboring gradients.

Simplifications of the algorithm are possible. Particularly the prevention of multiplication is useful, and possible, e.g., by only using the sign of the gradient to determine the direction of the update with a fixed length.

In the literature, many variants of the steepest descent or gradient summed error algorithm are described, which mainly differ from the above-mentioned algorithms in that the convergence speed determining constant α is substituted by variables to adapt the estimator to local picture statistics.

54.5.2 Block-Matching Algorithm

In block-matching motion estimation algorithms, a displacement vector is assigned to the center \underline{X} of a block of pixel positions $B(\underline{X})$ in the current field n by searching a similar block within a search

area $SA(\underline{X})$, also centered at \underline{X} , but in the previous field $n - 1$. The similar block has a center that is shifted with respect to \underline{X} over the displacement vector $\underline{D}(\underline{X}, n)$. To find $\underline{D}(\underline{X}, n)$, a number of candidate vectors \underline{C} are evaluated applying an error measure $\in(\underline{C}, \underline{X}, n)$ to quantify block similarity. Figure 54.8 illustrates the procedure.

FIGURE 54.8: Block of size $X \times Y$ in current field n and trial block in search area $SA(\underline{X})$ in previous field $n - 1$, shifted over candidate vector \underline{C} .

More formally, CS^{\max} is defined as the set of candidate vectors \underline{C} , describing all possible displacements (integer on the pixel grid) with respect to \underline{X} within the search area $SA(\underline{X})$ in the previous image:

$$CS^{\max} = \{ \underline{C} \mid -N \leq C_x \leq +N, -M \leq C_y \leq +M \} \quad (54.21)$$

where N and M are constants limiting $SA(\underline{X})$. Furthermore, a block $B(\underline{X})$ centered at \underline{X} and of size $X \times Y$ consisting of pixel positions \underline{x} in the present field n , is now considered:

$$B(\underline{X}) = \{ \underline{x} \mid X_x - X/2 \leq x \leq X_x + X/2 \wedge X_y - Y/2 \leq y \leq X_y + Y/2 \} \quad (54.22)$$

The displacement vector $\underline{D}(\underline{X}, n)$ resulting from the block-matching process is a candidate vector \underline{C} which yields the minimum value of an error function $\in(\underline{C}, \underline{X}, n)$:

$$\underline{D}(\underline{X}, n) \in \{ \underline{C} \in CS^{\max} \mid \in(\underline{C}, \underline{X}, n) \leq \in(\underline{F}, \underline{X}, n) \forall \underline{F} \in CS^{\max} \} \quad (54.23)$$

If the vector $\underline{D}(\underline{X}, n)$ with the smallest matching error is assigned to all pixel positions \underline{x} in the block $B(\underline{X})$:

$$\forall \underline{x} \in B(\underline{X}):$$

$$\underline{D}(\underline{x}, n) \in \{ \underline{C} \in CS^{\max} \mid \in(\underline{C}, \underline{X}, n) \leq \in(\underline{F}, \underline{X}, n) \forall \underline{F} \in CS^{\max} \} \quad (54.24)$$

rather than to the center pixel only, a large reduction of computations is achieved. As an implication, consecutive blocks $B(\underline{X})$ are not overlapping.

The error value for a given candidate vector \underline{C} is a function (COST) of the luminance values of the pixels in the current block and those of the shifted block from a previous field, summed over the block $B(\underline{X})$:

$$\in(\underline{C}, \underline{X}, n) = \sum_{\underline{x} \in B(\underline{X})} \text{COST} [F(\underline{x}, n), F(\underline{x} - \underline{C}, n - p)] \quad (54.25)$$

A common choice for p is either 1 or 2, depending on whether the signal is interlaced or not.

Although the COST function itself can be rather straightforward and simple to implement, the high repetition factor for this calculation creates a huge burden. To save calculational effort in block-matching motion estimation algorithms, several methods have been published. The usual ingredients are:

1. The use of a simpler COST function.
2. Estimation on sub-sampled picture material.
3. Design of a clever search strategy, preventing that all possible vectors need to be checked.

Concerning option 1, there is almost general consensus. The most popular choice thus far for the error function is the Summed Absolute Difference (SAD) criterion:

$$\epsilon(\underline{C}, \underline{X}, n) = SAD(\underline{C}, \underline{X}, n) = \sum_{\underline{x} \in B(\underline{X})} |F(\underline{x}, n) - F(\underline{x} - \underline{C}, n - p)| \quad (54.26)$$

Most important alternatives are the Mean Square Error (MSE), and the Normalized Cross Correlation Function (NCCF) criterion. The simpler error functions that have been designed will not be discussed here, as the economizing hardly ever justifies the performance loss.

Option 2 is straightforward and has little negative effect on the performance with sub-sampling factors up to four. Option 3 is the most effective, and will be dealt with separately in the next section.

54.5.3 Search Strategies

Sub-Sampled Full Search

In the most straightforward search strategy for all candidate vectors \underline{C} in the search area, the matching error for a block $B(\underline{X})$ of pixel positions is calculated. The method is referred to as full search, exhaustive search, or brute force block-matching. To economize the calculational effort, the matching errors of only half of the possible result vectors $\underline{D}(\underline{X}, n)$ can be calculated in a first step, using a first candidate set C^S which is a subset of $C^{S^{\max}}$. Figure 54.9 illustrates this option, further showing the candidate vectors in the second step of the algorithm.

FIGURE 54.9: Candidate vectors tested in the second step around $\underline{D}^1(\underline{X}, n)$ for sub-sampled full search block-matching. The grid shown is the pixel grid.

N-Step Search

The idea to adapt the search area from coarse to fine is not limited to a two-step process. As illustrated in Fig. 54.10, the first step of a three-step block-matcher performs a search on a coarse grid consisting of only nine candidate vectors in the entire search area. The second step includes a finer search, with eight candidate vectors around the best matching vector of the first step, and finally in

FIGURE 54.10: Illustration of the three-step search. Vectors resulting from the steps are indicated with the step number. The candidates in each step are shaded as in a, b, and c, respectively.

the third step a search on the full resolution grid is performed, with another eight candidates around the best vector of the second step. Note that a search range of ± 6 pels is assumed; other search areas require modifications, either resulting in less accurate vectors or in more consecutive steps. Generalizations to N-steps block-matching are obvious.

Related is the 2-D logarithmic, or cross-search, method that checks five vectors per step, one in the middle, four symmetrically around it (two with a different x-component and two with a different y-component). Again, four vectors are checked around the result, and the distance between the candidates is halved when the best matching vector is the middle one. Hence, the number of consecutive steps depends on the resulting vector, which is a drawback, as the hardware has to be designed for the worst case situation and cannot profit from a low average number of steps.

One-at-a-Time-Search

Yet a further reduction of candidate vectors can be realized if the two-dimensional optimization problem is split into two separate one-dimensional optimizations. The candidate set, for step i of the algorithm, $CS_x^i(\underline{X}, n)$, is adapted during the process, as in the previously discussed algorithms, but contains only three candidate vectors $\underline{C}(\underline{X}, n)$. Departing from vector $\underline{0}$, this method performs a search for the minimum error along the x -axis of the search area:

$$CS_x^i(\underline{X}, n) = \left\{ \underline{C} | \underline{C} = \underline{D}^{i-1}(\underline{X}, n) + \underline{U}, U_x = 0 \vee \pm 1, U_y = 0 \right\} \quad (54.27)$$

The procedure is repeated N times until $\underline{D}^N(\underline{X}, n) = \underline{D}^{N-1}(\underline{X}, n)$. From this minimum a search is started parallel to the y -axis and repeated M times until $\underline{D}^{M+N}(\underline{X}, n) = \underline{D}^{D+N-1}(\underline{X}, n)$.

In its simplest form, shown in Fig. 54.11, the process stops at this minimum and the estimated motion vector $\underline{D}(\underline{x}, n) = \underline{D}^{M+N}(\underline{X}, n)$ for all pixel positions \underline{x} in $B(\underline{X})$. It is possible, however, to refine the result by repeating the OTS procedure, departing with every iteration from the previous result $\underline{D}^{M+N}(\underline{X}, n)$.

FIGURE 54.11: One-at-a-time search (OTS) block-matching. The new candidate vectors that have to be evaluated for a number of successive steps is indicated.

A problem of all efficient search techniques is the risk of converging to a local rather than the global minimum of the match error function. The coarser the initial grid of candidate vectors is, the higher this risk. It can be reduced by prefiltering the video information prior to the motion estimation, but this introduces inaccuracies in detailed picture parts. If the prefiltering and the block size are adapted separately for every step in the search procedure, we arrive at the hierarchical block-matching algorithms, dealt with in the next subsection.

54.6 Motion Estimation and Scanning Format Conversion

In situations where motion vectors are generated for temporal interpolation of pictures, it is important that the vectors represent the real velocities of objects, or the “true-motion” as it is called, in the picture. None of the described motion estimators is guaranteed to yield true motion vectors. They generate a vector that yields the “best match” or the minimal displaced frame difference and often even only the *local* best match, or the *local* minimum of the *DFD*.

To improve this relation between estimated displacement vectors and actual object velocity, methods have been designed which modify either the algorithm or the displacement vectors. The common solution is based on the observation that the velocity field does not usually contain many fine details. In other words, the motion vector field is spatially consistent: large areas (objects, background) with identical vectors usually exist. Object inertia further causes velocity fields to be temporally consistent. To improve consistency, a number of methods have been proposed. Two classes can be distinguished, combinations of which are possible:

- Methods, that perform a *post-processing* on the output vector field to improve the consistency.
- Methods in which a smoothness constraint is *integrated* in the estimator.

Postprocessing can be straightforward, applying basically low-pass filtering to improve the spatial and/or temporal consistency or smoothness of the vector field generated by any motion estimation algorithm. Often the filter is a nonlinear one; the median particularly is popular as it is edge preserving. More sophisticated methods in this class merely use the output vector field of the estimator to initialize a simulated annealing or genetic optimization algorithm using a new cost function, usually including smoothness constraints.

Integrated solutions can be expected to realize a better performance than the straightforward representatives of the first class at a lower expense than the sophisticated processing methods. The

constraint can either be explicit, e.g., by adding a “discontinuity penalty” to the error criterion of a block-matcher:

$$\begin{aligned} \varrho(\underline{C}, \underline{X}, n) = & \sum_{\underline{x} \in B(\underline{X})} |F(\underline{x}, n), -F(\underline{x} - \underline{C}, n - 1)| \\ & + \alpha \cdot \left\| \underline{D}\left(\underline{X}, -\begin{pmatrix} X \\ 0 \end{pmatrix}, n\right) - \underline{C} \right\| + \beta \cdot \left\| \underline{D}\left(\underline{X}, -\begin{pmatrix} 0 \\ Y \end{pmatrix}, n\right) - \underline{C} \right\| \end{aligned} \quad (54.28)$$

(where the values of α and β determine the smoothness and it is proposed to adapt their value in the neighborhood of edges in the image), or implicit through *hierarchy* or *recursion*, which will be discussed separately. Again, both classes can be combined.

54.6.1 Hierarchical Motion Estimation

Hierarchical motion estimators realize a consistent velocity field by initializing local estimators with a global estimate, often in more than two steps. In sub-band coding terminology, a resolution pyramid is built and coarse vectors are estimated on the low frequency band. The result is used as a prediction for a more accurate estimate at the next sub-band, which contains higher frequencies, etc. At the top of the pyramid, the signal is strongly prefiltered and sub-sampled. The bandwidth of the filter increases and the sub-sampling factors decrease, going down in the hierarchy, until the full resolution is reached on the lowest hierarchical level.

The value of the motion vector in field n at hierarchical level l , $\underline{D}^{i-1}(\underline{X}, n, l)$, and using logarithmic search, is found as:

$$\begin{aligned} \underline{D}^{i-1}(\underline{X}, n, l) \in & \begin{cases} \left\{ \underline{D}^N(\underline{X}, n, l-1) \right\}, & (i = 1) \\ \left\{ \underline{C} \in CS^{i-1}(\underline{X}, n, l) \mid \varrho(\underline{C}, \underline{X}, n) \leq \varrho(\underline{F}, \underline{X}, n), \forall \underline{F} \in CS^{i-1}(\underline{X}, n, l) \right\}, & (i > 1) \end{cases} \end{aligned} \quad (54.29)$$

where the search area is defined as:

$$\begin{aligned} CS^i(\underline{X}, n, l) = & \left\{ \underline{C} \mid \underline{C} = \underline{D}^{i-1}(\underline{X}, n, l) + \underline{U}, U_x = 0 \vee \pm 2^{N-i} \wedge U_y = 0 \vee \pm 2^{N-i} \right\}, \\ & i = 1 \dots N, \quad l = 1 \dots L \end{aligned} \quad (54.30)$$

$\underline{D}^N(\underline{X}, n, l-1)$ is the result vector for the block at position \underline{X} in field n in the last (N th) step of the logarithmic search, at one higher ($l-1$) hierarchical level.

The method is also referred to as multi-resolution, or multi-grid motion estimation. The initial block size can be the total image, which prevents limitation of the consistency to parts of the picture. The inverted approach has also been published, performing block-matching on initially small blocks, which are grown to larger sizes until the minimum of the match error is considered clearly distinct. Combinations with other than the logarithmic search strategy are possible, and the hierarchical method is not limited to block-matching algorithms either.

Phase Plane Correlation

An important variant of a two step hierarchical motion estimation is a method called phase plane correlation (PPC). This algorithm is an extension of earlier Fourier techniques for motion estimation, which were capable of generating global displacement vectors only. In the PPC algorithm a two-level hierarchy is proposed.

In the first hierarchical level, on fairly large blocks (typically 64 by 64), a limited number of candidate vectors, usually less than 10, is generated, which are fed to the second level. Here one of

FIGURE 54.12: Hierarchical block-matching. Results from an estimation process at a down-sampled image are used to initialize the next estimation process on a higher resolution image.

these candidate vectors is assigned as the resulting vector to a much smaller area (typically 1 by 1 up to 8 by 8, is reported) inside the large initial block.

The name of the method refers to the procedure used for generating the candidate vectors in the first step. For the block in the current field n , the Discrete Fourier Transform (DFT) of the luminance function $F(\underline{x}, n)$ will be notated as $G(\underline{f}, n)$. The so-called phase difference matrix $PD(\underline{x}, n)$ is calculated according to:

$$PD(\underline{x}, n) = \mathcal{F}^{-1} \left(\frac{G(\underline{f}, n) \cdot G^*(\underline{f}, n - p)}{|G(\underline{f}, n)| \cdot |G(\underline{f}, n - p)|} \right) \quad (54.31)$$

The resulting matrix or “correlation surface” exhibits peaks corresponding to the relative displacement of the information in the two blocks. The Fourier transformation reduces the computational complexity, and enables simple filtering in the frequency domain. Most important is the significantly increased sharpness of the correlation peaks by normalizing each frequency component prior to the reverse transformation. A “peak hunting” algorithm is applied to find the largest peaks in the phase difference matrix, which correspond to the best matching candidate vectors. Sub-pixel accuracy better than a tenth of a pixel can be achieved by fitting a quadratic curve through the elements in this matrix. For interlaced video signals, $p = 2$ is the common choice.

The peaks in the phase plane can be applied to identify the most likely candidate vectors $\underline{C}(\underline{x}, n)$ for a consecutive block-matching algorithm, evaluating all candidates in each sub-block in the area to which the phase plane corresponds.

54.6.2 Recursive Search Block-Matching

Rather than calculating promising candidate vectors for a block-matching algorithm on a lower resolution level or in the frequency domain on larger blocks, the recursive search block-matcher takes spatial and/or temporal “prediction vectors” from a 3-D neighborhood. This implicitly assumes spatial and/or temporal consistency. If the assumption is false, this consistency in the vector field results anyway, as there are no other candidate vectors available. As far as the predictions are concerned, there is a strong similarity with the pel-recursive algorithms, and the various options described there are globally valid here too. Figure 54.13 illustrates a proposed choice of predictions.

The most common updating process involves a single, or a very few, update vectors added to either of the prediction vectors. It was suggested, for example, to apply a candidate set $CS(\underline{X}, n)$:

FIGURE 54.13: Relative position of current block and blocks from which prediction vectors can be taken in a recursive search block-matcher.

$$\begin{aligned}
 CS(\underline{X}, n) = & \\
 & \left\{ \underline{C} \in CS^{\max} \mid \underline{C} = \underline{D}\left(\underline{X} - \begin{pmatrix} X \\ Y \end{pmatrix}, n\right) + \underline{U}_a(\underline{X}, n) \vee \underline{C} = \underline{D}\left(\underline{X} - \begin{pmatrix} -X \\ Y \end{pmatrix}, n\right) + \underline{U}_b(\underline{X}, n) \right\} \\
 & \cup \left\{ \underline{D}\left(\underline{X} - \begin{pmatrix} X \\ Y \end{pmatrix}, n\right), \underline{D}\left(\underline{X} - \begin{pmatrix} -X \\ Y \end{pmatrix}, n\right), \underline{C} = \underline{D}\left(\underline{X} + \begin{pmatrix} 0 \\ 2Y \end{pmatrix}, n-1\right) \right\}
 \end{aligned} \quad (54.32)$$

where the update vectors $\underline{U}_a(\underline{X}, n)$ and $\underline{U}_b(\underline{X}, n)$ may be alternately available, and taken from a limited fixed integer update set, such as:

$$\begin{aligned}
 US_i = & \left\{ \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \begin{pmatrix} 0 \\ -1 \end{pmatrix}, \begin{pmatrix} 0 \\ 2 \end{pmatrix}, \begin{pmatrix} 0 \\ -2 \end{pmatrix}, \right. \\
 & \left. \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \begin{pmatrix} -1 \\ 0 \end{pmatrix}, \begin{pmatrix} 3 \\ 0 \end{pmatrix}, \begin{pmatrix} -3 \\ 0 \end{pmatrix} \right\}
 \end{aligned} \quad (54.33)$$

Result vectors can have sub-pixel accuracy, if the update set (also) contains fractional update values. Quarter pel resolution, for example, is realized with adding:

$$US_f = \left\{ \begin{pmatrix} 0 \\ 0.25 \end{pmatrix}, \begin{pmatrix} 0 \\ -0.25 \end{pmatrix}, \begin{pmatrix} 0.25 \\ 0 \end{pmatrix}, \begin{pmatrix} -0.25 \\ 0 \end{pmatrix} \right\} \quad (54.34)$$

The method is very efficient and realizes, due to the inherent smoothness constraint, very coherent and close to true-motion vector fields, most suitable for scanning format conversion.

The image and video processing literature is rich with video compression algorithms. This chapter overviews the basic blocks of most video compression systems, discusses some important features required by many applications, e.g., scalability and error resilience, and reviews the existing video compression standards such as H.261, H.263, MPEG-1, MPEG-2, and MPEG-4.

55.1 Introduction

Video sources produce data at very high bit rates. In many applications, the available bandwidth is usually very limited. For example, the bit rate produced by a 30 frame/s color common intermediate format (CIF) (352×288) video source is 73 Mbits/s. In order to transmit such a sequence over a 64 Kbits/s channel (e.g., ISDN line), we need to compress the video sequence by a factor of 1140. A simple approach is to subsample the sequence in time and space. For example, if we subsample both chroma components by 2 in each dimension, i.e., 4:2:0 format, and the whole sequence temporally by 4, the bit rate becomes 9.1 Mbits/s. However, to transmit the video over a 64 kbits/s channel, it is necessary to compress the subsampled sequence by another factor of 143. To achieve such high compression ratios, we must tolerate some distortion in the subsampled frames.

Compression can be either lossless (reversible) or lossy (irreversible). A compression algorithm is lossless if the signal can be reconstructed from the compressed information; otherwise it is lossy. The compression performance of any lossy algorithm is usually described in terms of its *rate-distortion* curve, which represents the potential trade-off between the bit rate and the distortion associated with the lossy representation. The primary goal of any lossy compression algorithm is to optimize the rate-distortion curve over some range of rates or levels of distortion. For video applications, rate

is usually expressed in terms of bits per second. The distortion is usually expressed in terms of the peak-signal-to-noise ratio (PSNR) per frame or, in some cases, measures that try to quantify the subjective nature of the distortion.

In addition to good compression performance, many other properties may be important or even critical to the applicability of a given compression algorithm. Such properties include robustness to errors in the compressed bit stream, low complexity encoders and decoders, low latency requirements, and scalability. Developing scalable video compression algorithms has attracted considerable attention in recent years. Generally speaking, scalability refers to the potential to effectively decompress subsets of the compressed bit stream in order to satisfy some practical constraint, e.g., display resolution, decoder computational complexity, and bit rate limitations.

The demand for compatible video encoders and decoders has resulted in the development of different video compression standards. The international standards organization (ISO) has developed MPEG-1 to store video on compact discs, MPEG-2 for digital television, and MPEG-4 for a wide range of applications including multimedia. The international telecommunication union (ITU) has developed H.261 for video conferencing and H.263 for video telephony.

All existing video compression standards are hybrid systems. That is, the compression is achieved in two main stages. The first stage, motion compensation and estimation, predicts each frame from its neighboring frames, compresses the prediction parameters, and produces the prediction error frame. The second stage codes the prediction error. All existing standards use block-based discrete cosine transform (DCT) to code the residual error. In addition to DCT, others non-block-based coders, e.g., wavelets and matching pursuit, can be used.

In this chapter, we will provide an overview of hybrid video coding systems. In Section 55.2, we discuss the main parts of a hybrid video coder. This includes motion compensation, signal decompositions and transformations, quantization, and entropy coding. We compare various transformations such as DCT, subband, and matching pursuit. In Section 55.3, we discuss scalability and error resilience in video compression systems. We also describe a non-hybrid video coder that provides scalable bit-streams [28]. Finally, in Section 55.4, we review the key video compression standards: H.261, H.263, MPEG 1, MPEG 2, and MPEG 4.

55.2 Motion Compensated Video Coding

Virtually all video compression systems identify and reduce four basic types of video data redundancy: inter-frame (temporal) redundancy, interpixel redundancy, psychovisual redundancy, and coding redundancy. Figure 55.1 shows a typical diagram of a hybrid video compression system. First the current frame is predicted from previously decoded frames by estimating the motion of blocks or objects, thus reducing the inter-frame redundancy. Afterwards to reduce the interpixel redundancy, the residual error after frame prediction is transformed to another format or domain such that the energy of the new signal is concentrated in few components and these components are as uncorrelated as possible. The transformed signal is then quantized according to the desired compression performance (subjective or objective). The quantized transform coefficients are then mapped to codewords that reduce the coding redundancy. The rest of this section will discuss the blocks of the hybrid system in more detail.

55.2.1 Motion Estimation and Compensation

Neighboring frames in typical video sequences are highly correlated. This inter-frame (temporal) redundancy can be significantly reduced to produce a more compressible sequence by predicting each frame from its neighbors. Motion compensation is a nonlinear predictive technique in which the feedback loop contains both the inverse transformation and the inverse quantization blocks, as

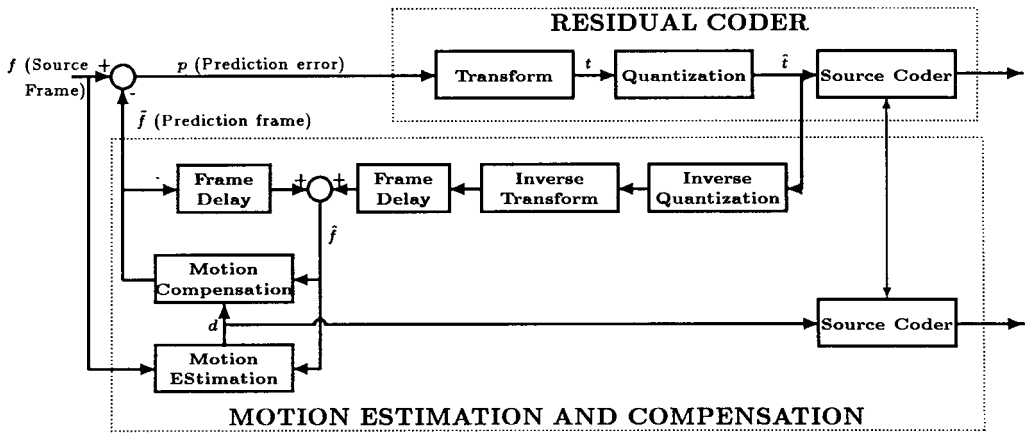

FIGURE 55.1: Motion compensated coding of video.

shown in Fig. 55.1.

Most motion compensation techniques divide the frame into regions, e.g., blocks. Each region is then predicted from the neighboring frames. The displacement of the block or region, d , is not fixed and must be encoded as side information in the bit stream. In some cases, different prediction models are used to predict regions, e.g., affine transformations. These prediction parameters should also be encoded in the bit stream.

To minimize the amount of side information, which must be included in the bit stream, and to simplify the encoding process, motion estimation is usually block based. That is, every pixel \vec{i} in a given rectangular block is assigned the same motion vector, d . Block-based motion estimation is an integral part of all existing video compression standards.

55.2.2 Transformations

Most image and video compression schemes apply a transformation to the raw pixels or to the residual error resulting from motion compensation before quantizing and coding the resulting coefficients. The function of the transformation is to represent the signal in a few uncorrelated components. The most common transformations are linear transformations, i.e., the multi-dimensional sequence of input pixel values, $f[\vec{i}]$, is represented in terms of the transform coefficients, $t[\vec{k}]$, via

$$f[\vec{i}] = \sum_{\vec{k}} t[\vec{k}] w_{\vec{k}}[\vec{i}] \quad (55.1)$$

for some $w_{\vec{k}}[\vec{i}]$. The input image is thus represented as a linear combination of basis vectors, $w_{\vec{k}}$. It is important to note that the basis vectors need not be orthogonal. They only need to form an over-complete set (matching pursuits), a complete set (DCT and some subband decompositions), or very close to complete (some subband decompositions). This is important since the coder should be able to code a variety of signals. The remainder of the section discusses and compares DCT, subband decompositions, and matching pursuits.

The DCT

There are two properties desirable in a unitary transform for image compression: the energy should be packed into a few transform coefficients, and the coefficients should be as uncorrelated

as possible. The optimum transform under these two constraints is the Karhunen-Loève transform (KLT) where the eigenvectors of the covariance matrix of the image are the vectors of the transform [10]. Although the KLT is optimal under these two constraints, it is data-dependent, and is expensive to compute. The discrete cosine transform (DCT) performs very close to KLT especially when the input is a first order Markov process [10].

The DCT is a block-based transform. That is, the signal is divided into blocks, which are independently transformed using orthonormal discrete cosines. The DCT coefficients of a one-dimensional signal, f , are computed via

$$t^{\text{DCT}}[Nb + k] = \frac{1}{\sqrt{N}} \begin{cases} \sum_{i=0}^{N-1} f[Nb + i], & k = 0 \\ \sum_{i=0}^{N-1} \sqrt{2} f[Nb + i] \cos \frac{(2i+1)k\pi}{2N}, & 1 \leq k < N \end{cases} \quad \forall b \quad (55.2)$$

where N is the size of the block and b denotes the block number.

The orthonormal basis vectors associated with the one-dimensional DCT transformation of Eq. (55.2) are

$$w_k^{\text{DCT}}[i] = \frac{1}{\sqrt{N}} \begin{cases} 1, & k = 0, 0 \leq i < N \\ \sqrt{2} \cos \frac{(2i+1)k\pi}{2N}, & 1 \leq k < N, 0 \leq i < N \end{cases} \quad (55.3)$$

Figure 55.2(a) shows these basis vectors for $N = 8$.

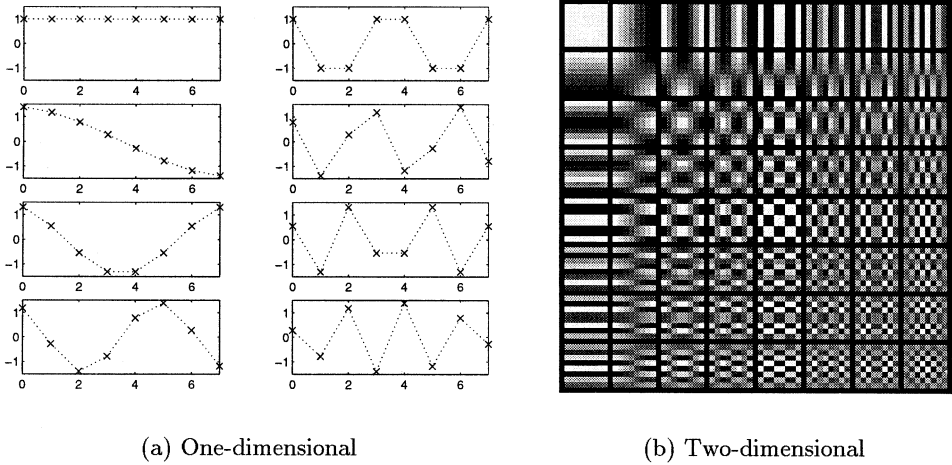

FIGURE 55.2: DCT basis vectors ($N = 8$): (a) one-dimensional and (b) separable two-dimensional.

The one-dimensional DCT described above is usually separably extended to two dimensions for image compression applications. In this case, the two-dimensional basis vectors are formed by the tensor product of one-dimensional DCT basis vectors and are given by

$$w_k^{\text{DCT}}[\vec{i}] = w_{k_1, k_2}^{\text{DCT}}[i_1, i_2] \triangleq w_{k_1}^{\text{DCT}}[i_1] \cdot w_{k_2}^{\text{DCT}}[i_2]; \quad 0 \leq k_1, k_2, i_1, i_2 < N$$

Figure 55.2(b) shows the two-dimensional basis vectors for $N = 8$.

The DCT is the most common transform in video compression. It is used in the JPEG still image compression standard, and all existing video compression standards. This is because it performs reasonably well at different bit rates. Moreover, there are fast algorithms and special hardware chips to compute the DCT efficiently.

The major objection to the DCT in image or video compression applications is that the non-overlapping blocks of basis vectors, $w_{\vec{k}}$, are responsible for distinctly “blocky” artifacts in the decompressed frames, especially at low bit rates. This is due to the quantization of the transform coefficients of a block independent from neighboring blocks. Overlapped DCT representation addresses this problem [15]; however, the common solution is to post-process the frame by smoothing the block boundaries [18, 22].

Due to bit rate restrictions, some blocks are only represented by one or a small number of coarsely quantized transform coefficients, hence the decompressed block will only consist of these basis vectors. This will cause artifacts commonly known as ringing and mosquito noise.

Figure 55.8(b) shows frame 250 of the 15 frame/s CIF Coast-guard sequence coded at 112 Kbits/s using a DCT hybrid video coder.¹ This figure provides a good illustration of the “blocking” artifacts.

Subband Decomposition

The basic idea of subband decomposition is to split the frequency spectrum of the image into (disjoint) subbands. This is efficient when the image spectrum is not flat and is concentrated in a few subbands, which is usually the case. Moreover, we can quantize the subbands differently according to their visual importance.

As for the DCT, we begin our discussion of subband decomposition by considering only a one-dimensional source sequence, $f[i]$. Figure 55.3 provides a general illustration of an N -band one-dimensional subband system. We refer to the subband decomposition itself as *analysis* and to the

FIGURE 55.3: 1D, N -band subband analysis and synthesis block diagrams. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

inverse transformation as *synthesis*. The transformation coefficients of bands 1, 2, \dots , N are denoted by the sequences $u_1[k]$, $u_2[k]$, \dots , $u_N[k]$, respectively. For notational convenience and consistency with the DCT formulation above, we write $t^{\text{SB}}[\cdot]$ for the sequence of all subband coefficients, arranged

¹ It is coded using H.263 [3], which is an ITU standard.

according to $t^{\text{SB}}[(\beta - 1) + Nk] = u_{\beta}[k]$, where $1 \leq \beta \leq N$ is the subband number. These coefficients are generated by filtering the input sequence with filters H_1, \dots, H_N and downsampling the filtered sequences by a factor of N , as depicted in Fig. 55.3. In subband synthesis, the coefficients for each band are upsampled, interpolated with the synthesis filters, G_1, \dots, G_N , and the results summed to form a reconstructed sequence, $\tilde{f}[i]$, as depicted in Fig. 55.3.

If the reconstructed sequence, $\tilde{f}[i]$, and the source sequence, $f[i]$, are identical, then the subband system is referred to as perfect reconstruction (PR) and the corresponding basis set is a complete basis set. Although perfect reconstruction is a desirable property, near perfect reconstruction (NPR), for which subband synthesis is only approximately the inverse of subband analysis, is often sufficient in practice. This is because distortion introduced by quantization of the subband coefficients, $t^{\text{SB}}[k]$, usually dwarfs that introduced by an imperfect synthesis system.

The filters, H_1, \dots, H_N , are usually designed to have band-pass frequency responses, as indicated in Fig. 55.4, so that the coefficients $u_{\beta}[k]$ for each subband, $1 \leq \beta \leq N$, represent different spectral components of the source sequence.

FIGURE 55.4: Typical analysis filter magnitude responses. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

The basis vectors for subband decomposition are the N -translates of the impulse responses, $g_1[i], \dots, g_N[i]$, of synthesis filters G_1, \dots, G_N . Specifically, denoting the k th basis vector associated with subband β by $w_{Nk+\beta-1}^{\text{SB}}$, we have

$$w_{Nk+\beta-1}^{\text{SB}}[i] = g_{\beta}[i - Nk] \quad (55.4)$$

Figure 55.5 illustrates five of the basis vectors for a particularly simple, yet useful, two-band PR subband decomposition, with symmetric FIR analysis and synthesis impulse responses. As shown in Fig. 55.5 and in contrast with the DCT basis vectors, the subband basis vectors overlap.

As for the DCT, one-dimensional subband decompositions may be separably extended to higher dimensions. By this we mean that a one-dimensional subband decomposition is first applied along one dimension of an image or video sequence. Any or all of the resulting subbands are then further decomposed into subbands along another dimension and so on. Figure 55.6 depicts a separable two-dimensional subband system. For video compression applications, the prediction error is sometimes decomposed into subbands of equal size.

Two-dimensional subband decompositions have the advantage that they do not suffer from the disturbing blocking artifacts exhibited by the DCT at high compression ratios. Instead, the most noticeable quantization-induced distortion tends to be ‘ringing’ or ‘rippling’ artifacts, which become most bothersome in the vicinity of image edges. Figures 55.11(c) and 55.8(c) clearly show this effect. Figure 55.11 shows frame 210 of the Ping-pong sequence compressed using a scalable, three-dimensional subband coder [28] at 1.5 Mbits/s, 300 Kbits/s, and 60 Kbits/s. As the bit rate decreases, we notice loss of detail and introduction of more ringing noise. Figure 55.8(c) shows frame 250 of the Coast-guard sequence compressed at 112 Kbits/s using a zerotree scalable coder [16]. The edges of the trees and the boat are affected by ringing noise.

FIGURE 55.5: Subband basis vectors with $N = 2$, $h_1[-2 \dots 2] = \sqrt{2} \cdot (-\frac{1}{8}, \frac{1}{4}, \frac{3}{4}, \frac{1}{4}, -\frac{1}{8})$, $h_2[-2 \dots 0] = \sqrt{2} \cdot (-\frac{1}{4}, \frac{1}{2}, -\frac{1}{4})$, $g_1[-1 \dots 1] = \sqrt{2} \cdot (\frac{1}{4}, \frac{1}{2}, \frac{1}{4})$, and $g_2[-1 \dots 3] = \sqrt{2} \cdot (-\frac{1}{8}, -\frac{1}{4}, \frac{3}{4}, -\frac{1}{4}, -\frac{1}{8})$. h_i and g_i are the impulse responses of the H_i (analysis) and G_i (synthesis) filters, respectively. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

Matching Pursuit

Representing a signal using an over-complete basis set implies that there is more than one representation for the signal. For coding purposes, we are interested in representing the signal with the fewest basis vectors. This is an NP-complete problem [14]. Different approaches have been investigated to find or approximate the solution. Matching pursuits is a multistage algorithm, which in each stage finds the basis vector that minimizes the mean-squared-error [14].

Suppose we want to represent a signal $f[i]$ using basis vectors from an over-complete dictionary (basis set) \mathcal{G} . Individual dictionary vectors can be denoted as:

$$w_\gamma[i] \in \mathcal{G}. \quad (55.5)$$

Here γ is an indexing parameter associated with a particular dictionary element. The decomposition begins by choosing γ to maximize the absolute value of the following inner product:

$$t = \langle f[i], w_\gamma[i] \rangle, \quad (55.6)$$

where t is the transform (expansion) coefficient. A residual signal is computed as:

$$R[i] = f[i] - t w_\gamma[i]. \quad (55.7)$$

This residual signal is then expanded in the same way as the original signal. The procedure continues iteratively until either a set number of expansion coefficients are generated or some energy threshold for the residual is reached. Each stage k yields a dictionary structure specified by γ_k , an expansion coefficient $t[k]$, and a residual R_k , which is passed on to the next stage. After a total of M stages, the signal can be approximated by a linear function of the dictionary elements:

$$\hat{f}[i] = \sum_{k=1}^M t[k] w_{\gamma_k}[i]. \quad (55.8)$$

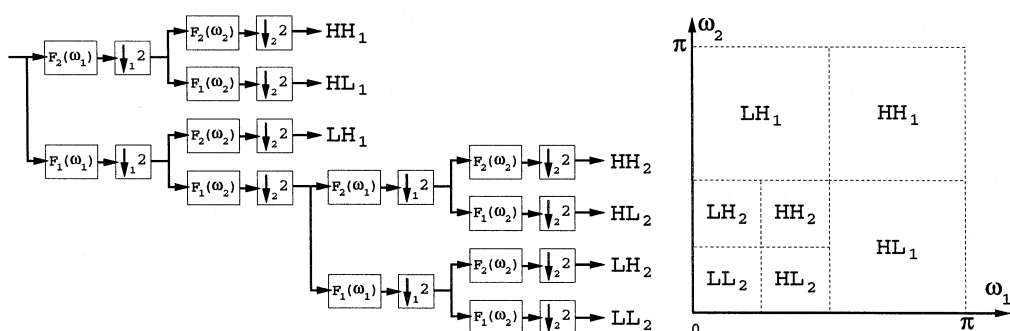

FIGURE 55.6: Separable spatial subband pyramid. Two level analysis system configuration and subband passbands shown. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

The above technique has useful signal representation properties. For example, the dictionary element chosen at each stage is the element that provides the greatest reduction in mean square error between the true signal $f[i]$ and the coded signal $\hat{f}[i]$. In this sense, the signal structures are coded in order of importance, which is desirable in situations where the bit budget is limited. For image and video coding applications, this means that the most visible features tend to be coded first. Weaker image features are coded later, if at all. It is even possible to control which types of image features are coded well by choosing dictionary functions to match the shape, scale, or frequency of the desired features.

An interesting feature of the matching pursuit technique is that it places very few restrictions on the dictionary set. The original Mallat and Zhang paper considers both Gabor and wave-packet function dictionaries, but such structure is not required by the algorithm itself [14]. Mallat and Zhang showed that if the dictionary set is at least complete, then $\hat{f}[i]$ will eventually converge to $f[i]$, though the rate of convergence is not guaranteed [14]. Convergence speed and thus coding efficiency are strongly related to the choice of dictionary set. However, true dictionary optimization can be difficult because there are so few restrictions. Any collection of arbitrarily sized and shaped functions can be used with matching pursuits, as long as completeness is satisfied.

Bergeaud and Mallat used the matching pursuit technique to represent and process images [1]. Neff and Zakhor have used the matching pursuit technique to code the motion prediction error signal [20]. Their coder divides each motion residual into blocks and measures the energy of each block. The center of the block with the largest energy value is adopted as an initial estimate for the inner product search. A dictionary of Gabor basis vectors, shown in Fig. 55.7, is then exhaustively matched to an $S \times S$ window around the initial estimate. The exhaustive search can be thought of as follows. Each $N \times N$ dictionary structure is centered at each location in the search window, and the inner product between the structure and the corresponding $N \times N$ region of image data is computed. The largest inner-product is then quantized. The location, basis vector index, and quantized inner product are then coded together.

Video sequences coded using matching pursuit do not suffer from either blocking or ringing artifacts, because the basis vectors are only coded when they are well-matched to the residual signal. As bit rate decreases, the distortion introduced by matching pursuit coding takes the form of a gradually increasing blurriness (or loss of detail). Since matching pursuits involves exhaustive search, it is more complex than DCT approaches, especially at high bit rates.

FIGURE 55.7: Separable two-dimensional 20×20 Gabor dictionary.

Figure 55.8(d) shows frame 250 of the 15 frame/s CIF Coast-guard sequence coded at 112 Kbits/s using the matching pursuit video coder described by Neff and Zakhor [20]. This frame does not suffer from the blocky artifacts, which affect the DCT coders as shown in Fig. 55.8(b). Moreover, it does not suffer from the ringing noise, which affects the subband coders as shown in Figs. 55.8(c) and 55.11(c).

55.2.3 Discussion

Figure 55.8 shows frame 250 of the 15 frame/s CIF Coast-guard sequence coded at 112 Kbits/s using DCT, subband, and matching pursuit coders. The DCT coded frame suffers from blocking artifacts. The subband coded frame suffers from ringing artifact.

Figure 55.9 compares the PSNR performance of the matching pursuit coder [20] to a DCT (H.263) coder [3] and a zerotree subband coder [16] when coding the Coast-guard sequence at 112 Kbits/s. The matching pursuit coder [20] in this example has consistently higher PSNR than the H.263 [3] and the zerotree subband [16] coders. Table 55.1 shows the average luminance PSNRs for different sequences at different bit rates. In all examples mentioned in Table 55.1, the matching pursuit coder has higher average PSNR than the DCT coder. The subband coder has the lowest average PSNR.

TABLE 55.1 The Average Luminance PSNR of Different Sequences at Different Bit Rates When Coding Using a DCT Coder (H.263) [3], Zero-Tree Subband Coder (ZTS) [16], and Matching Pursuit Coder (MP) [20]

Sequence	Format	Rate		PSNR (dB)		
		Bit	Frame	DCT	ZTS	MP
Container-ship	QCIF	10 K	7.5	29.43	28.01	31.10
Hall-Monitor	QCIF	10 K	7.5	30.04	28.44	31.27
Mother-Daughter	QCIF	10 K	7.5	32.50	31.07	32.78
Container-ship	QCIF	24 K	10.0	32.77	30.44	34.26
Silent-Voice	QCIF	24 K	10.0	30.89	29.41	31.71
Mother-Daughter	QCIF	24 K	10.0	35.17	33.77	35.55
Coast-Guard	QCIF	48 K	10.0	29.00	27.65	29.82
News	CIF	48 K	7.5	30.95	29.97	31.96

FIGURE 55.8: Frame 250 of Coast-guard sequence, original shown in (a), coded at 112 Kbits/s using (b) DCT based coder (H.263) [3], (c) zerotree subband coder [16], and (d) matching pursuit coder [20]. Blocking artifacts can be noticed on the DCT coded frame. Ringing artifacts can be noticed on the subband coded frame.

55.2.4 Quantization

Motion compensation and residual error decomposition reduce the redundancy in the video signal. However, to achieve low bit rates, we must tolerate some distortion in the video sequence. This is because we need to map the residual and motion information to a fewer collection of codewords to meet the bit rate requirements.

Quantization, in a general sense, is the mapping of vectors (or scalars) of an information source into a finite collection of codewords for storage or transmission [8]. This involves two processes: encoding and decoding. The encoder blocks the source $\{t[i]\}$ into vectors of length n , and maps each vector $T^n \in \mathcal{T}^n$ into a codeword c taken from a finite set of codewords \mathcal{C} . The decoder maps the codeword c into a reproduction vector $Y^n \in \mathcal{Y}^n$ where \mathcal{Y} is a reproduction alphabet. If $n = 1$, it is called *scalar quantization*. Otherwise, it is called *vector quantization*.

The problem of optimum mean squared scalar quantization for a given reproduction alphabet size was independently solved by Lloyd [13] and Max [17]. They found that if t is a real scalar random

FIGURE 55.9: Frame-by-frame distortion of the luminance component of the Coast-guard sequence, reconstructed from 112 Kbits/s H.263 bit stream (solid line) [3], a zerotree subband bit-stream (dotted line) [16], and from a matching pursuit bit stream (dashed line) [20]. Consistently, the matching pursuit coder had the highest PSNR while the DCT coder had the lowest PSNR.

variable with continuous probability density function $p_t(t)$, then the quantization thresholds are

$$\hat{t}_k = \frac{r_k + r_{k-1}}{2}, \quad (55.9)$$

which is the geometric mean of the interval $(r^{k-1}, r^k]$, where

$$r_k = \frac{\int_{\hat{t}_k}^{\hat{t}_{k+1}} x p_x(x) dx}{\int_{\hat{t}_k}^{\hat{t}_{k+1}} p_x(x) dx} \quad (55.10)$$

are the reconstruction levels. Iterative numerical methods are required to solve for the reconstruction and quantization levels.

The simplest scalar quantizer is the uniform quantizer for which the reconstruction intervals are of equal length. The uniform quantizer is optimal when the coefficients have a uniform distribution. Moreover, due to its simplicity and good general performance, it is commonly used in coding systems.

A fundamental result of Shannon's rate distortion theory is that better performance can be achieved by coding vectors instead of scalars, even if the source is memoryless [8, 19]. Linde et al. [12] generalized the Lloyd-Max algorithm to vector quantization. Vector quantization exploits spatial redundancy in images, a function also served by the transformation block of Fig. 55.1, so it is sometimes applied directly to the image or video pixels [19].

Memory can be incorporated into scalar quantization by predicting the current sample from the previous samples and quantizing the residual error, e.g., linear predictive coding.

The human visual system is sensitive to some frequency bands more than others. So, humans tolerate more losses in some bands and less in others. In practice, the DCT coefficients corresponding to a particular frequency are grouped together to form a band, or in the case of subband decomposi-

tion, the bands are simply the subband channels. Different quantizers are then applied to each band according to its visual importance.

55.2.5 Coding of Quantized Symbols

The simplest method to code quantized symbols is to assign a fixed number of bits per symbol. For an alphabet of L symbols, this approach requires $\lceil \log_2 L \rceil$ bits per symbol. This method, however, does not exploit the coding redundancy in the symbols. Coding redundancy is eliminated by minimizing the average number of bits per symbol. This is achieved by giving fewer bits to more frequent symbols and more bits to less frequent symbols. Huffman [9] or arithmetic coding [21] schemes are usually used for this purpose.

In image and video coding, a significant number of the transform coefficients are zeros. Moreover, the “significant” DCT transform coefficients (low frequency coefficients) of a block can be predicted from the neighboring blocks resulting in a larger number of zero coefficients. To code the zero coefficients, run-length is performed on a reordered version of the transform coefficients. Figure 55.10(a) shows a commonly used zigzag scan to code 8×8 block DCT coefficients. Figure 55.10(b) shows a scan used to code subband coefficients commonly known as zero-tree coding [24]. The basic idea behind zero-tree coding is that if a coefficient in a lower frequency band (coarse scale) is zero or insignificant, then all the coefficients of the same orientation at higher frequencies (finer scales) are very likely to be zero or insignificant [16, 24]. Thus, the subband coefficients are organized in a data structure design based on this observation.

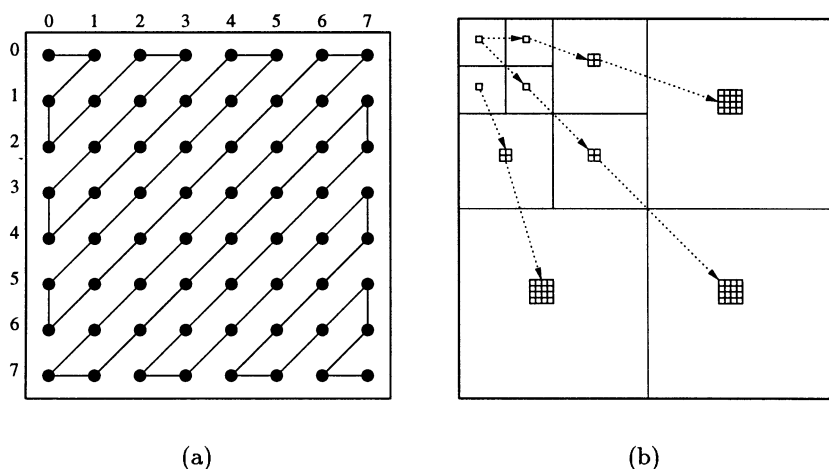

FIGURE 55.10: (a) A common scan for an 8×8 block DCT. (b) A common scan for subband decompositions (zero-tree).

55.3 Desirable Features

Some video applications require the encoder to provide more than good compression performance. For example, it is desirable to have scalable video compression schemes so that different users with different bandwidth, resolution, or computational capabilities can decode from the same bit-stream.

Cellular applications require the coder to provide a bit-stream that is robust when transmission errors occur. Other features include object-based manipulation of the bit-stream and the ability to perform content search. This section addresses two important desired features, namely scalability and error resilience.

55.3.1 Scalability

Developing scalable video compression algorithms has attracted considerable attention in recent years. Scalable compression refers to encoding a sequence in such a way so that subsets of the encoded bit-stream correspond to compressed versions of the sequence at different rates and resolutions. Scalable compression is useful in today's heterogeneous networking environment in which different users have different rate, resolution, display, and computational capabilities.

In rate scalability, appropriate subsets are extracted in order to trade distortion for bit rate at a fixed display resolution. Resolution-scalability, on the other hand, means that extracted subsets represent the image or video sequence at different resolutions. Rate- and resolution-scalability usually also provide a means of scaling the computational demands of the decoder. Resolution-scalability is best thought of as a property of the transformation block of Fig. 55.1. Both the DCT and subband transformations may be used to provide resolution-scalability. Rate-scalability, however, is best thought of as a property of the quantization and coding blocks.

Hybrid video coders can achieve scalability using multi-layer schemes. For example, in a two layer rate-scalable coder, the first layer codes the video at a low bit rate, while the second layer codes the residual error based on the source material and what has been coded thus far. These layers are usually called the base and enhancement layers. Such schemes, however, do not support fully scalable video, i.e., they can only provide a few levels of scalability, e.g., a few rates. The bottleneck is motion compensation, which is a nonlinear feedback predictor. To understand this, observe that the storage block of Fig. 55.1 is a memory element, storing values $\tilde{f}[\vec{i}]$ or $\tilde{t}[\vec{k}]$, recovered during decoding, until they are required for prediction. In scalable compression algorithms, the value of $\tilde{f}[\vec{i}]$ or $\tilde{t}[\vec{k}]$, obtained during decoding, depends on constraints, which may be imposed after the bit-stream has been generated. For example, if the algorithm is to permit rate scalability, then the value of $\tilde{f}[\vec{i}]$ or $\tilde{t}[\vec{k}]$ obtained by decoding a low rate subset of the bit-stream can be expected to be a poorer approximation to $f[\vec{i}]$ or $t[\vec{k}]$, respectively, than the value obtained by decoding from a higher rate subset of the bit-stream. This ambiguity presents a difficulty for the compression algorithm, which must select a particular value for $\tilde{f}[\vec{i}]$ or $\tilde{t}[\vec{k}]$ to serve as a prediction reference.

This inherent non-scalability of motion compensation is particularly problematic for video compression where scalability and motion compensation are both highly desirable features. As a solution, Taubman and Zakhor [28, 29] used three-dimensional subband decompositions to code video. They first compensated for the camera pan motion, then used three-dimensional subband decomposition. The coefficients in each subband are then quantized by a layered quantizer in order to generate a fully scalable video with fine granularity of bit rates. Temporal filtering, however, introduces significant overall latency, a critical parameter for interactive video compression applications. To reduce this effect, it is possible to use a 2-tap temporal filter, which results in one frame of delay.

As a visual demonstration of the quality tradeoff inherent to rate-scalable video compression, Fig. 55.11 shows frame 210 of the Ping-pong video sequence, decompressed at bit rates of 1.5 Mbits/s, 300 kbits/s, and 60 kbits/s for monochrome display using the scalable coder developed by Taubman and Zakhor [28]. As the bit rate decreases, the frame is less detailed and suffers more from ringing noise, i.e., the visual quality decreases. Figure 55.12 shows the PSNR characteristics of the scalable coder and MPEG-1 coder as a function of bit rate. The curve corresponding to the scalable coder corresponds to one encoded bit-stream decoded at arbitrary bit rates, while the three points for the MPEG-1 coder correspond to three different encoded bit-streams encoded and decoded at these different rates. As seen the scalable codec offers a fine granularity of available bit rates with

little or no loss in PSNR as compared to MPEG-1 codec.

FIGURE 55.11: Frame 210 of PING-PONG sequence decoded from scalable bit stream at (a) 1.5 Mbits/s, (b) 300 Kbits/s, and (c) 60 Kbits/s [28]. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

Real time software only implementation of scalable video codec has also received a great deal of attention over the past few years. Tan et al. [27] have recently proposed a real-time software only implementation of the modified version of the algorithm in [28] by replacing the arithmetic coding with block coding. The resulting scalable coder is symmetric in encoding and decoding complexity and can encode up to 17 frames/s for rates as high as 1 Mbits/s on a 171 MHz Ultra-Sparc workstation.

55.3.2 Error Resilience

When transmitting video over noisy channels, it is important for bit-streams to be robust to transmission errors. It is also important, in case of errors, for the error to be limited to a small region and not to propagate to other areas. If the coder is using fixed-length codes, the error will be limited to the region of the bit-stream where it occurred and the rest of the bit-stream will not be affected. Unfortunately, fixed-length codes do not provide good compression performance, especially since the histogram of the transform coefficients has a significant peak around low frequency.

FIGURE 55.12: Rate-distortion curves for PING-PONG sequence. Overall PSNR values for Y, U, and V components for the codec in [28] are plotted against the bit rate limit imposed on the rate-scalable bit stream prior to decompression. MPEG-1 distortion values are also plotted as connected dots for reference. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

In order to achieve such features when using variable length codes, the bit-stream is usually partitioned into segments that can be independently decoded. Thus, if a segment is lost, only that region of the video is affected. A segment is usually a small part of a frame. If an error occurs, the decoder should have enough information to know the beginning and the end of a segment. Therefore, synchronization codes are added to the beginning and end of each segment. Moreover, to limit the error to a smaller part of the segment, reversible variable length codes may be used [26]. So, if an error occurs, the decoder will advance to the next synchronization code and can decode in the backward direction till the error is reached.

As is evident, there is a tradeoff between good compression performance and error resilience. In order to reduce the cost of error resilient codes, some approaches jointly optimize the source and channel codes [6, 23].

55.4 Standards

In this section we review the major video compression standards. Essentially, these schemes are based on the building blocks introduced in Section 55.2. All these standards use the DCT. Table 55.2 summarizes the basic characteristics and functionalities supported by existing standards. Sections 55.4.2, 55.4.3, and 55.4.5 outline the Motion Picture Experts Group (MPEG) standards for video compression. Sections 55.4.1 and 55.4.4 review the CCITT H.261 and H.263 standards for digital video communications. This section lists the standards according to their chronological order in order to provide an understanding of the progress of the video compression standardization process.

TABLE 55.2 Summary of the Functionalities and Characteristics of the Existing Standards

	ITU		ISO		
Attribute	H.261	H.263	MPEG-1	MPEG-2	MPEG-4
Applications	Video-conferencing	Video-phone	CD storage	Broadcast	Wide range (multimedia)
Bit rate	64K - 1M	< 64K	1.0 - 1.5M	2 - 10M	5K - 4M
Material	Progressive	Progressive	Progressive, interlaced	Progressive, interlaced	Progressive, interlaced
Object shape	Rectangular	Arbitrary (simple)	Rectangular	Rectangular	Arbitrary
Residual Coding					
Transform	8×8 DCT	8×8 DCT	8×8 DCT	8×8 DCT	8×8 DCT
Quantizer	Uniform	Uniform	Weighted uniform	Weighted uniform	Weighted uniform
Motion Compensation					
Type	Block	Block	Block	Block	Block, sprites
Block size	16×16	16×16 , 8×8	16×16	16×16	16×16 , 8×8
Prediction type	Forward	Forward, backward	Forward, backward	Forward, backward	Forward, backward
Accuracy	One pixel	Half pixel	Half pixel	Half pixel	Half pixel
Loop filter	Yes	No	No	No	No

Spatial	No	Yes	No	Yes	Yes
Bit rate	No	Yes	No	Yes	Yes
Object	No	No	No	No	Yes

55.4.1 H.261

Recommendation H.261 of the CCITT Study Group XV was adopted in December 1990 [2] as a video compression standard to be used for video conferencing applications. The bit rates supported by H.261 are $p \times 64$ Kbits/s, where p is in the range 1 to 30. H.261 supports two source formats: CIF (352×288 luminance and 176×144 chrominance) and QCIF (176×144 luminance and 88×72 chrominance). The chrominance components are subsampled by two in both the vertical and horizontal directions.

The transformation used in H.261 is the 8×8 block-DCT. Thus, there are four luminance (Y) DCT blocks for each pair of U and V chrominance DCT blocks. These six DCT blocks are collectively referred to as a *macro-block*. The macro-blocks are grouped together to construct a group of blocks (GOB), which relates to 11×3 region of macro-blocks. Each macro-block may individually be specified as intra-coded or inter-coded. The Intra-coded blocks are coded independently of the previous frame and so do not conform to the model of Fig. 55.1. They are used when successive frames are not related, such as during scene changes, and to avoid excessive propagation of the effects of communication errors. Inter-coded blocks use the motion compensation predictive feedback loop of Fig. 55.1 to improve compression performance. The motion estimation scheme is based on 16×16 pixel blocks. Each macro-block is predicted from the previous frame and is assigned exactly one motion vector with one pixel accuracy.

The data for each frame consists of a picture header that includes a start code, a temporal reference for the current coded picture, and the source format. The picture header is followed by the GOB layer. The data of each GOB has a header that includes a start code to indicate the beginning of a GOB, the GOB number to indicate the position of the GOB, and all information necessary to code each GOB independently. This will limit the loss if an error occurs during the transmission of a GOB. The header of the GOB is followed by the motion data, then followed by the block information.

55.4.2 MPEG-1

The first (MPEG) video compression standard [7], MPEG-1, is intended primarily for progressive video at 30 frames/s. The targeted bit rate is in the range 1.0 to 1.5 Mbits/s. MPEG-1 was designed to store video on compact discs. Such applications require MPEG-1 to support random access to the material on the disc, fast forward and backward searches, reverse playback, and audio visual synchronization. MPEG-1 is also a hybrid coder that is based on the 8×8 block DCT and 16×16 motion compensated macro-blocks with half pixel accuracy.

The most significant departure from H.261 in MPEG-1 is the introduction of the concept of bi-directional prediction, together with that of group of pictures (GOP). These concepts may be understood with the aid of Fig. 55.13. Each GOP commences with an intra-coded picture (frame), denoted I in the figure. The motion compensated predictive feedback loop of Fig. 55.1 is used to compress the subsequent inter-coded frames, marked P. Finally, the bi-directionally predicted frames, marked B in Fig. 55.13, are coded using motion compensated prediction based on both previous and successive I or P frames. Bidirectional prediction conforms essentially to the model of Fig. 55.1, except that the prediction signal is given by

$$a \tilde{f}[\vec{i} - \vec{d}_i^f] + b \tilde{f}[\vec{i} - \vec{d}_i^b]$$

In this notation, \tilde{f} is a reconstructed frame, $\vec{d}_i^f = (h_i^f, v_i^f, n^f)$, where (h_i^f, v_i^f) is a forward motion vector describing the motion from the previous I or P frame, and n^f is the frame distance to this previous I or P frame. Similarly, $\vec{d}_i^b = (h_i^b, v_i^b, -n^b)$, where (h_i^b, v_i^b) is a backward motion vector describing the motion to the next I or P frame, and n^b is the temporal distance to that frame. The weights a and b are given either by

$$\begin{array}{lcl} a = 1 & a = 0 & a = n_b / (n_f + n_b) \\ b = 0 & b = 1 & b = n_f / (n_f + n_b) \end{array} \quad , \quad \text{or} \quad \begin{array}{l} a = n_b / (n_f + n_b) \\ b = n_f / (n_f + n_b) \end{array}$$

corresponding to forward, backward, and average prediction, respectively. Each bi-directionally predicted macro-block is independently assigned one of these three prediction strategies.

FIGURE 55.13: MPEG's group of pictures (GOP). Arrows represent direction of prediction. (Source: Taubman, D., Chang, E., and Zakhor, A., Directionality and scalability in subband image and video compression, in *Image Technology: Advances in Image Processing, Multimedia, and Machine Vision*, Jorge L.C. Sanz, Ed., Springer-Verlag, New York, 1996. With permission).

An MPEG-1 decoder can reconstruct the I and P frames without the need to decode the B frames. This is a form of temporal scalability and is the only form of scalability supported by MPEG-1.

55.4.3 MPEG-2

The second MPEG standard, MPEG-2, targets 60 fields/s interlaced television; however, it also supports progressive video. The targeted bit rate is between 2 Mbits/s and 10 Mbits/s. MPEG supports frames sizes up to $2^{14} - 1$ in each direction; however, the most popular formats are CCIR 601 (720×480), CIF (352×288), and SIF (352×240). The chrominance can be sampled in either the 4:2:0 (half as many samples in the horizontal and vertical directions), 4:2:2 (half as many samples in the horizontal direction only), or 4:4:4 (full chrominance size) formats.

MPEG-2 supports scalability by offering four tools: data partitioning, signal-to-noise-ratio (SNR) scalability, spatial scalability, and temporal scalability. Data partitioning can be used when two channels are available. The bit-stream is partitioned into two streams according to their importance. The most important stream is transmitted in the more reliable channel for better error resilience performance. SNR (rate), spatial, and temporal scalable bit-streams are achieved through the definition of a two-layer coder. The sequence is encoded into two bit-streams called lower and enhancement layer bit-streams. The lower bit-stream can be encoded independently from the enhancement layer using an MPEG-2 basic encoder. The enhancement layer is combined with the lower layer to get a higher quality sequence. The MPEG-2 standard supports hybrid scalabilities by combining these tools.

55.4.4 H.263

The international telecommunication union recommended H.263 standard to be used for video telephony (video coding for narrow telecommunications channels) [3]. Although, the bit rates specified are smaller than 64 Kbits/s, H.263 is also suitable for higher bit rates. H.263 supports three source formats: CIF (352×288 luminance and 176×144 chrominance), QCIF (176×144 luminance and 88×72 chrominance), and sub-QCIF (128×96 luminance and 64×48 chrominance).

The transformation used in H.263 is the 8×8 block-DCT. As in H.261, a macro-block consists of four luminance and two chrominance blocks. The motion estimation scheme is based on 16×16 and 8×8 pixel blocks. It alternates between them according to the residual error in order to achieve better performance. Each inter-coded macro-block is assigned one or four motion vectors with half pixel accuracy. Motion estimation is done in both forward and backward directions.

H.263 provides a scalable bit-stream in the same fashion MPEG-2 does. This includes temporal, spatial, and rate (SNR) scalabilities. Moreover, H.263 has been extended to support coding of video objects of arbitrary shape. The objects are segmented and then coded the same way rectangular objects are coded with slight modification at the boundaries of the object. The shape information is embedded in the chrominance part of the stream by assigning the least used color to the parts outside the object in the rectangular frame. The decoder uses the color information to detect the object in the decoded stream.

55.4.5 MPEG-4

The moving picture expert group is developing a video standard that targets a wide range of applications including Internet multimedia, interactive video games, video-conferencing, video-phones, multimedia storage, wireless multimedia, and broadcasting applications. Such a wide range of applications needs a large range of bit rates, thus MPEG-4 supports a bit rate range of 5 Kbits/s to 4 Mbits/s. In order to support multimedia applications effectively, MPEG-4 supports synthetic and natural image and video in both progressive and interlaced formats. It is also required to provide object-based scalabilities (temporal, spatial, and rate) and object-based bit-stream manipulation, editing, and access [5, 25]. Since it is also intended to be used in wireless communications, it should be robust to high error rates. The standard is expected to be finalized in 1998.

Acknowledgment

The authors would like to acknowledge support from AFOSR grants F49620-93-1-0370 and F49620-94-1-0359, ONR grant N00014-92-J-1732, Tektronix, HP, SUN Microsystems, Philips, and Rockwell. Thanks to Iraj Sodagar of David Sarnoff Research Center for providing the zerotree coded video sequence.

56.1 Introduction

Digital television is being widely adopted for various applications ranging from high-end applications, such as studio recording, to consumer applications, such as digital cable TV and digital DBS (Direct Broadcasting Satellite) TV. For example, several digital video tape recording standards, using component format (D1 and D5), composite format (D2 and D3), or compressed component formats (Digital Betacam) are commonly used by broadcasters and TV studios [1]. These standards preserve the best possible picture quality at the expense of high data rates, ranging from approximately 150 to 300 Mbps. When captured in a digital format, the picture quality can be free from degradation during multiple generations of recording and playback, which is extremely attractive to studio editing. However, transmission of these high data-rate signals may be hindered due to lack of transmission media with an adequate bandwidth. Although it is possible, the associated transmission cost will be very high. The bit rate requirement for high definition television (HDTV) is even more demanding, which may exceed 1 Gbps in an uncompressed form. Therefore, data compression is essential for economical transmission of digital TV/HDTV.

Before motion-compensated DCT coding technology became mature in recent years, transmission of high-quality digital television used to be carried out at 45 Mbps using DPCM techniques. Today, by incorporating advanced motion-compensated DCT coding, comparable picture quality can be achieved at about one-third of the rate required by DPCM-coded video. For entertainment applications, the requirement on picture quality can be relaxed a little bit to allow more TV channels to fit into the same bandwidth. It is generally agreed that 3 to 4 Mbps for movie-originated or low-activity interlaced video (talk shows, etc.) materials is acceptable, and 6-8 Mbps for high-activity interlaced video (sports, etc.) is acceptable. The targeted bit rate for HDTV transmission is usually around

20 Mbps, which is chosen to match the available digital bandwidth of terrestrial broadcast channels allocated for conventional TV signals.

56.2 EDTV/HDTV Standards

The concept of HDTV system and efficient transmission format was originally explored by researches at NHK (Japan Broadcasting Corp.) more than 20 years ago [2] in order to offer superior picture quality while conserving bandwidth. Main HDTV features, including more scan lines, higher horizontal resolution, wider aspect ratio, better color representation, and higher frame rate, were identified. With these new features, HDTV is geared to offer picture quality close to that of 35-mm prints. However, the transmission of such a signal will require a very wide bandwidth. During the last 20 years, intensive research efforts have been engaged toward video coding to reduce bandwidth.

Currently there are two dominant HDTV production formats being used worldwide; one is the 1125-line/60-Hz system primarily used in Japan and the U.S. and the other is the 1250-line/50-Hz system primarily used in Europe. The main scanned raster characteristics of these two formats are listed in Table 56.1. The nominal bandwidth of the luminance component is about 30 MHz (in some cases, 20 MHz was quoted). Roughly speaking, the HDTV signal can carry about six times as much information as a conventional TV signal.

TABLE 56.1 Main Scanned Raster Characteristics of the 1125-line/60-Hz System and the 1250-line/50-Hz System

Format	Total scan lines per frame	Active lines per frame	Scanning format	Aspect ratio	Field rate
1	1125	1035	2:1 interlaced	16:9	60.00/59.94
2	1250	1152	2:1 interlaced	16:9	50.00

Development of HDTV transmission techniques in the early days was focused on bandwidth-compatible approaches that use the same analog bandwidth as a conventional TV signal. In some cases, in order to conserve bandwidth or to offer compatibility with an existing conventional signal or display, a compromised system—Enhanced or Extended Definition TV—was developed instead. The EDTV signal does not offer the picture quality and resolution required for an HDTV signal; however, it enhances the picture quality/resolution of conventional TV.

56.2.1 MUSE System

The most well-known early development in HDTV coding is the MUSE (Multiple Sub-Nyquist Sampling Encoding) system at NHK [3, 4]. The main concept of the MUSE system is adaptive spatial-temporal subsampling. Since human eyes have better spatial sensitivity for stationary or slow-moving scenes, the full spatial resolution is preserved while the temporal resolution is reduced for these scenes in the MUSE system. For fast moving scenes, the spatial sensitivity of human eyes declines so that reducing the spatial resolution will not significantly affect perceived picture quality. The MUSE signal is intended for analog transmission with a baseband bandwidth of 8.1 MHz, which can be fitted into a satellite transponder for a conventional analog TV signal. However, it should be noted that most signal processing employed in the MUSE system is in the digital domain. The MUSE coding technique was later modified to reduce bandwidth requirement for transmission over 6-MHz terrestrial broadcasting channels (Narrow-MUSE) [5]. Currently, MUSE-based HDTV programming is being broadcast regularly through a DBS in Japan.

56.2.2 HD-MAC System

A development similar to the MUSE was initiated in Europe as well. The system, HD-MAC (High-Definition Multiplexed Analog Component), is also based on the concept of adaptive spatial-temporal subsampling. Depending on the amount of motion, each block, consisting of 8×8 pixels, is classified into either the 20-, 40-, or 80-ms mode [6]. For a fast-moving block (the 20-ms mode), it is transmitted at the full temporal resolution, but at $1/4$ spatial resolution. For a stationary or slow-moving block (the 80-ms mode), it is transmitted at full spatial resolution, but at $1/4$ temporal resolution (25/4 frames/sec). For the 40-ms block, it is transmitted at half spatial and half temporal resolutions. The mode associated with each block is transmitted as side information through a digital channel at a bit rate nearly 1 Mbps. The subsampling process of the HD-MAC system is illustrated in Fig. 56.1, where the numbers indicate the corresponding fields of transmitted pixels and the “.” indicates a pixel not transmitted.

FIGURE 56.1: Adaptive spatial-temporal subsampling of the HD-MAC system. (a) The 80-ms mode for stationary to very-slow moving scenes, (b) the 40-ms mode for medium-speed moving scenes, and (c) the 20-ms mode for fast moving scene.

56.2.3 HDTV in North America

HDTV development in North America started much later than that in Japan and Europe. The Advisory Committee on Advanced Television Services (ACATS) was formed in 1987 to advise Federal Communications Commission (FCC) on the facts and circumstances regarding advanced television systems for terrestrial broadcasting. The proposed systems in early days were all intended for analog transmission [7]. However, the direction of U.S. HDTV development took a 180-degree turn in 1990 since General Instrument (GI) entered the U.S. HDTV race by submitting an all-digital HDTV system proposal to the FCC. The final contender in the U.S. HDTV race consisted of one analog system (Narrow-MUSE) and four digital systems, which all employed motion compensated DCT coding. Extensive testings on the five proposed systems were conducted in 1991 and 1992 and the testing concluded that there are major advantages in the performance of the digital HDTV systems and only the digital system shall be considered as the standard. However, none of these four digital systems was ready to be selected as the standard without implementing improvements.

With the encouragement from ACATS, the four U.S. HDTV proponents formed the Grand Alliance (GA) to combine their efforts for developing a better system. Two HDTV scan formats were adopted by the GA. The main parameters are shown in Table 56.2. The lower-resolution format, 1280×720 , is only used for progressive source materials while the high-resolution format, 1920×1080 , can be used for both progressive and interlaced source materials. The digital formats of GA HDTV are carefully designed to accommodate the square-pixel feature, which provides better interoperability with digital video/graphics in the computer environment. Since the main structure of MPEG-2

system and video coding standards were settled at that time and the MPEG-2 video coding standard provides extension to accommodate HDTV formats, the GA adopted MPEG-2 system and video coding (Main Profile (MP) at High Level (HL)) standards for the U.S. HDTV, instead of creating another standard [8]. However, the GA HDTV adopted the AC-3 audio compression standard [9] instead of the MPEG-2 Layer 1 and Layer 2 audio coding.

TABLE 56.2 Main Scanned Raster Characteristics of the GA HDTV
Input Signals

Active samples/line	Active lines per frame	Scanning format	Aspect ratio	Frame rate
1280	720	1:1 progressive	16:9 square pixels	60.00/59.94 30/29.97 24/23.976
1920	1080	1:1 progressive	16:9 square pixels	30/29.97 24/23.976
1920	1080	2:1 interlaced	16:9 square pixels	30/29.97

56.2.4 EDTV

EDTV refers to the TV signal that offers quality between the conventional TV and HDTV. Usually, EDTV has the same number of scan lines as the conventional TV, but offers better horizontal resolution. Though it is not a required feature, most EDTV systems offer a wide aspect ratio. When the compatibility with a conventional TV signal is of concern, the additional information (more horizontal details, side panels, etc.) required by the EDTV signal is embedded in the unused spatial-temporal spectrum (called *spectrum holes*) of the conventional TV signal and can be transmitted in either an analog or digital form [10, 11]. When the compatibility with the conventional TV is not required, EDTV can use the component format to avoid the artifacts caused by mixing of chrominance and luminance signals in the composite format. For example, several MAC (Multiplexed Analog Component) systems for analog transmission were adopted in Europe for DBS and cable TV applications [12, 13]. Usually, these signals offer better horizontal resolution and better color fidelity. There were many fully digital TV systems developed in the past. These systems that used adequate spatial resolution and higher bit rates were likely to achieve superior quality to the conventional TV and were qualified as EDTV [14]. Nevertheless, an efficient EDTV system is already embedded in the MPEG-2 video coding standard. Within the context of the standard, the 16:9 aspect ratio and horizontal and vertical resolutions exceeding the conventional TV can be specified in the “Sequence Header”. When coded with adequate bit rates, the resulting signal can be qualified as EDTV.

56.3 Hybrid Analog/Digital Systems

Today, existing conventional TV sets and other home video equipment represent a massive investment by consumers. The introduction of any new video system that is not compatible with the existing system may face strong resistance in initial acceptance and may take a long time to penetrate households. One way to circumvent this problem during the transition period is to “simulcast” a program in both formats. The redundant conventional TV, being simulcast in a separate channel, can be phased out gradually when most households are able to receive the EDTV or HDTV signal. Intuitively, a more bandwidth efficient approach may be achieved if the transmitted conventional TV signal can be incorporated as a baseline signal and only the enhancement signal is transmitted in an additional channel (called “augmentation channel”). In order to facilitate the compatibility,

an analog conventional TV signal has to be transmitted to allow conventional TV sets to receive the signal. On the other hand, digital video compression techniques may be employed to code the enhancement signals in order to accomplish the best compression efficiency. Such systems belong to the category of hybrid analog/digital system. A generic system structure for the hybrid analog/digital approach is shown in Fig. 56.2. Due to the interlacing processing used in TV standards, there are some unused holes in the spatial-temporal spectrum [15], which can be used to carry partial enhancement components as shown in Fig. 56.2.

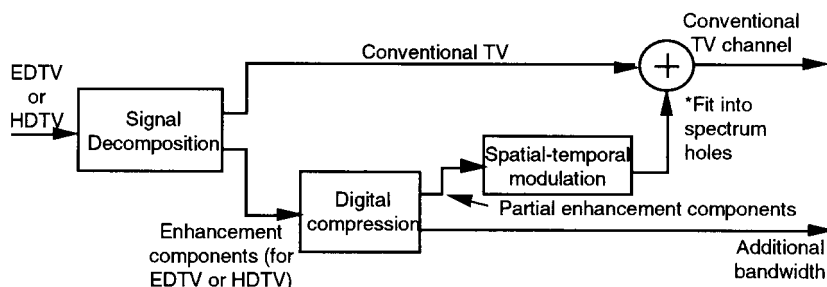

FIGURE 56.2: A generic hybrid analog digital HDTV coding system.

The Advanced Compatible Television System II (ACTV-II), developed by the consortium of NBC, RCA, and the David Sarnoff Research Center during the U.S. ATV standardization process, is an example of a hybrid system. The ACTV-II signal uses a 6-MHz channel to carry an NTSC compatible ACTV-I signal and uses an additional 6-MHz channel to carry the enhancement signal. The ACTV-I consists of a main signal, which is fully compatible with the conventional NTSC signal, and enhancement components (luminance horizontal details, luminance vertical-temporal details, and side-panel details of the wide-screen signal), which are transmitted in 3-D spectrum holes of the NTSC signal. The differences between the input HDTV signal and the ACTV-I signal are digitally coded using 4-band subband coding. The digitally coded video difference signal and digital audio signal require a total bandwidth of 20 Mbps and are expected to fit into the 6-MHz bandwidth by using the 16-QAM modulation. The enhancement components of the ACTV-I signal are digitally processed (time expansion and compression) and transmitted in an analog format. Nevertheless, they could be digitally compressed and transmitted, which would result in a hybrid analog/digital ACTV-I signal. For users with conventional TV sets, conventional TV pictures (4:3 aspect ratio) will be displayed. For users with an ACTV-I decoder and a wide screen (16:9) TV monitor, the wide-screen EDTV can be viewed by receiving the signal from the main channel. For those who have an ACTV-II decoder and an HDTV monitor, the HDTV picture can be received by using signals from both the main channel and the associated augmentation channel.

The HDS/NA system developed by Philips Laboratories is another example of hybrid analog/digital system where the augmentation signal is carried in a 3-MHz channel [16]. The augmentation signal consists of side panels to convert the aspect ratio from 4:3 to 16:9, and high-resolution spatial components. The side panels from two consecutive frames are combined into one frame of panels and are intraframe compressed by using DCT coding with a block size of 16×16 pixels. Both the horizontal and vertical high-resolution components are also compressed by intraframe DCT coding with some modifications to take into account the characteristics of these signals. The augmentation signals result in a total bit rate of 6 Mbps, which is expected to fit into a 3-MHz channel using modulation schemes with efficiency of 2 bits/Hz. However, the HDS/NA system was later modified into an analog simulcast system, HDS/NA-6, which occupies only a 6-MHz bandwidth and is intended

to be transmitted simultaneously with a conventional TV in a *taboo* channel.

The augmentation-based hybrid analog/digital approach may be more efficient than the simulcast approach when both conventional TV and HDTV receivers have to be accommodated at the same time. However, for the augmentation-based approach, the reconstruction of the HDTV signal relies on the availability of the conventional TV signal, which implies that the main channel carrying the conventional TV signal can never be eliminated. Due to the inefficient use of bandwidth by the conventional analog TV signal, the overall bandwidth efficiency of the hybrid analog/digital approach is inferior to that of the fully digital-based simulcast approach. Furthermore, the system complexity of the hybrid approach is likely to be higher than that of the fully digital approach because it requires both analog and digital types of processing.

56.4 Error Protection and Concealment

Video coding results in a very compact representation of digital video by removing its redundancy, which leaves the compressed data very vulnerable to transmission errors. Usually, a single transmission error will only affect a single pixel for uncompressed data. However, due to the coding process employed, such as DCT transform and motion-compensated inter-field/frame prediction, a single transmission error may affect a whole block or blocks in consecutive frames. Furthermore, variable length coding is extensively used in most video coding systems, which is even more susceptible to transmission errors. For variable-length coded data, a single bit error may cause the decoder to lose track of codeword boundaries and results in decoding errors in subsequent data. Generally speaking, a single transmission error may result in noticeable picture impairment if no error concealment is applied.

56.4.1 FEC

The first effort to protect the compressed digital video in an environment susceptible to transmission errors should be to reduce transmission errors by employing forward error correction (FEC) coding. FEC adds redundancy, just opposite to data compression, in order to protect the underlying data from transmission errors. One trivial FEC example is to transmit each bit repeatedly, say three times. A single bit error in each three transmitted bits can be easily corrected by a majority-vote circuit. There are many known FEC techniques which can achieve much better protection without devoting too much bandwidth to redundancy. Today, two types of FEC codes are popularly used for digital transmission over various media. One is Reed-Solomon (RS) code, which belongs to the class of block codes. The other is the convolutional code, which usually operates on continuous data.

The RS code appends a number of redundant bytes to a block of data to achieve error correction. Usually $2n$ redundant bytes can correct up to n byte errors. When a higher level protection is required, more redundant bytes can be attached or alternatively the redundant bytes can be added to shorter data blocks. For digital transmission using the MPEG-2 transport format, in order to maintain the structure of the MPEG-2 transport packets, the (204,188) RS code has been particularly chosen by many standards, which appends 16 redundant bytes to each MPEG-2 transport packet. On the other hand, the U.S. GA-HDTV chose the (207,187) RS code, where the RS redundancy computation is based on the 187-byte data block with the sync byte excluded.

The convolutional code is a powerful FEC code, which generates m output bits for every n input bits. The code rate, r , is defined as $r = n/m$. The output bits are not only determined by the current input bits, but also depend on previous input bits. The depth of the previous input data affecting the output is called the constraint length, k . The output stream of the convolutional code is the result of a generator function convolved with the input stream. Viterbi decoding is an efficient algorithm to decode convolutionally coded data. The complexity of the Viterbi algorithm is proportional to

2^k . Therefore, longer constraint length results in higher decoding complexity. However, longer constraint length also improves FEC performance. A lower rate convolutional code provides more protection at the expense of higher redundancy. For a $r = 1/2$ and $k = 7$ convolutional code, a BER of 10^{-2} can be reduced to below 10^{-5} .

In order to maintain nearly error-free transmission, a very low BER has to be achieved. For example, if an average error-free interval of two hours needs to be achieved for a 6-Mbps compressed bit stream, the required BER is 2.3×10^{-11} . For some transmission media that have limited carrier-to-noise ratio, such a low BER may not be achievable using the RS code or convolutional code alone. However, an extremely powerful coding can be accomplished by concatenating the RS code and the convolutional code, where the RS code (called outer code) is used toward the source or sink side and the convolutional code (called inner code) is used toward the channel side. An interleaver to spread bursts of errors is usually used between the inner and outer code in order to improve error correction capability. The interleaver needs to be carefully designed so that the locations of the sync byte in the ATM packets remain unchanged through the interleaver. A block diagram of the concatenated RS code and convolutional code is shown in Fig. 56.3. Some simulations showed that satisfactory performance can be achieved by using the concatenate codes for digital video transmission over the satellite link [17]. In [17], the overall BER is about 2^{-11} , which corresponds to a BER of about $2 \cdot 10^{-4}$ using the convolutional code only.

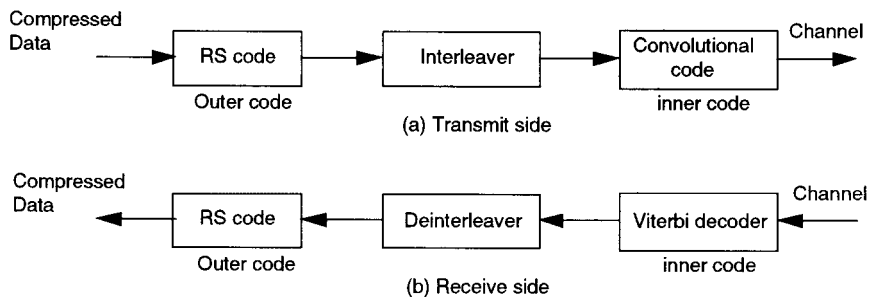

FIGURE 56.3: Block diagram of concatenated RS code and convolutional code.

56.4.2 Error Detection and Confinement

While FEC techniques can improve BER significantly, there are still chances that errors may occur. As mentioned earlier, a single bit error may cause catastrophic effects on compressed digital video if precaution is not exercised. To avoid the infinite error propagation, one needs to identify the occurrences of errors and to confine the errors during decoding. Due to the use of variable length coding, a single bit error in the compressed bit stream may cause the decoder to lose track of codeword boundaries. Even though the decoder may regain code synchronization later, the number of decoded data may be more or less than the actual number of samples transmitted, which will affect proper display of the remaining samples. To avoid error propagation, compressed data need to be organized into smaller self-contained data units with *unique words* to identify the beginning or boundaries of the data unit. In case transmission errors occur in preceding data units, the current data unit can still be properly decoded. In the MPEG-2 video coding standard, the *slice* is the smallest self-contained data unit, which has a unique 32-bit *slice_start_code* and information regarding its location within a picture [18]. Therefore, a transmission error in one *slice* will not affect the proper decoding of subsequent *slices*.

However, for inter-field/frame coded pictures, the artifacts in the error-contaminated slice will still propagate to subsequent pictures, which use this slice as reference. Error concealment is a technique to mitigate artifacts caused by transmission errors in the reconstructed picture.

56.4.3 Error Concealment

For DCT-based video coding, some analytic work was conducted in [19] to derive an optimal reconstruction method based on received blocks with missing DCT coefficients. The solution consists of three linear interpolation in the spatial, temporal, and frequency domains from the boundary data, reconstructed reference block, and received DCT block, respectively. When the complete block is missing, the optimal solution becomes a linear combination of a block replaced by the corresponding block in the previous frame and a spatially interpolated block from boundary pixels. This method needs to go through an iterative process to restore damaged data when consecutive blocks are corrupted by errors. The above concealment technique was further improved in [20, 21] by incorporating an adaptive spatial-temporal interpolation scheme and a multi-directional spatial interpolation scheme.

When a temporal concealment scheme is used, the picture quality in the moving area can be improved by incorporating a motion compensation technique. The motion vector for a missing or corrupted macroblock can be estimated from the motion vectors of surrounding macroblocks. For example, the motion vector can be estimated based on the averaged motion vector from the macroblocks above and below the underlying block, as suggested in the MPEG-2 video standard. However, when the neighboring reference macroblocks are intra-coded, there are no motion vectors associated with these macroblocks. The MPEG-2 video coding standard allows transmission of the “*concealment_motion_vectors*” associated with intra-coded macroblocks, which can be used to estimate the motion vector for the missing or corrupted macroblock.

56.4.4 Scalable Coding for Error Concealment

When the requirement of error-free transmission cannot be met, it may be useful to provide different protection of underlying data according to the visual importance of the compressed data. This will be useful for transmission media which have different delivery priorities or provide different levels of FEC protection for underlying data. The data that can be used to reconstruct basic pictures are usually treated as high-priority data while the data used to enhance the pictures are treated as low-priority data. For these visually important data, high redundancy is used to offer more protection (or high priority in a cell-based transport system). Therefore, the high-priority data can always be reliably delivered. On the other hand, any errors in the low-priority data will only result in minor degradation. Therefore, if any error is detected in the low-priority data, the affected data can be discarded without significantly degrading the picture quality. Nevertheless, if concealment techniques by spatial-temporal interpolation as described above can be applied to affected areas, this will further improve picture quality. The scalable source coding processes the underlying signal in a hierarchical fashion according to the spatial resolution, temporal resolution, or picture signal-to-noise ratio, and organizes the compressed data into layers so that a lower-level data set can be used to reconstruct a basic video sequence and the quality can be improved by adding higher levels. Many coding systems can offer the scalable coding feature if the underlying data is carefully partitioned [22, 23]. The MPEG-2 video coding standard also offers scalable extension to accommodate spatial, temporal, and SNR scalability.

56.5 Terrestrial Broadcasting

In conventional analog TV standards, in order to allow low-cost TV receivers to acquire the carrier and subcarrier frequencies easily, the transmitted analog signals always contain these two frequencies in high strength, which are the potential cause for co-channel and adjacent-channel interferences. This problem becomes more prominent in the terrestrial broadcasting environment, where the transmitter of an undesired signal (adjacent channel) may be much closer than that of a desired signal. The strong undesired signal may interfere with the desired weak signal. Therefore, some of the terrestrial broadcasting channels (*taboo* channels) are prohibited in the same coverage area in order to reduce the potential interference. In digital TV transmission, the power spectrum of the signal is widespread over the allocated spectrum, which substantially reduces the potential interference. On the other hand, the bandwidth efficiency of digital coding may significantly increase the capacity of terrestrial broadcasting. Therefore, digital video coding is a very attractive alternative to solving the channel congestion problem in major cities.

56.5.1 Multipath Interference

One notorious impairment of the terrestrial broadcasting channel is the multipath interference, which manifests as the ghost effect in received pictures. For digital transmission, the multi-path interference will cause signal distortion and degrade system performance. An effective way to cope with multipath interference is to use adaptive equalization, which can restore the impaired signal by using a known training data sequence. The GA HDTV system for terrestrial broadcasting adopted this method to overcome the multipath problem [9]. A very different approach—Coded Orthogonal Frequency Division Multiplexing (COFDM)—has been advocated in Europe for terrestrial broadcasting [10]. The COFDM technology employs multiple carriers to transport parallel data so that the data rate for each carrier is very low. The COFDM system is carefully designed to ensure that the symbol duration for each carrier is longer than the multipath delay. Consequently, the effect of multipath interference will be significantly reduced. The carrier spacing of the COFDM system is carefully arranged so that each subcarrier is orthogonal to the other subcarriers, which achieves high spectrum efficiency. A performance simulation of COFDM for terrestrial broadcasting was reported in [24], which indicated that COFDM is a viable alternative to digital transmission of 20 Mbps in a 6-MHz terrestrial channel.

56.5.2 Multi-Resolution Transmission

In terrestrial broadcasting, the carrier-to-noise ratio (CNR) of the received signal decreases gradually when the distance between a receiver and the transmitter increases. In an analog transmission system, the picture quality usually degrades gracefully when the CNR decreases. In a digital transmission system, a lower CNR will result in a higher BER and the decoded picture contaminated by errors may become unusable when the BER exceeds a certain threshold. A technique to extend the coverage area of terrestrial broadcasting is to use scalable source coding in conjunction with multiresolution (MR) channel coding [25, 26]. In MR modulation, the constellation of the modulated signal is carefully organized in a hierarchical fashion so that a low-density modulation can be derived from the constellation with high protection while a high-density modulation can be achieved by further demodulation of the received signal. An example of MR modulation using QAM (Quadrature Amplitude Modulation) is shown in Fig. 56.4, where the nonuniform constellation represents 4-QAM/16-QAM MR modulation. The scalable source coding processes the underlying signal in a hierarchical fashion according to the spatial resolution, temporal resolution, or picture signal-to-noise ratio, and organizes the compressed data in layers so that a lower-level data set can be used to reconstruct a basic video sequence and the quality can be improved by adding more levels. The MPEG-2 video coding standard also offers scalable extension to accommodate spatial, temporal,

and SNR scalability. In light of the fact that MPEG-2-based systems are being widely used for digital satellite TV broadcasting and being adopted by the Digital Audio-Visual Interactive Council (DAVIC) for the set-top box standard, MPEG-2-based scalable coding in conjunction with the MR modulation likely will be used to offer graceful degradation in terrestrial broadcasting if it is desired.

FIGURE 56.4: The constellation of a MR modulation for a 4-QAM/16-QAM.

56.6 Satellite Transmission

Satellite video broadcasting provides an effective way for point-to-multipoint video distribution. It has been widely used in video distribution to cable headends and to satellite TVRO (TV Receive Only) users for years. Due to recent development in high-powered Ku-band satellite transponders, satellite video broadcasting to small home antennas becomes feasible. The cost of consumer satellite receive systems, including receive dish antenna/LNB and Integrated Receiver/Decoder (IRD) falls below U.S. \$600 today and is expected to decline gradually. Furthermore, due to advances in digital video compression technology, the capacity of the satellite transponder has been increased substantially. Today, digital TV with 100 or more channels per satellite is being broadcast in North America.

In an analog satellite transmission system, the baseband video signal is FM modulated and transmitted from an uplink site to geo-stationary satellite. The signal is received by the satellite and retransmitted downward at a different frequency. At a receive site, the signal is received by the receive antenna, block frequency converted to a lower frequency band, and carried through a coax cable to an indoor IRD unit. A simplified system is shown in Fig. 56.5.

Due to constraint on the power limit, the satellite transmitters are normally operated in the saturated mode, which introduces system nonlinearity and causes waveform distortion. The available signal-to-noise ratio for satellite channels is usually much lower than that for cable channels. In order to overcome the nonlinearity as well as to improve the signal-to-noise ratio, the FM technique is always used for analog TV transmission over satellites. For Ku-band applications, a 27-MHz bandwidth is normally allocated to carry one analog TV signal.

For digital transmission over satellite, the QPSK (Quadrature Phase Shift Keying) modulation is the most popular technique. The QAM (Quadrature Amplitude Modulation) technique, which requires a linear system response, is not suitable for satellite applications. In the North American region, the Ku-band DBS uses the 12/14 GHz frequency band (14 GHz for uplink and 12 GHz for downlink), which allows the subscribers to use a smaller dish antenna. However, the Ku-band link is more susceptible to rain fading than the C-band link and, therefore, more margin for rain fading is required for the Ku-band link. Due to the typical low signal-to-noise ratio available for satellite links, powerful coding techniques are required in order to achieve a high-quality link. For an MPEG-2 video

FIGURE 56.5: A satellite video transmission system.

stream at 10 Mbit/s, an average of 1-h error-free transmission will require a BER of 2.778×10^{-11} .

Satellite link has been notorious for its nonlinearly and relatively low carrier-to-noise ratio. Due to the nonlinearity, any amplitude modulation technique is discouraged in satellite environment. Without forward error correction coding, typical satellite links can only achieve a BER around 10^{-2} to 10^{-5} . This BER is far from the targeted quality of service for compressed digital video. As discussed earlier, concatenated inner and outer codes are very effective for satellite communications, which can reduce the BER to below 10^{-12} from 10^{-4} .

Recently, European Broadcasting Union (EBU) launched a project intended to set a standard for digital video transmission over satellite, cable, and Satellite Master Antenna TV (SMATV) channels. A draft standard [27] was published by EBU/European Telecommunications Standards Institute (ETSI). This draft specifies a powerful error correction scheme based on concatenation of convolutional and Reed-Solomon (RS) codes as shown in Fig. 56.3. The convolutional code can be configured to operate at different rates, including 1/2, 2/3, 3/4, 5/6, 7/8, and 1 to optimize the performance for transponder power and bandwidth. At the receive end, Viterbi decoding with soft-decision is often used to decode the convolutional code. By using the convolutional code alone, a BER between 10^{-3} and 10^{-8} may be achieved for typical satellite links. However, this is still not adequate for real-time digital video applications.

In order to further improve the BER performance, an outer code using the Reed-Solomon code is applied to correct errors remaining uncorrected by the convolutional code. Channel errors generated at the output of Viterbi decoder tend to occur in bursts. The Reed-Solomon code operates on byte-oriented data and is effective in correcting burst errors. To improve the effectiveness of the RS code, an interleaver is usually used between the convolutional code and the RS code. By using the (204,188) RS code and a convolutional interleaver of depth 12, the BER of $2 \cdot 10^{-4}$ for the convolutional code can be improved to around 10^{-11} . A recent report [28] showed that a BER around 10^{-11} can be achieved for typical high-powered DBS with bit rates ranging from 23 to 41 Mbit/s by using concatenate convolutional and RS codes.

56.7 ATM Transmission of Video

ATM is a cell-based transport technology that multiplexes fixed-length cells from a variety of sources to a variety of remote locations. Each ATM cell consists of a 5-byte header and 48-byte payload. The routing, flow control and payload type information is carried in the header, which is then protected by a 1-byte error correction code. However, unlike the packet data communication, ATM

is a connection-oriented protocol. Connections, either permanent, semi-temporary, or permanent, between ATM users are established before data exchanges commence. The header information in each cell determines to which port at an ATM switch the cell should be routed. This substantially reduces the processing complexity required in a switching equipment. The flexibility of ATM technology allows both constant rate and variable rate services to be easily offered through the network. Also, it allows multimedia services, such as video, voice, and data of different characteristics to be multiplexed into a single stream and delivered to customers.

56.7.1 ATM Adaptation Layer for Digital Video

In order to carry data units other than the 48-octets payload size in ATM cells, an adaptation layer is needed. The ATM Adaptation Layer (AAL) provides for segmentation and reassembly (SAR) of higher-layer data units and detection of errors in transmission. Five AALs are specified in ITU-T Recommendation, I.363. AAL1 is intended for constant bit rate services while AAL2 is intended for variable bit rate services with a required timing relationship between the source and destination. AAL3/4 is intended for variable bit rate services that require bursty bandwidth. AAL5 is a simple and efficient adaptation layer intended to reduce the complexity and overhead of AAL3/4. Both AAL1 and AAL5 have been seriously considered as a candidate for real-time digital video applications. However, the AAL5 was adopted by the ATM Forum as the standard for Audiovisual Multimedia Services (AMS) [29].

The standard process of ATM is undertaken by several international standard bodies such as ATM Forum, and International Telecommunication Union–Transmission (ITU-T) Study Groups (SG) 9, 13, and 15. For digital television transmission, the MPEG-2 transport standard seems to be the sole format being considered. MPEG-2 transport standard relies on frequent and low-jitter delivery of transport stream (TS) packets containing PCR (Presentation Clock References) to recover the 27-MHz clock at the receiving end. There are several key parameters in designing an AAL for digital video, which include packaging efficiency, complexity, error handling capability and performance, and PCR jitter. When AAL1 is employed, each MPEG-2 TS packet is mapped into 4 ATM cells as shown in Fig. 56.6(a). A 1-byte AAL1 header is inserted into the first payload byte of each ATM cell. The AAL1 header contains a sequence number field and a sequence number protection field. The AAL1 uses the synchronous residual time stamp (SRTS) method to support source clock recovery.

The AAL5 specified in [29] maps N MPEG-2 Single Program TS (SPTS) packets into an AAL5-SDU (service data unit) unless there are fewer than N TS packets left in the sequence. In the case when there are fewer than N packets left in the SPTS, the last AAL5-SDU contains all the remaining packets. The default value for N is 2, which results in a default SDU size of 376 bytes. This default SDU along with an 8-byte trailer fits nicely into the payloads of 8 ATM cells, as shown in Fig. 56.6(b). The trailer contains a 2-byte alignment field, a 2-byte length indicator field, and a 4-byte CRC field. For constant bit rate transmission, the MPEG-2 SPTS is considered as a constant packet rate (CPR) stream of information, which implies that the interarrival time between packets of the MPEG-2 TS is constant. In order to ensure satisfactory timing recovery, the time interval of the last byte containing the PCR should be constant.

The AAL5 is meant for both constant bit rate and variable bit rate applications while the AAL1 is mainly intended for constant bit rate applications. The AAL5 contains a 4-byte CRC field and a 2-byte length indicator field to check the payload integrity. On the other hand, the AAL1 only offers sequence integrity to detect lost cells. The most attractive factor of AAL5 is the wide support of major service and equipment vendors.

FIGURE 56.6: Mapping MPEG-2 TS packets into AAL PDU. (a) AAL-1 and (b) AAL5.

56.7.2 Cell Loss Protection

In the ATM environment, cells may be corrupted due to transmission errors or lost due to traffic congestion. The transmission bit error rate usually is very small for fiber-based systems. However, the cell loss due to congestion seems to be unavoidable in order to increase link utilization efficiency. Depending on how compressed data is mapped into ATM cells, the loss of a single cell may corrupt a number of cells. In the ATM header, there is 1-bit information to indicate the delivery priority of the underlying payload. This priority bit can be used to cope with the cell loss issue. To take advantage of the priority bit, the coding systems will have to separate the compressed data into high- and low-priority layers and to pack the data into cells with a corresponding priority indicator. When network congestion occurs, these cells labeled with low priority are subject to discarding at the switch. Since the low-priority cells carry visually less important information, the impairments in the reconstructed low-priority data will be less objectionable. Some two-layer coding techniques were proposed for MPEG-2 video and have shown significant improvement over a single-layer coding under cell loss circumstance [20, 21].

57.1 Introduction

Static images and dynamic image sequences are the projection of time-varying three-dimensional real world scenes onto a two-dimensional plane. As a result of this planar projection, depth information of objects in the scene is generally lost. Only by *cues* such as shadow, relative size and sharpness, interposition, perspective factors, and object motion, can we form an impression of the depth organization of the real world scene.

In a wide variety of image processing applications, explicit depth information is required in addition to the scene's gray value information (representing intensities, color, densities, etc.) [2, 4, 7]. Examples of such applications are found in 3-D vision (robot vision, photogrammetry, remote sensing systems); in medical imaging (computer tomography, magnetic resonance imaging, microsurgery); in remote handling of objects, for instance in inaccessible industrial plants or in space exploration; and in visual communications aiming at virtual presence (conferencing, education, virtual travel and shopping, virtual reality). In each of these cases, depth information is essential for accurate image analysis or for enhancing the realism. In remote sensing the terrain's elevation needs to be accurately determined for map production, in remote handling an operator needs to have precise knowledge of the three-dimensional organization of the area to avoid collisions and misplacements, and in visual communications the quality and ease of information exchange significantly benefits from the high degree of realism provided by scenes with depth.

Depth in real world scenes can be explicitly measured by a number of range sensing devices such as by laser range sensors, structured light, or ultrasound. Often it is, however, undesirable or unnecessary to have separate systems for acquiring the intensity and the depth information because

¹This work was supported in part by the European Union under the RACE-II project DISTIMA and the ACTS project PANORAMA.

of the relative low resolution of the range sensing devices and because of the question of how to fuse information from different types of sensors.

An often used alternative to acquire depth information is to record the real world scene from different perspective viewpoints. In this way, multiple images or (preferably time-synchronized) image sequences are obtained that implicitly contain the scene's depth information. In the case that multiple views of a single scene are taken without any specific relation between the spatial positions of the viewpoints, such recordings are called *multiview images*. Generally speaking, when recordings are obtained from an increasing number of different viewpoints, the 3-D surfaces and/or interior structures of the real world scene can be reconstructed more accurately. The terms *stereoscopic image* and *stereoscopic image sequence* are reserved for the special case that two perspective viewpoints are recorded or computed such that they can be viewed by a human observer to produce the effect of natural depth perception (see Fig. 57.1). Therefore, the two views are required to be recorded under specific constraints such as the cameras' separation, convergence angle, and alignment [8]. Stereoscopic images are not truly 3-D images since they merely contain information about the 2-D projected real world surfaces plus the depth information at the perspective viewpoints. They are, therefore, sometimes called 2.5-D images.

FIGURE 57.1: Illustration of system for stereoscopic image (sequence) recording, processing, transmission, and display.

In the broadest meaning of the word, a digital stereoscopic system contains the following components: stereoscopic camera setup, depth analysis of the digitized and recorded views, compression, transmission or storage, decompression, preprocessing prior to display, and, finally, the stereoscopic display system. The emphasis here is on the image processing components of this stereoscopic system; that is, depth analysis, compression, and preprocessing prior to the stereoscopic display. Nonetheless, we first briefly review the perceptual basis for stereoscopic systems and techniques for stereoscopic recording and display in Section 57.2. The issue of depth or *disparity analysis* of stereoscopic images is discussed in Section 57.3, followed by the application of compression techniques to stereoscopic images in Section 57.4. Finally, Section 57.5 considers the issue of stereoscopic image interpolation as a preprocessing step required for multiviewpoint stereoscopic display systems.

57.2 Acquisition and Display of Stereoscopic Images

The human perception of depth is brought about by the hardly understood brain process of fusing two planar images obtained from slightly different perspective viewpoints. Due to the different viewpoint of each eye, a small horizontal shift exists, called *disparity*, between corresponding image points in the left and right view images on the retinas. In stereoscopic vision, the objects to which the eyes are focused and accommodated have zero disparity, while objects to the front and to the back have negative and positive disparity, respectively, as is illustrated in Figure 57.2. The differences in

disparity are interpreted by the brain as differences in depth ΔZ .

FIGURE 57.2: Stereoscopic vision, resulting in different disparities depending on depth.

In order to be able to perceive depth using recorded images, a stereoscopic camera is required which consists of two cameras that capture two different, horizontally shifted perspective viewpoints. This results in a shift (or disparity) of objects in the recorded scene between the left and the right view depending on their depth. In most cases, the interaxial separation or baseline B between the two lenses of the stereoscopic camera is in the same order as the eye distance E (6 to 8 cm). In a simple camera model, the optical axes are assumed to be parallel. The depth Z and disparity d are then related as follows:

$$d = \lambda \frac{B}{\lambda - Z}, \quad (57.1)$$

where λ is the focal length of the cameras. Fig. 57.3(a) illustrates this relation for a camera with $B = 0.1$ m and $\lambda = 0.05$ m. A more complicated camera model takes into account the convergence of the camera axes with angle β . The resulting relation between depth and disparity, which is a much more elaborate expression in this case, is illustrated in Fig. 57.3(b) for the same camera parameters and $\beta = 1^\circ$. It shows that, in this case, the disparity is not only dependent on the depth Z of an object, but also on the horizontal object position X . Furthermore, a converging camera configuration also leads to small vertical disparity components, which are, however, often ignored in subsequent processing of the stereoscopic data. Figures. 57.4(a) and (b) show as an example a pair of stereoscopic images encountered in video communications.

When recording stereoscopic image sequences, the camera setup should be such that, when displaying the stereoscopic images, the resulting shifts between corresponding points in the left and right view images on the display screen allow for comfortable viewing. If the observer is at a distance Z_s from the screen, then the observed depth Z_{obs} and displayed disparity d are related as:

$$Z_{\text{obs}} = Z_s \frac{E}{E - d}. \quad (57.2)$$

In the case that the camera position and focusing are changing dynamically, as is the case, for instance, in stereoscopic television production where the stereoscopic camera may be zooming, the camera geometry is controlled by a set of production rules. If the recorded images are to be used for multiviewpoint stereoscopic display, a larger interaxial lens separation needs to be used, sometimes even up to 1 m. In any case, the camera setup should be geometrically calibrated such that the two cameras capture the same part of the real world scene. Furthermore, the two cameras and A/D converters need to be electronically calibrated to avoid unbalances in gray value of corresponding points in the left and right view image.

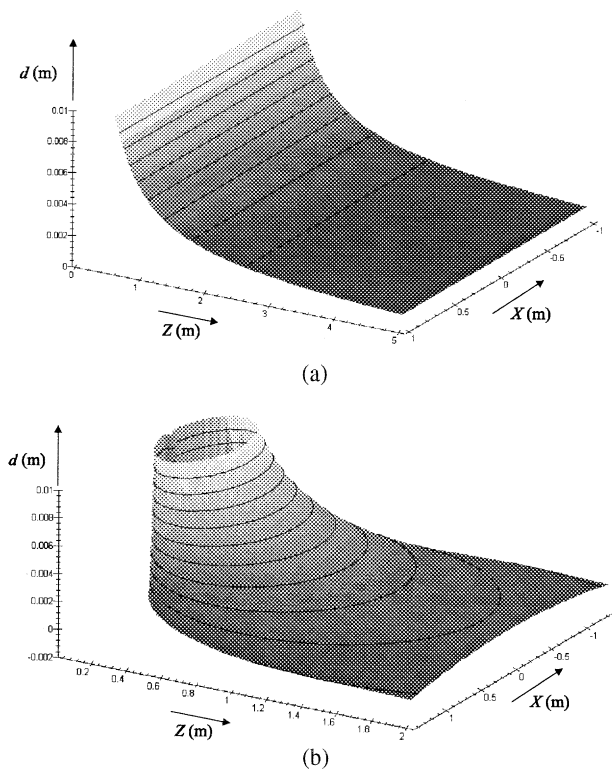

FIGURE 57.3: (a) Disparity as a function of depth for a sample parallel camera configuration; (b) disparity for a sample converging camera configuration.

The stereoscopic image pair should be presented such that each perspective viewpoint is seen only by one of the eyes. Most practical state-of-the-art systems require viewers to wear special viewing glasses [6]. In a *time-parallel* display system, the left and right view images are presented simultaneously to the viewer. The views are separated by passive viewing glasses such as red-green viewing glasses requiring the left and right view to be displayed in red and green, respectively, or polarized viewing glasses requiring different polarization of the two views. In a *time-sequential* stereoscopic display, the left and right view images are multiplexed in time and displayed at a double field rate, for instance 100 or 120 Hz. The views are separated by means of the active synchronized shuttered glasses that open and close the left and right eyeglasses depending on the viewpoint being shown. Alternatively, lenticular display screens can be used to create spatial interference patterns such that the left and right view images are projected directly into the viewer's eyes. This avoids the need of wearing viewing glasses.

57.3 Disparity Estimation

The key difference between planar and stereoscopic images and image sequences is that the latter implicitly contains depth information in the form of disparity between the left and right view images. Not only is the presence of disparity information essential to the ability of humans to perceive depth, disparity can also be exploited for automated depth segmentation of real world scenes, and for compression and interpolation of stereoscopic images or image sequences [1].

FIGURE 57.4: The left (a) and right (b) view image from a stereoscopic image pair. (c) Disparity field in the stereoscopic image pair represented as gray values (black is foreground, gray is background, white is occlusion).

To be able to exploit disparity information in a stereoscopic pair in image processing applications, the relation between the contents of the left view image and the right view image has to be established, yielding the *disparity (vector) field*. The disparity field indicates for each point in the left view image the relative shift of the corresponding point in the right view image and vice versa. Since some parts of one view image may not be visible in the alternate view image due to occlusion, not all points in the image pair can be assigned a disparity vector.

Disparity estimation is essentially a correspondence problem. The correspondence between the two images can be determined by either matching features or by operating on or matching of small patches of gray values. Feature matching requires as a preprocessing step the extraction of appropriate features from the images, such as object edges and corners. After obtaining the features, the correspondence problem is first solved for the spatial locations at which the features occur, from which next the full disparity field can be deduced by, for instance, interpolation or segmentation procedures. Feature-based disparity estimation is especially useful in the analysis of scenes for robot vision applications [4, 11].

Disparity field estimation by operating directly on the image gray value information is not unlike the problem of motion estimation [11, 12]. The first difference is that disparity vectors are approximately horizontally oriented. Deviations from the horizontal orientation are caused by the convergence of the camera axes and by differences between the camera optics. Usually vertical disparity components are either ignored or rectified. A second difference is that disparity vectors can take on a much larger range of values within a single image pair. Furthermore, the disparity field may have large discontinuities associated with objects neighboring in the planar projection but having a very much different depth. In those regions of the stereoscopic image pair where one finds large discontinuities in the disparity

field due to abrupt depth changes, large regions of occlusion will be present. Estimation methods for disparity fields must therefore be able not only to find the correspondence between information in the left and right view images, but must also be able to detect and handle discontinuities and occlusions [1].

Most disparity estimation algorithms used in stereoscopic communications rely on matching small patches of gray values from one view to the gray values in the alternate view. The matching of this small patch is not carried out in the entire alternate image, but only within a relatively small search region to limit the computational complexity. Standard methods typically use a rectangular match block of relatively small size (e.g., 8×8 pixels), as illustrated in Fig. 57.5. The relative horizontal

FIGURE 57.5: Block matching disparity estimation procedure by comparing a match block from the left image to the blocks within a horizontally oriented search region in the right image.

shift between a match block and the block within the search region of the alternate image that results in the smallest value of a criterion function used is then assigned as disparity vector to the center of that match block. Often used criterion functions are the sum of squares and the sum of the absolute values of the differences between the gray values in the match block and the block being considered in the search region [3, 12].

The above procedure is carried out for all pixels, first matching the blocks from the left view image to the right view image, then vice versa. From the combination of the two resulting disparity fields and the values of the criterion function, the final disparity field is computed, and occluding areas in the stereoscopic image pair are detected. For instance, one way of detecting occlusions is a local abrupt increase of the criterion function, indicating that no acceptable correspondence between the two image pairs could be found locally. Fig. 57.4(c) illustrates the result of a disparity estimation process as an image in which different gray values correspond to different disparities (and thus depth), and in which "white" indicates occluding regions that can be seen in the left view image but that cannot be seen in the right view image.

More advanced versions of the above *block matching disparity estimator* use hierarchical or recursive approaches to improve the consistency or smoothness of the resulting disparity field, or are based on the optical flow model often used in motion estimation. Other approaches use preprocessing steps to determine the dominant disparity values that are then used as candidate solutions during the actual estimation procedure. Finally, most recent approaches use advanced Markov random field models for the disparity field and/or they make use of more complicated cost functions such as the *disparity space image*. These approaches typically require exhaustive optimization procedures but they have the potential of accurately estimating large discontinuities and of precisely detecting the presence of occluding regions [1].

In image analysis problems, disparity estimation is often considered in combination with the segmentation of the stereoscopic image pair. Joint disparity estimation and texture segmentation

methods partition the image pair into spatially homogeneous regions of approximately equal depth. Disparity estimation in image sequences is typically carried out independently on successive frame pairs. Nevertheless, the need for temporal consistency of successive disparity fields often requires temporal dependencies to be exploited by postprocessing of the disparity fields. If an image sequence is recorded as an interlaced video signal, disparity estimation should be carried out on the individual fields instead of frames to avoid confusion between motion displacements and disparity.

57.4 Compression of Stereoscopic Images

Compression of digital images and image sequences is necessary to limit the required transmission bandwidth or storage capacity [3, 5]. One of the compression principles underlying the JPEG and MPEG standards is to avoid transmitting or storing gray value information that is predictable from the signal's spatial or temporal past, i.e., information that is redundant. In both JPEG and MPEG, this principle is exploited by a spatial DPCM system, while in MPEG motion-compensated temporal prediction is also used to exploit temporal redundancies.

When dealing with stereoscopic image pairs, a third dimension of redundancy appears, namely the mutual predictability of the two perspective views [9]. Although the left and right view images are not identical, gray value information in, for instance, the left view image is highly predictable from the right view image if the horizontal shift of corresponding points, i.e., the disparity, is taken into account. Thus, instead of transmitting or storing both views of a stereoscopic image pair, only the right view image is retained, together with the disparity field. Since the construction of the left view image from the right view is not perfect due to errors in the estimated disparity field and due to presence of occluding areas and perspective differences, some information of the *disparity-compensated prediction error* of the left view (i.e., the difference between the predicted gray values and the actual gray values in the left view image) also needs to be retained. Figure 57.6 shows the *disparity-compensated prediction* and the *disparity-compensated prediction error* of the left view image from Fig. 57.4(a) using the right view image in Fig. 57.4(b) and the disparity field in Fig. 57.4(c). In most cases, the sum of the bit rates needed for coding the disparity vector field and the disparity-compensated prediction error is much smaller than the bit rate needed for the left view image when compressed without disparity compensation.

FIGURE 57.6: (a) Disparity-compensated prediction and (b) disparity-compensated prediction error of the left view image (scaled for maximal visibility) in Fig. 57.4. Black areas indicate a large error.

In image sequence, left view images can be compressed efficiently by carrying out motion-compensated prediction from previous left view images, by disparity-compensated prediction from the corresponding right view image, or by a combination of the two by choosing for motion-compensation or disparity-compensation on a block-by-block basis, as illustrated in Fig. 57.7(a). Basically this is a direct extension of the MPEG compression standard with an additional prediction mode for the left view image sequence. The effect of this additional (disparity-compensated) prediction mode is that the variance of the prediction error of the left view image sequence is further decreased [see Fig. 57.7(b)], meaning that more compression of the left view sequence is possible than when independently compressing the two views of the stereoscopic sequence. Figure 57.8 schematically shows the architecture of a disparity- and motion-compensated encoder for stereoscopic video.

57.5 Intermediate Viewpoint Interpolation

The system illustrated in Fig. 57.1 assumes that the stereoscopic image captured by the cameras is directly displayed at the receiver's end. One of the shortcomings of such a two-channel stereoscopic system is that shape and depth distortion occur when the stereoscopic images are viewed from an off-center position. Furthermore, since the cameras are in a fixed position, the viewer's (horizontal) movements do not provide additional information about, for instance, objects that are partly occluded. The lack of this "look around" capability especially is a limiting factor in the truly realistic visualization of a recorded real world scene.

In a multi-channel or *multiview stereoscopic system*, multiple viewpoints of the same real world scene are available. The stereoscopic display then shows only those two perspective views which correspond as well as possible with the viewer's position. To this end some form of tracking the viewer's position is necessary. The additional viewpoints could be obtained by installing more cameras at a wide range of possible viewpoints. On grounds of complexity and costs the number of cameras will typically be limited to three to five, meaning that not all possible positions of the viewer are covered in this way. If, because of the viewer's position, a view of the scene is needed from an unavailable camera position, a *virtual camera* or *intermediate viewpoint* must be constructed from the available camera viewpoints (see Fig. 57.9).

The construction of intermediate viewpoints is an interpolation problem, which has much in common with the problem of video standards conversion [11]. In its most simple form, the interpolated viewpoint is merely a weighted average between the images from the nearest two camera viewpoints, which are called the key images. Such a straightforward averaging ignores the presence of disparity between the key images, yielding a highly blurred and essentially useless result [see Fig. 57.10(a)]. If, however, the disparity vector field between the two key images has been estimated and the areas of occlusions are known, the interpolation can be carried out along the *disparity axis*, such that the disparity information in the interpolated image corresponds exactly to the virtual camera position. For the points where a correspondence exists between the two key images, this construction process is called *disparity-compensated interpolation*, while for the occluding regions *extrapolation* has to be carried out from the key images [10]. Figure 57.10(b) illustrates the result of intermediate viewpoint interpolation on the stereoscopic image pair in Figs. 57.4(a) and (b).

FIGURE 57.7: (a) Principle of joint disparity- and motion-compensated prediction for the left view of a stereoscopic image sequence; (b) variance of the prediction error of the left view image sequence when using motion-compensation, disparity-compensation, or joint motion-disparity compensation on a block-by-block basis.

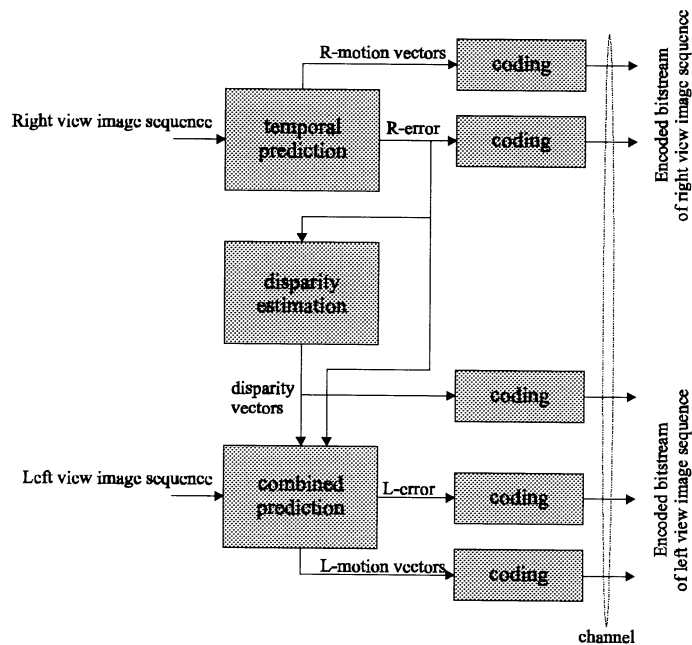

FIGURE 57.8: Architecture of a disparity- and motion-compensated encoder for stereoscopic video.

FIGURE 57.9: Multiview stereoscopic system with interpolated intermediate viewpoint (virtual camera).

A Survey of Image Processing Software and Image Databases

58.1 Image Processing Software

General Image Utilities • Specialized Image Utilities • Programming/Analysis Environments

58.2 Image Databases

Images by Form

Stanley J. Reeves
Auburn University

Image processing has moved into the mainstream, not only of the engineering world, but of society in general. Personal computers are now capable of handling large graphics and images with ease, and fast networks and modems transfer images in a fraction of the time required just a few years ago. Image manipulation software is a common item on PCs, and CD-ROMs filled with images and multimedia databases are standard fare in the realm of electronic publishing. Furthermore, the development of areas such as data compression, neural networks and pattern recognition, computer vision, and multimedia systems have all contributed to the use of and interest in image processing. Likewise, the growth of image processing as an engineering discipline has fueled interest in these other areas. As a result of this symbiotic growth, image processing has increasingly become a standard tool in the repertoire of the engineer.

Because of the popularity of image processing, a large array of tools has emerged for accomplishing various image processing tasks. In addition, a variety of image databases has been created to address the needs of various specialty areas. In this article, we will survey some of the tools available for accomplishing basic image processing tasks and indicate where they may be obtained. Furthermore, we will describe and provide pointers to some of the most generally useful images and image databases. The goal is to identify a basic collection of images and software that will be of use to the nonspecialist. It should also be of use to the specialist who needs a general tool in an area outside his or her specialty.

58.1 Image Processing Software

Image processing has become such a broad area that it is sometimes difficult to distinguish what might be considered an image processing package from other software systems. The boundaries among the areas of computer graphics, data visualization, and image processing have become blurred. Furthermore, to discuss or even to list all the image processing software available would require many pages and would not be particularly useful to the nonspecialist. Therefore, we emphasize a representative set of image processing software packages that embody core capabilities in scientific image processing applications. Core capabilities, in our view, include the following:

- **Image utilities:** These include display, manipulation, and file conversion. Images come in such a variety of formats that a package for converting images from one format to another is essential. Furthermore, basic display and manipulation (cropping, rotating, etc.) are essential for almost any image processing task. The ability to edit images using cut-and-paste, draw, and annotate operations is also useful in many cases.
- **Image filtering and transformation:** These are necessary capabilities for most scientific applications of image processing. Convolution, median filtering, FFTs, morphological operations, scaling, and other image functions form the core of many scientific image processing algorithms.
- **Image compression:** Anyone who works with images long enough will learn that they require a large amount of storage space. A number of standard image compression utilities are available for storing images in compressed form and for retrieving compressed images from image databases.
- **Image analysis:** Scientific image processing applications often have the goal of deriving information from an image. Simple image analysis tools such as edge detection and segmentation are powerful methods for gleaning important visual information.
- **Programming and data analysis environment:** While many image processing packages have a wide variety of functions, a whole new level of utility and flexibility arises when the image processing functions are built around a programming and/or data analysis environment. Programming environments allow for tailoring image processing techniques to the specific task, developing new algorithms, and interfacing image processing tasks with other scientific data analysis and numerical computational techniques.

Other capabilities include higher-level object recognition and other computer vision tasks, visualization and rendering techniques, computed imaging such as medical image reconstruction, and morphing and other special effects of the digital darkroom and the film industry. These areas require highly specialized software and/or very specialized skills to apply the methods and are not likely to be part of the image processing world of the nonspecialist.

The packages to be discussed here encompass as a group all of the core image processing capabilities mentioned above. Because these packages offer such a wide variety and mix of functions, they defy simple categorization. We have chosen to group the packages into three categories: general image utilities, specialized utilities, and programming/analysis environments. Keep in mind, however, that the distinctions among these groups is blurry at best. We have chosen to emphasize packages that are freely distributable and available on the Internet because these can be obtained and used with a minimum of expense and hassle.

58.1.1 General Image Utilities

netpbm

pbmplus is a set of tools that allows the user to convert to and from a large number of common image formats. The package has its own intermediate formats so that the conversion routines can be written to convert to or from one of these formats. The user can then convert to and from any combination of formats by going through one of the intermediate formats. Functions are also provided to convert from different color resolutions, such as from color to grayscale. Several other functions do basic image manipulation such as cropping, rotating, and smoothing. The source is available from

<ftp://ftp.wustl.edu/graphics/packages/NetPBM/>.

xv is an X11 utility that combines several important image handling functions. It can display images in a wide variety of display formats, including binary, 8-bit, and 24-bit. It allows the user to manipulate the colormap both in RGB and HSV space. It crops, resizes, smooths, rotates, detects edges, and produces other special effects. In addition, it reads and writes a large variety of image formats, so it can serve as a format conversion utility. Until recently, xv has been freely distributable. The latest version, however, is shareware and requires a small fee to become a registered user. The source is available from <http://www.trilon.com/xv>.

NCSA Image

NCSA Image is available in versions for the Mac, DOS, and Unix (X11). The Unix version is called ximage. ximage allows the user to display color images. It can also display the actual data in the form of a spreadsheet. A number of other display options are available. Like xv, it allows for manipulation of the colormap in a variety of ways. In addition, the user may display multiple images as an animated sequence, either from disk or server memory. The functionality of NCSA Image is augmented by other programs available from NCSA, including DataSlice for visualization tasks and Reformat for converting image formats. The source is available from NCSA by ftp at <ftp://ftp.ncsa.uiuc.edu/Visualization/Image/>.

ImageMagick

ImageMagick is an X11 package for display and interactive image manipulation. It reads and writes a large number of standard formats, does standard operations such as cropping and rotating as well as more specialized editing operations such as cutting, pasting, color filling, annotating, and drawing. Separate utilities are provided for grabbing images from a display, for converting, combining, resizing, blurring, adding borders, and doing many other operations. The source is available by ftp from <ftp://ftp.x.org/contrib/applications/ImageMagick/>.

NIH Image

NIH Image is available only in a Macintosh version. However, the popularity of NIH Image among Mac users and the breadth of features justify inclusion of the package in this survey. It reads/writes a small number of image formats, acquires images using compatible frame grabbers, and displays. It allows image manipulation such as flipping, rotating, and resizing; and editing such as drawing and annotating. It has a number of built-in enhancement and filtering functions: contrast enhancement, smoothing, sharpening, median filtering, and convolution. It supports a number of analysis operations such as edge detection and measurement of area, mean, centroid, and perimeter of user-defined regions of interest. It also performs automated particle analysis. In addition, the user can animate a set of images. NIH Image has a Pascal-like macro capability and the ability to add precompiled plug-in modules. The source is available from NIH by ftp at <ftp://zipper.nimh.nih.gov/pub/nih-image/>.

LaboImage

LaboImage is an X11 package for mouse- and menu-driven interactive image processing. It reads/writes a special format as well as Sun raster format and displays grayscale and RGB and provides dithering. Basic filtering operations are possible, as well as enhancement tasks such as background subtraction and histogram equalization. It computes various measures such as histograms, image statistics, and image power. Region outlining and object counting can be done as well. Images can

be modified interactively at the pixel level, and an expert system is available for region segmentation. LaboImage has a macro capability for combining operations. LaboImage can be obtained from <http://cuiwww.unige.ch/ftp/sgaico/research/geneve/vision/labo.html>.

Paint Shop Pro

Paint Shop Pro is a Windows-based package for creating, displaying, and manipulating images. It has a large number of image editing features, including painting, photo retouching, and color enhancement. It reads and writes a large number of formats. It includes several standard image processing filters and geometrical transformations. It can be obtained from <http://www.jasc.com/psp.html>. It is shareware and costs \$69.

58.1.2 Specialized Image Utilities

Compression

JPEG is a standard for image compression developed by the Joint Photographic Experts Group. Free, portable C code that implements JPEG compression and decompression has been developed by the Independent JPEG Group, a volunteer organization. It is available from <ftp://ftp.uu.net/graphics/jpeg>. The downloadable package contains source and documentation. The code converts between JPEG and several other common image formats. A lossless JPEG implementation can be obtained from <ftp://ftp.cs.cornell.edu/pub/multimed/>.

A fractal image compression program is available from <ftp://inls.ucsd.edu/pub/young-fractal/>. The package contains source for both compression and decompression. A number of other fractal compression programs are also available and can be found in the sci.fractal FAQ at <ftp://rtfm.mit.edu/pub/usenet/news.answers/sci/fractals-faq>.

JBIG is a standard for binary image compression developed by the Joint Binary Images Group. A JBIG coder/decoder can be obtained from <ftp://nic.funet.fi/pub/graphics/misc/test-images/>.

MPEG is a standard for video/audio compression developed by the Moving Pictures Experts Group. A set of MPEG tools is available from <ftp://mm-ftp.cs.berkeley.edu/pub/multimedia/mpeg/>. These tools allow for encoding, decoding (playing), and analyzing the MPEG data.

H.261 and H.263 are standards for video compression for videophone applications. An H.261 coder/decoder is available from <ftp://havefun.stanford.edu/pub/p64/>. An H.263 video coder/decoder is available from http://www.fou.telenor.no/brukere/DVC/h263_software/.

Computer Vision

Vista is an X11-based image processing environment specifically designed for computer vision applications. It allows a variety of display and manipulation options. It has a library that lets the user easily create applications with menus, mouse interaction, and display options. Vista defines a very flexible data format that represents a variety of images, collections of images, or other objects. It also has the ability to add new objects or new image attributes without changing existing software or data files. It does edge detection and linking, optical flow estimation and camera calibration, and viewing of images and edge vectors. Vista includes routines for common image processing operations such as convolution, FFTs, simple enhancement tasks, scaling, cropping, and rotating. Vista is available from <http://www.cs.ubc.ca/nest/lci/vista/vista.html>.

58.1.3 Programming/Analysis Environments

Khoros

Khoros is a comprehensive software development and data analysis environment. It allows the user to perform a large variety of image and signal processing and visualization tasks. A graphical programming environment called Cantata allows the user to construct programs visually using a data flowgraph approach. It has a user interface design tool with automatic code generation for writing customized applications. Software objects (programs) are accessible from the command line, from within Cantata, and in libraries.

A large set of standard numerical and statistical algorithms are available within Khoros. Common image processing operations such as FFTs, convolution, median filtering, and morphological operators are available. In addition, a variety of image display and geometrical manipulation programs, animation, and colormap editing are included. Khoros has a very general data model that allows for images of up to five dimensions.

Khoros is free-access software — it is available for downloading free of charge but cannot be distributed without a license. It can be obtained from Khoros Research, Inc., at <ftp://ftp.khoros.com/pub/>. Note that the Khoros distribution is quite large and requires significant disk space.

MATLAB

MATLAB is a general numerical analysis and visualization environment. Matrices are the underlying data structure in MATLAB, and this structure lends itself well to image processing applications. All data in MATLAB is represented as double-precision, which makes the calculations more precise and interaction more convenient. However, it may also mean that MATLAB uses more memory and processing time than necessary.

A large number of numerical algorithms and visualization options are available with the standard package. The Image Processing Toolbox provides a great deal of added functionality for image processing applications. It reads/writes several of the most common image formats; does convolution, FFTs, median filtering, histogram equalization, morphological operations, two-dimensional filter design, general nonlinear filtering, colormap manipulation, and basic geometrical manipulation. It also allows for a variety of display options, including surface warping and movies.

MATLAB is an interactive environment, which makes interactive image processing and manipulation convenient. One can also add functionality by creating scripts or functions that use MATLAB's functions and other user-added functions. Additionally, one can add functions that have been written in C or Fortran. Conversely, C or Fortran programs can call MATLAB and MATLAB library functions. MATLAB is commercial software. More information on MATLAB and how to obtain it can be found through the homepage of The Mathworks, Inc., at <http://www.mathworks.com/>.

PV-Wave

PV-Wave is a general graphical/visualization and numerical analysis environment. It can handle images of arbitrary dimensionality — 2-D, 3-D, and so on. The user can specify the data type of each data structure, which allows for flexibility but may be inconvenient for interactive work.

PV-Wave contains a large collection of visualization and rendering options, including colormap manipulation, volume rendering, and animation. In addition, the IMSL library is available through PV-Wave. Basic image processing operations such as convolution, FFTs, median filtering, morphological operations, and contrast enhancement are included.

Like MATLAB, PV-Wave is an interactive environment. One can create scripts or functions from the PV-Wave language to add functionality. It can also call C or Fortran functions. PV-Wave can be invoked from within C or Fortran too. PV-Wave is commercial software. More information on PV-Wave can be found through the homepage of Visual Numerics, Inc., at <http://www.vni.com/>.

58.2 Image Databases

A huge number of image databases and archives are available on the Internet now, and more are continually being added. These databases serve various purposes. For the practicing engineer, the primary value of an image database is for developing, testing, evaluating, or comparing image processing and manipulation algorithms. Standard images provide a benchmark for comparing various algorithms. Furthermore, standard test images can be selected so that their characteristics are particularly suited to demonstrating the strengths and weaknesses of particular types of image processing techniques. In some areas of image processing no real standards exist, although de facto standards have arisen. In the discussion that follows, we provide pointers to some standard images, some de facto standards, and a few other databases that might provide images of value to algorithm work in image processing. We have deliberately steered away from images whose copyright is known to prohibit use for research purposes. However, some of the images in the list have certain copyright restrictions. Be sure to check any auxiliary information provided with the images before assuming that they are public domain.

The images listed are in a variety of formats and may require conversion using one of the packages discussed previously such as netpbm. We list the databases according to two categories: (1) form and (2) content. By form, we mean that the images are organized according to the form of the image — color, stereo, sequence, etc. By content, we mean that the images are grouped according to the image content — faces, fingerprints, etc.

58.2.1 Images by Form

Binary Images

A set of standard CCITT fax test images has been made available for testing compression schemes. These are binary images that have come from scanning actual documents. They can be found at <ftp://nic.funet.fi/pub/graphics/misc/test-images/> under ccitt[1-8].pbm.gz.

Grayscale Images

A collection of grayscale images can be obtained from <ftp://ipl.rpi.edu/pub/image/still/canon/gray/>. A compilation of de facto standard images can be found at http://www.sys.uea.ac.uk/Research/ResGroups/SIP/images_ftp/index.html. Note that the Lena image is copyrighted and should not be used in publications.

Color Images

A set of test images that were used by the JPEG committee in the development of the JPEG algorithm are available from <ftp://ipl.rpi.edu/pub/image/still/jpeg/bgr/>. These are 24-bit RGB images. Other 24-bit color images can be found at <ftp://ipl.rpi.edu/pub/image/still/canon/bgr/>. A set of miscellaneous images in JPEG and Kodak CD format can be found at <http://www.kodak.com/digitalImages/samples/samples.shtml>.

Image Sequences

Image sequences may be intended for study of computer vision applications or video coding. A huge set of sequences for computer vision applications are archived at <http://www.ius.cs.cmu.edu/idb/>.

A set of sequences commonly used for video coding applications can be found at <ftp://ipl.rpi.edu/pub/image/sequence/>.

Stereo Image Pairs

Stereo image pairs are available from <http://www.ius.cs.cmu.edu/idb/>.

Texture Images

A large set of texture images can be found at <http://www-white.media.mit.edu/vismod/imagery/VisionTexture/vistex.html>. These images include textures from various angles and under different lighting conditions.

Face Images

The USENIX FACES database contains hundreds of face images in various formats. The database is archived at <ftp://ftp.uu.net/published/usenix/faces/>.

Fingerprint Images

Fingerprint images can be obtained from <ftp://sequoyah.ncsl.nist.gov/pub/databases/data/>.

Medical Images

A variety of medical images are available over the Internet. An excellent collection of CT, MRI, and cryosection images of the human body has been made available by the National Library of Medicine's The Visual Human Project. Samples of these images can be acquired at http://www.nlm.nih.gov/research/visible/visible_human.html. A collection of over 3500 images that cover an entire human body is available via ftp and on tape by signing a license agreement.

MRI and CT volume images are available from <ftp://omicron.cs.unc.edu/pub/projects/softlab.v/CHVRTD/>. PET images and other modalities can be found in <gopher://gopher.austin.unimelb.edu.au/11/images/petimages>.

Astronomical Images

A collection of astronomical images can be found at <https://www.univ-rennes.fr/ASTRO/astro.english.html>. Hubble telescope imagery can be obtained from <http://archive.stsci.edu/archive.html>.

Range Images

Range images are available from <http://www.eecs.wsu.edu/~irl/3DDB/RID/>, along with a list of other sources of range imagery, and also from <http://marathon.csee.usf.edu/range/DataBase.html>.

The tools and databases discussed here should provide a convenient set of capabilities for the nonspecialist. The capabilities that are readily available are not static, however. Image processing will continue to become more and more mainstream, so we expect to see the development of image processing tools representing greater variety and sophistication. The advent of the World Wide Web will also stimulate further development and publishing of image databases on the Internet. Therefore, image processing capabilities will continue to grow and will be more readily available. The items discussed here are only a small sample of what will be available as time goes on.

VLSI Architectures for Image Communications

59.1 Introduction

Video processing has been a rapidly evolving field for telecommunications, computer, and media industries. In particular, for real time video compression applications a growing economical significance is expected for the next years. Besides digital TV broadcasting and videophone, services such as multimedia education, teleshopping, or video mail will become audiovisual mass applications.

To facilitate worldwide interchange of digitally encoded audiovisual data, there is a demand for international standards, defining coding methods, and transmission formats. International standardization committees have been working on the specification of several compression schemes. The Joint Photographic Experts Group (JPEG) of the International Standards Organization (ISO) has specified an algorithm for compression of still images [4]. The ITU proposed the H.261 standard for video telephony and video conference [1]. The Motion Pictures Experts Group (MPEG) of ISO has completed its first standard MPEG-1, which will be used for interactive video and provides a picture quality comparable to VCR quality [2]. MPEG made substantial progress for the second phase of standards MPEG-2, which will provide audiovisual quality of both broadcast TV and HDTV [3]. Besides the availability of international standards, the successful introduction of the named services depends on the availability of VLSI components, supporting a cost efficient implementation of video compression applications. In the following, we give a short overview of recent coding schemes and discuss implementation alternatives. Furthermore, the efficiency estimation of architectural alternatives is discussed and implementation examples of dedicated and programmable architectures are presented.

59.2 Recent Coding Schemes

Recent video coding standards are based on a hybrid coding scheme that combines transform coding and predictive coding techniques. An overview of these hybrid encoding schemes is depicted in Fig. 59.1.

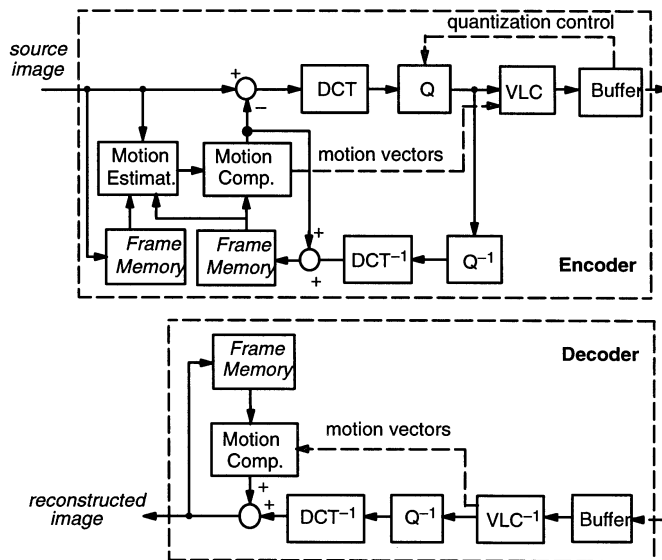

FIGURE 59.1: Hybrid encoding and decoding scheme.

The encoding scheme consists of the tasks motion estimation, typically based on blockmatching algorithms, computation of the prediction error, discrete cosine transform (DCT), quantization (Q), variable length coding (VLC), inverse quantization (Q^{-1}), and inverse discrete cosine transform (IDCT or DCT-1). The reconstructed image data are stored in an image memory for further predictions. The decoder performs the tasks variable length decoding (VLC^{-1}), inverse quantization, and motion compensated reconstruction.

Generally, video processing algorithms can be classified in terms of regularity of computation and data access. This classification leads to three classes of algorithms:

- **Low-Level Algorithms** — These algorithms are based on a predefined sequence of operations and a predefined amount of data at the input and output. The processing sequence of low-level algorithms is predefined and does not depend on the values of data processed. Typical examples of low-level algorithms are block matching or transforms such as the DCT.
- **Medium-Level Algorithms** — The sequence and number of operations of medium-level algorithms depend on the data. Typically, the amount of input data is predefined, whereas the amount of output data varies according to the input data values. With respect to hybrid coding schemes, examples for these algorithms are quantization, inverse quantization, or variable length coding.
- **High-Level Algorithms** — High-level algorithms are associated with a variable amount of input and output data and a data-dependent sequence of operations. As for medium-

level algorithms, the sequence of operations is highly data dependent. Control tasks of the hybrid coding scheme can be assigned to this class.

Since hybrid coding schemes are applied for different video source rates, the required absolute processing power varies in the range from a few hundred MOPS (Mega Operations Per Second) for video signals in QCIF format to several GOPS (Giga Operations Per Second) for processing of TV or HDTV signals. Nevertheless, the relative computational power of each algorithmic class is nearly independent of the processed video format. In case of hybrid coding applications, approximately 90% of the overall processing power is required for low-level algorithms. The amount of medium-level tasks is about 7% and nearly 3% is required for high-level algorithms.

59.3 Architectural Alternatives

In terms of a VLSI implementation of hybrid coding applications, two major requirements can be identified. First, the high computational power requirements have to be provided by the hardware. Second, low manufacturing cost of video processing components is essential for the economic success of an architecture. Additionally, implementation size and architectural flexibility have to be taken into account.

Implementations of video processing applications can either be based on standard processors from workstations or PCs or on specialized video signal processors. The major advantage of standard processors is their availability. Application of these architectures for implementation of video processing hardware does not require the time consuming design of new VLSI components. The disadvantage of this implementation strategy is the insufficient processing power of recent standard processors. Video processing applications would still require the implementation of cost intensive multiprocessor systems to meet the computational requirements. To achieve compact implementations, video processing hardware has to be based on video signal processors, adapted to the requirements of the envisaged application field.

Basically, two architectural approaches for the implementations of specialized video processing components can be distinguished. *Dedicated architectures* aim at an efficient implementation of one specific algorithm or application. Due to the restriction of the application field, the architecture of dedicated components can be optimized by an intensive adaptation of the architecture to the requirements of the envisaged application, e.g., arithmetic operations that have to be supported, processing power, or communication bandwidth. Thus, this strategy will generally lead to compact implementations. The major disadvantage of dedicated architecture is the associated low flexibility. Dedicated components can only be applied for one or a few applications. In contrast to dedicated approaches with limited functionality, *programmable architectures* enable the processing of different algorithms under software control. The particular advantage of programmable architectures is the increased flexibility. Changes of architectural requirements, e.g., due to changes of algorithms or an extension of the aimed application field, can be handled by software changes. Thus, a generally cost-intensive redesign of the hardware can be avoided. Moreover, since programmable architectures cover a wider range of applications, they can be used for low-volume applications, where the design of function specific VLSI chips is not an economical solution.

For both architectural approaches, the computational requirements of video processing applications demand for the exploitation of the algorithm-inherent independence of basic arithmetic operations to be performed. Independent operations can be processed concurrently, which enables the decrease of processing time and thus an increased through-put rate. For the architectural implementation of concurrency, two basic strategies can be distinguished: pipelining and parallel processing.

In case of pipelining several tasks, operations or parts of operations are processed in subsequent steps in different hardware modules. Depending on the selected granularity level for the implemen-

tation of pipelining, intermediate data of each step are stored in registers, register chains, FIFOs, or dual-port memories. Assuming a processing time of T_P for a non-pipelined processor module and $T_{D,IM}$ for the delay of intermediate memories, we get in the ideal case the following estimation for the throughput-rate $R_{T, \text{Pipe}}$ of a pipelined architecture applying N_{Pipe} pipeline stages:

$$R_{T, \text{Pipe}} = \frac{1}{\frac{T_P}{N_{\text{Pipe}}} + T_{D,IM}} = \frac{N_{\text{Pipe}}}{T_P + N_{\text{Pipe}} \cdot T_{D,IM}} \quad (59.1)$$

From this follows that the major limiting factor for the maximum applicable degree of pipelining is the access delay of these intermediate memories.

The alternative to pipelining is the implementation of parallel units, processing independent data concurrently. Parallel processing can be applied on operation level as well as on task level. Assuming the ideal case, this strategy leads to a linear increase of processing power and we get:

$$R_{T, \text{Par}} = \frac{N_{\text{Par}}}{T_P} \quad (59.2)$$

where N_{Par} = number of parallel units.

Generally, both alternatives are applied for the implementation of high-performance video processing components. In the following sections, the exploitation of algorithmic properties and the application of architectural concurrency is discussed considering the hybrid coding schemes.

59.4 Efficiency Estimation of Alternative VLSI Implementations

Basically, architectural efficiency can be defined by the ratio of performance over cost. To achieve a figure of merit for architectural efficiency we assume in the following that performance of a VLSI architecture can be expressed by the achieved throughput rate R_T and the cost is equivalent to the required silicon area A_{Si} for the implementation of the architecture:

$$E = \frac{R_T}{A_{Si}} \quad (59.3)$$

Besides the architecture, efficiency mainly depends on the applied semiconductor technology and the design-style (semi-custom, full-custom). Therefore, a realistic efficiency estimation has to consider the gains provided by the progress in semiconductor technology. A sensible way is the normalization of the architectural parameters according to a reference technology. In the following we assume a reference process with a grid length $\lambda_0 = 1.0$ micron. For normalization of silicon area, the following equation can be applied:

$$A_{Si,0} = A_{Si} \left(\frac{\lambda_0}{\lambda} \right)^2 \quad (59.4)$$

where the index 0 is used for the system with reference gate length λ_0 .

According to [7] the normalization of throughput can be performed by:

$$R_{T,0} = R_T \left(\frac{\lambda}{\lambda_0} \right)^{1.6} \quad (59.5)$$

From Eqs. (59.3), (59.4), and (59.5), the normalization for the architectural efficiency can be derived:

$$E_0 = \frac{R_{T,0}}{A_{Si,0}} = \frac{R_T}{A_{Si}} \left(\frac{\lambda}{\lambda_0} \right)^{3.6} \quad (59.6)$$

E can be used for the selection of the best architectural approach out of several alternatives. Moreover, assuming a constant efficiency for a specific architectural approach leads to a linear relationship of throughput rate and silicon area and this relationship can be applied for the estimation of the required silicon area for a specific application. Due to the power of 3.6 in Equ. (59.6), the chosen semiconductor technology for implementation of a specific application has a significant impact on the architectural efficiency.

In the following, examples of dedicated and programmable architectures for video processing applications are presented. Additionally, the discussed efficiency measure is applied to achieve a figure of merit for silicon area estimation.

59.5 Dedicated Architectures

Due to their algorithmic regularity and the high processing power required for the discrete cosine transform and motion estimation, these algorithms are the first candidates for a dedicated implementation. As typical examples, alternatives for a dedicated implementation of these algorithms are discussed in the following.

The discrete cosine transform (DCT) is a real-valued frequency transform similar to the Discrete Fourier transform (DFT). When applied to an image block of size $L \times L$, the two dimensional DCT (2D-DCT) can be expressed as follows:

$$Y_{k,l} = \sum_{i=0}^{L-1} \sum_{j=0}^{L-1} x_{i,j} \cdot C_{i,k} \cdot C_{j,l} \quad (59.7)$$

$$\text{where } C_{n,m} = \begin{cases} \frac{1}{\sqrt{2}} & \text{for } m = 0 \\ \cos \left[\frac{(2n+1)m\pi}{2L} \right] & \text{otherwise} \end{cases}$$

with

(i, j) = coordinates of the pixels in the initial block

(k, l) = coordinates of the coefficients in the transformed block

$x_{i,j}$ = value of the pixel in the initial block

$Y_{k,l}$ = value of the coefficient in the transformed block

Computing a 2D DCT of size $L \times L$ directly according to Eq. (59.7) requires L^4 multiplications and L^4 additions.

The required processing power for the implementation of the DCT can be reduced by the exploitation of the arithmetic properties of the algorithm. The two-dimensional DCT can be separated into two one-dimensional DCTs according to Eq. (59.8)

$$Y_{k,l} = \sum_{i=0}^{L-1} C_{i,k} \cdot \left[\sum_{j=0}^{L-1} x_{i,j} \cdot C_{j,l} \right] \quad (59.8)$$

The implementation of the separated DCT requires $2L^3$ multiplications and $2L^3$ additions. As an example, the DCT implementation according to [9] is depicted in Fig. 59.2. This architecture is based on two one-dimensional processing arrays. Since this architecture is based on a pipelined multiplier/accumulator implementation in carry-save technique, vector merging adders are located at the output of each array. The results of the 1D-DCT have to be reordered for the second 1D-DCT stage. For this purpose, a transposition memory is used. Since both one-dimensional processor arrays require identical DCT coefficients, these coefficients are stored in a common ROM.

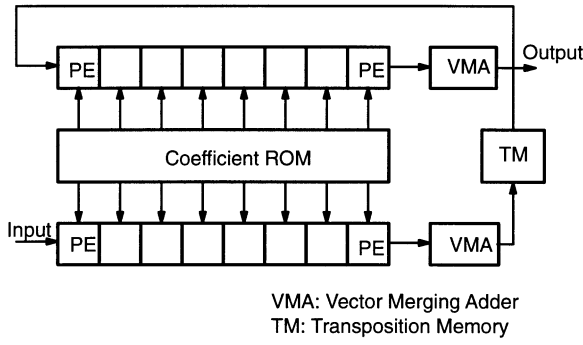

FIGURE 59.2: Separated DCT implementation according to [9].

Moving from a mathematical definition to an algorithm that can minimize the number of calculations required is a problem of particular interest in the case of transforms such as the DCT. The 1D-DCT can also be expressed by the matrix-vector product :

$$[\mathbf{Y}] = [\mathbf{C}][\mathbf{X}] \quad (59.9)$$

where $[\mathbf{C}]$ is an $L \times L$ matrix and $[\mathbf{X}]$ and $[\mathbf{Y}]$ 8-point input and output vectors. As an example, with $\theta = \pi/16$, the 8-points DCT matrix can be computed as denoted in Eq. (59.10)

$$\begin{bmatrix} Y_0 \\ Y_1 \\ Y_2 \\ Y_3 \\ Y_4 \\ Y_5 \\ Y_6 \\ Y_7 \end{bmatrix} = \begin{bmatrix} \cos 4\theta & \cos 4\theta & \cos 4\theta & \cos 4\theta & \cos 4\theta & \cos 4\theta & \cos 4\theta & \cos 4\theta \\ \cos \theta & \cos 3\theta & \cos 5\theta & \cos 7\theta & -\cos 7\theta & -\cos 5\theta & -\cos 3\theta & -\cos \theta \\ \cos 2\theta & \cos 6\theta & -\cos 6\theta & -\cos 2\theta & -\cos 2\theta & -\cos 6\theta & \cos 6\theta & \cos 2\theta \\ \cos 3\theta & -\cos 7\theta & -\cos \theta & -\cos 5\theta & \cos 5\theta & \cos \theta & \cos 7\theta & -\cos 3\theta \\ \cos 4\theta & -\cos 4\theta & -\cos 4\theta & \cos 4\theta & \cos 4\theta & -\cos 4\theta & -\cos 4\theta & \cos 4\theta \\ \cos 5\theta & -\cos \theta & \cos 7\theta & \cos 3\theta & -\cos 3\theta & -\cos 7\theta & \cos \theta & -\cos 5\theta \\ \cos 6\theta & -\cos 2\theta & \cos 2\theta & -\cos 6\theta & -\cos 6\theta & \cos 2\theta & -\cos 2\theta & \cos 6\theta \\ \cos 7\theta & -\cos 5\theta & \cos 3\theta & -\cos \theta & \cos \theta & -\cos 3\theta & \cos 5\theta & -\cos 7\theta \end{bmatrix} \begin{bmatrix} x_0 \\ x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \\ x_7 \end{bmatrix} \quad (59.10)$$

$$\begin{bmatrix} Y_0 \\ Y_2 \\ Y_4 \\ Y_6 \end{bmatrix} = \begin{bmatrix} \cos 4\theta & \cos 4\theta & \cos 4\theta & \cos 4\theta \\ \cos 2\theta & \cos 6\theta & -\cos 6\theta & -\cos 2\theta \\ \cos 4\theta & -\cos 4\theta & -\cos 4\theta & \cos 4\theta \\ \cos 6\theta & -\cos 2\theta & \cos 2\theta & -\cos 6\theta \end{bmatrix} \begin{bmatrix} x_0 + x_7 \\ x_1 + x_6 \\ x_2 + x_5 \\ x_3 + x_4 \end{bmatrix} \quad (59.11)$$

$$\begin{bmatrix} Y_1 \\ Y_3 \\ Y_5 \\ Y_7 \end{bmatrix} = \begin{bmatrix} \cos \theta & \cos 3\theta & \cos 5\theta & \cos 7\theta \\ \cos 3\theta & -\cos 7\theta & -\cos \theta & -\cos 5\theta \\ \cos 5\theta & -\cos \theta & \cos 7\theta & \cos 3\theta \\ \cos 7\theta & -\cos 5\theta & \cos 3\theta & -\cos \theta \end{bmatrix} \begin{bmatrix} x_0 + x_7 \\ x_1 + x_6 \\ x_2 + x_5 \\ x_3 + x_4 \end{bmatrix} \quad (59.12)$$

More generally, the matrices in Eqs. (59.11) and (59.12) can be decomposed in a number of simpler matrices, the composition of which can be expressed as a flowgraph. Many fast algorithms have been proposed. Figure 59.3 illustrates the flowgraph of the B.G. Lee's algorithms, which is commonly used [10]. Several implementations using fast flow-graphs have been reported [11, 12].

Another approach that has been extensively used is based on the technique of distributed arithmetic. Distributed arithmetic is an efficient way to compute the DCT totally or partially as scalar products. To illustrate the approach, let us compute a scalar product between two length-M vectors \mathbf{C} and \mathbf{X} :

$$Y = \sum_{i=0}^{M-1} c_i \cdot x_i \text{ with } x_i = -x_{i,0} + \sum_{j=1}^{B-1} x_{i,j} \cdot 2^{-j} \quad (59.13)$$

where $\{c_i\}$ are N-bit constants and $\{x_i\}$ are coded in B bits in 2s complement. Then Eq. (59.13) can be rewritten as :

$$Y = \sum_{j=0}^{B-1} C_j \cdot 2^{-j} \text{ with } C_{j \neq 0} = \sum_{i=0}^{M-1} c_i x_{i,j} \text{ and } C_0 = - \sum_{i=0}^{M-1} c_i x_{i,0} \quad (59.14)$$

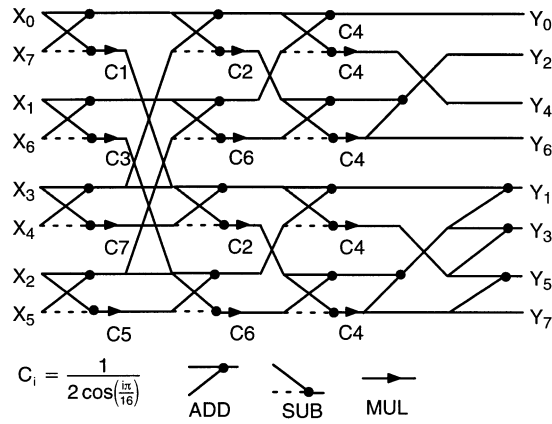

FIGURE 59.3: Lee FDCT flowgraph for the one-dimensional 8-points DCT [10].

The change of summing order in i and j characterizes the distributed arithmetic scheme in which the initial multiplications are distributed to another computation pattern. Since the term C_j has only 2^M possible values (which depend on the $x_{i,j}$ values), it is possible to store these 2^M possible values in a ROM. An input set of M bits $\{x_{0,j}, x_{1,j}, x_{2,j}, \dots, x_{M-1,j}\}$ is used as an address, allowing retrieval of the C_j value. These intermediate results are accumulated in B clock cycles, for producing one Y value. Figure 59.4 shows a typical architecture for the computation of a M input inner product. The inverter and the MUX are used for inverting the final output of the ROM in order to compute C_0 .

FIGURE 59.4: Architecture of a M input inner product using distributed arithmetic.

Figure 59.5 illustrates two typical uses of distributed arithmetic for computing a DCT. Figure 59.5(a) implements the scalar products described by the matrix of Eq. (59.10). Figure 59.5(b) takes advantage of a first stage of additions and subtractions and the scalar products described by the matrices of Eq. (59.11) and Eq. (59.12).

Properties of several dedicated DCT implementations have been reported in [6]. Figure 59.6 shows the silicon area as a function of the throughput rate for selected design examples. The design parameters are normalized to a fictive $1.0 \mu\text{m}$ CMOS process according to the discussed normalization strategy. As a figure of merit, a linear relationship of throughput rate and required silicon area can be derived:

$$\alpha_{T,0} \approx 0.5 \text{ mm}^2 / \text{Mpel/s} \quad (59.15)$$

Equation (59.15) can be applied for the silicon area estimation of DCT circuits. For example, assuming TV signals according to the CCIR-601 format and a frame rate of 25Hz, the source rate

FIGURE 59.5: Architecture of an 8-point one-dimensional DCT using distributed arithmetic. (a) Pure distributed arithmetic. (b) Mixed D.A.: first stage of flowgraph decomposition products of 8 points followed by 2 times 4 scalar products of 4 points.

equals 20.7 Mpel/s. As a figure of merit from Eq. (59.15) a normalized silicon area of about 10.4 mm^2 can be derived. For HDTV signals the video source rate equals 110.6 Mpel/s and approximately 55.3 mm^2 silicon area is required for the implementation of the DCT. Assuming an economically sensible maximum chip size of about 100 mm^2 to 150 mm^2 , we can conclude that the implementation of the DCT does not necessarily require the realization of a dedicated DCT chip and the DCT core can be combined with several other on-chip modules that perform additional tasks of the video coding scheme.

For motion estimation several techniques have been proposed in the past. Today, the most important technique for motion estimation is block matching, introduced by [21]. Block matching is based on the matching of blocks between the current and a reference image. This can be done by a full (or exhaustive) search within a search window, but several other approaches have been

FIGURE 59.6: Normalized silicon area and throughput for dedicated DCT circuits.

reported in order to reduce the computation requirements by using an “intelligent” or “directed” search [17, 18, 19, 23, 25, 26, 27].

In case of an exhaustive search block matching algorithm, a block of size $N \times N$ pels of the current image (reference block, denoted X) is matched with all the blocks located within a search window (candidate blocks, denoted Y). The maximum displacement will be denoted by w . The matching criterium generally consists in computing the mean absolute difference (MAD) between the blocks. Let $x(i, j)$ be the pixels of the reference block and $y(i, j)$ the pixels of the candidate block. The matching distance (or distortion) D is computed according to Eq. (59.16). The indexes m and n indicate the position of the candidate block within the search window. The distortion D is computed for all the $(2w + 1)^2$ possible positions of the candidate block within the search window [Eq. (59.16)] and the block corresponding to the minimum distortion is used for prediction. The position of this block within the search window is represented by the motion vector \mathbf{v} (59.17).

$$D(m, n) = \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} |x(i, j) - y(i + m, j + n)| \quad (59.16)$$

$$\mathbf{v} = \left[\begin{matrix} m \\ n \end{matrix} \right] |_{D_{\min}} \quad (59.17)$$

The operations involved for computing $D(m, n)$ and DMIN are associative. Thus, the order for exploring the index spaces (i, j) and (m, n) are arbitrary and the block matching algorithm can be described by several different dependence graphs. As an example, Fig. 59.7 shows a possible dependence graph (DG) for $w = 1$ and $N = 4$. In this figure, AD denotes an absolute difference and an addition, M denotes a minimum value computation.

FIGURE 59.7: Dependence graphs of the block matching algorithm. The computation of $\mathbf{v}(X, Y)$ and $D(m, n)$ are performed by 2D linear DGs.

The dependence graph for computing $D(m, n)$ is directly mapped into a 2-D array of processing elements (PE), while the dependence graph for computing $\mathbf{v}(X, Y)$ is mapped into time (59.8). In other words, block matching is performed by a sequential exploration of the search area, while the computation of each distortion is performed in parallel. Each of the AD nodes of the DG is implemented by an AD processing element (AD-PE). The AD-PE stores the value of $x(i, j)$ and receives the value of $y(m + i, n + j)$ corresponding to the current position of the reference block in the search window. It performs the subtraction and the absolute value computation, and adds the

result to the partial result coming from the upper PE. The partial results are added on columns and a linear array of adders performs the horizontal summation of the row sums, and computes $D(m, n)$. For each position (n, m) of the reference block, the M-PE checks if the distortion $D(m, n)$ is smaller than the previous smaller distortion value, and, in this case, updates the register which keeps the previous smaller distortion value.

To transform this naive architecture into a realistic implementation, two problems must be solved: (1) a reduction of the cycle time and (2) the I/O management.

1. The architecture of Fig. 59.8 implicitly supposes that the computation of $D(m, n)$ can be done combinatorially in one cycle time. While this is theoretically possible, the resulting cycle time would be very large and would increase as $2N$. Thus, a pipeline scheme is generally added.
2. This architecture also supposes that each of the AD-PE receives a new value of $y(m + i, n + j)$ at each clock cycle.

FIGURE 59.8: Principle of the 2-D block-based architecture.

Since transmitting the N^2 values from an external memory is clearly impossible, advantage must be taken from the fact that these values belong to the search window. A portion of the search window of size $N^*(2w + N)$ is stored in the circuit, in a 2-D bank of shift registers able to shift in the up, down, and right direction. Each of the AD-PEs has one of these registers and can, at each cycle, obtain the value of $y(m + i, n + j)$ that it needs. To update this register bank, a new column of $2w + N$ pixels of the search area is serially entered in the circuit and is inserted in the bank of registers. A mechanism must also be provided for loading a new reference with a low I/O overhead: a double buffering of $x(i, j)$ is required, with the pixels $x'(i, j)$ of a new reference block serially loaded during the computation of the current reference block (Fig. 59.9).

Figure 59.10 shows the normalized computational rate vs. normalized chip area for block matching circuits. Since one MAD operation consists of three basic ALU operations (SUB, ABS, ADD), for a 1.0 micron CMOS process, we can derive from this figure that:

$$\alpha_{T,0} \approx 30 \text{ mm}^2 + 1.9 \text{ mm}^2 / \text{GOPS} \quad (59.18)$$

The first term of this expression indicates that the block matching algorithm requires a large storage area (storage of parts of the actual and previous frame), which cannot be reduced even when the

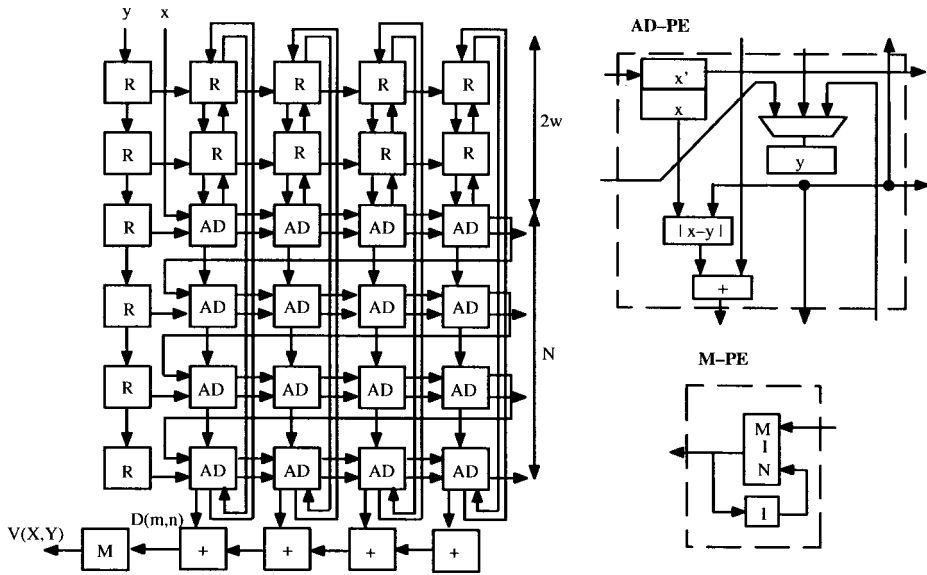

FIGURE 59.9: Practical implementation of the 2-D block-based architecture.

throughput is reduced. The second term corresponds to the linear dependency on computation throughput. The second term has the same amount as that determined for the DCT for GADDs because the three types of operations for the matching require approximately the same expense of additions.

From equation Eq. (59.18), the silicon area required for the dedicated implementation of the exhaustive search block matching strategy for a displacement of $\pm w$ pels can be derived by:

$$\alpha_{T,0} \approx 0.0057 \cdot (2w + 1)^2 \cdot R_S + 30 \text{ mm}^2 \quad (59.19)$$

According to Eq. (59.19), a dedicated implementation of exhaustive search block matching for telecommunication applications based on a source rate of $R_S = 1.01$ Mpel/s (CIF format, 10 Hz frame rate) and a maximum displacement of $w = 15$, the required silicon area can be estimated to 35.5 mm^2 . For TV ($R_S = 10.4$ Mpel/s) the silicon area for $w = 31$ can be estimated to 265 mm^2 . Estimating the required silicon area for HDTV signals and $w = 31$ leads to 1280 mm^2 for

FIGURE 59.10: Normalized silicon area and computational rate for dedicated motion estimation architectures.

the fictive 1.0 μm CMOS process. From this follows that the implementation for TV and HDTV applications will require the realization of a dedicated block matching chip. Assuming a recent 0.5 μm semiconductor processes the core size estimation leads to about 22 mm^2 for TV signals and 106 mm^2 for HDTV signals.

To reduce the high computational complexity required for exhaustive search block matching, two strategies can be applied:

1. Decrease of the number of candidate blocks.
2. Decrease of the pels per block by subsampling of the image data.

Typically, (1) is implemented by search strategies in successive steps. As an example, a modified scheme according to the original proposal of [25] will be discussed. In this scheme, the best match \mathbf{v}_{s-1} in the previous step $s - 1$ is improved in the present step s by comparison with displacements $\pm\Delta_s$. The displacement vector \mathbf{v}_s for each step s is calculated according to

$$D_s(m_s, n_s) = \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} |x(i, j) - y(i + m_s + q \cdot \Delta_s, j + n_s + q \cdot \Delta_s)|$$

with $q \in \{-1, 0, 1\}$

$$\begin{aligned} \begin{bmatrix} m_s \\ n_s \end{bmatrix} &= \mathbf{v}_{s-1} && \text{for } s > 0 \\ \begin{bmatrix} m_s \\ n_s \end{bmatrix} &= \begin{bmatrix} 0 \\ 0 \end{bmatrix} && \text{for } s = 0 \end{aligned}$$

and

$$\mathbf{v}_s = \left[\begin{bmatrix} m_s \\ n_s \end{bmatrix} \right]_{|D_{s,\min}} \quad (59.20)$$

Δ_s depends on the maximum displacement w and the number of search steps N_s . Typically, when $w = 2^k - 1$, N_s is set to $k = \log_2(w + 1)$ and $\Delta_s = 2^{k-s+1}$. For example, for $w = 15$, four steps with $\Delta_s = 8, 4, 2, 1$ are performed. This strategy reduces the number of candidate blocks from $(2w + 1)^2$ in case of exhaustive search to $1 + 8 * \log_2(w + 1)$, e.g., for $w = 15$ the number of candidate blocks is reduced from 961 to 33 which leads to a reduction of processing power by a factor of 29. For large block sizes N , the number of operations for the match can be further reduced by combining the search strategy with subsampling in the first steps. Architectures for block matching based on hierarchical search strategies are presented in [20, 22, 24, 30].

59.6 Programmable Architectures

According to the three ways for architectural optimization, adaptation, pipelining, and parallel processing, three architectural classes for the implementation of video signal processors can be distinguished:

- *Intensive Pipelined Architectures* — These architectures are typically scalar architectures that achieve high clock frequencies of several hundreds of MHz due to the exploitation of pipelining.
- *Parallel Data Paths* — These architectures exploit data distribution for the increase of computational power. Several parallel data paths are implemented on one processor die, which leads in the ideal case to a linear increase of supported computational power. The number of parallel data paths is limited by the semiconductor process, since an increase of silicon area leads to a decrease of hardware yield.

- *Coprocessor Architectures* — Coprocessors are known from general processor designs and are often used for specific tasks, e.g., floating point operations. The idea of the adaptation to specific tasks and increase of computational power without an increase of the required semiconductor area has been applied by several designs. Due to their high regularity and the high processing power requirements, low-level tasks are the most promising candidates for an adapted implementation. The main disadvantage of this architectural approach is the decrease of flexibility by an increase of adaptation.

59.6.1 Intensive Pipelined Architectures

Applying pipelining for the increase of clock frequency leads to an increased latency of the circuit. For algorithms that require a data dependent control flow, this fact might limit the performance gain. Additionally, increasing arithmetic processing power leads to an increase of data access rate. Generally, the required data access rate cannot be provided by external memories. The gap between provided external and required internal data access rate increases for processor architectures with high clock frequency. To provide the high data access rate, the amount of internal memory which provides a low access time has to be increased for high-performance signal processors. Moreover, it is unfeasible to apply pipelining to speed-up on-chip memory. Thus, the minimum memory access time is another limiting factor for the maximum degree of pipelining. At least speed optimization is a time consuming task of the design process, which has to be performed for every new technology generation.

Examples for video processors with high clock frequency are the S-VSP [39] and the VSP3 [40]. Due to intensive pipelining, an internal clock frequency of up to 300 MHz can be achieved. The VSP3 consists of two parallel data paths, the Pipelined Arithmetic Logic Unit (PAU) and Pipelined Convolution Unit (PCU) (Fig. 59.11). The relatively large on-chip data memory of size 114 kbit is split into seven blocks, six data memories and one FIFO memory for external data exchange. Each of the six data memories is provided with an address generation unit (AGU), which provides the addressing modes “block”, “DCT”, and “zig-zag”. Controlling is performed by a Sequence Control Unit (SCU) which involves a 1024x32bit instruction memory. A Host Interface Unit (HIU) and a Timing Control Unit (TCU) for the derivation of the internal clock frequency are integrated onto the VSP3 core.

The entire VSP3 core consists of 1.27 million transistors, implemented based on a 0.5 micron BiCMOS technology on a 16.5 x 17.0-mm² die. The VSP3 performs the processing of the CCITT-H.261 tasks (neglecting Huffman coding) for one macroblock in 45 μ s. Since realtime processing of 30Hz-CIF signals requires a processing time of less than 85 μ s for one macroblock, a H.261 coder can be implemented based on one VSP3.

59.6.2 Parallel Data Paths

In the previous section, pipelining was presented as a strategy for processing power enhancement. Applying pipelining leads to a subdivision of a logic operation into sub-operations, which are processed in parallel with increased processing speed. An alternative to pipelining is the distribution of data among functional units. Applying this strategy leads to an implementation of parallel data paths. Typically, each data path is connected to an on-chip memory which provides the access distributed image segments.

Generally, two types of controlling strategies for parallel data paths can be distinguished. An MIMD concept provides a private control unit for each data path, whereas SIMD-based controlling provides a single common controller for parallel data paths. Compared to SIMD, the advantage of MIMD is a greater flexibility and a higher performance for complex algorithms with highly data dependent control flow. On the other hand, MIMD requires a significantly increased silicon area.

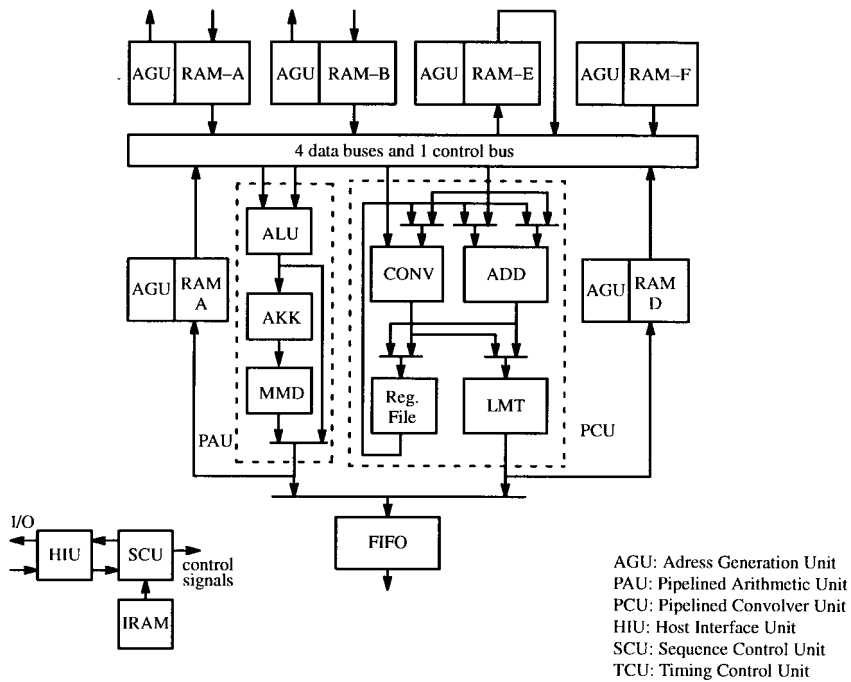

FIGURE 59.11: VSP3 architecture [40].

Additionally, the access rate to the program memory is increased, since several controllers have to be provided with program data. Moreover, a software-based synchronization of the data paths is more complex. In case of an SIMD concept synchronization is performed implicitly by the hardware.

Since actual hybrid coding schemes require a large amount of processing power for tasks that require a data independent control flow, a single control unit for the parallel data path provides sufficient processor performance. The controlling strategy has to provide the execution of algorithms that require a data dependent control flow, e.g., quantization. A simple concept for the implementation of a data dependent control flow is to disable the execution of instruction in dependence of the local data path status. In this case, the data path utilization might be significantly decreased, since several of the parallel data path idle while others perform the processing of image data. An alternative is a hierarchical controlling concept. In this case, each data path is provided with a small local control unit with limited functionality and the global controller initiates the execution of control sequences of the local data path controllers. To reduce the required chip area for this controlling concept, the local controller can be reduced to a small instruction memory. Addressing of this memory is performed by the global control unit.

An example of a video processor based on parallel identical data path with a hierarchical controlling concept is the IDSP [42] (Fig. 59.12). The IDSP processor includes four pipelined data processing units (DPU0-DPU3), three parallel I/O ports (PIO0-PIO2), one 8×16 -bit register file, five dual-ported memory blocks of size 512×16 -bit each, an address generation unit for the data memories, and a program sequencer with 512×32 -bit instruction memory and 32×32 -bit boot ROM.

The data processing units consist of a three-stage pipeline structure based on a ALU, multiplier, and an accumulator. This data path structure is well suited for L1 and L2 norm calculations and convolution-like algorithms. The four parallel data paths support a peak computational power of 300 MOPS at a typical clock frequency of 25 MHz. The data required for parallel processing are supplied by four cache memories (CM0-CM3) and a work memory (WM). Address generation for

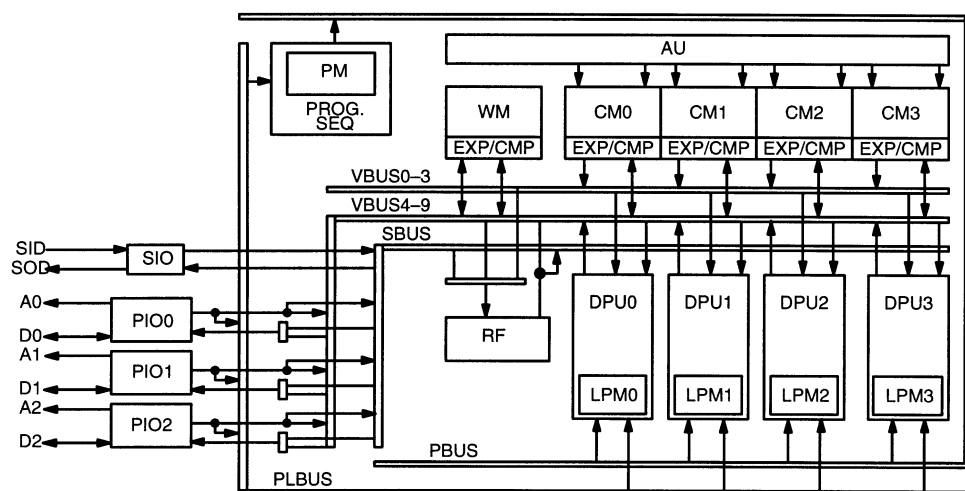

FIGURE 59.12: IDSP architecture [42].

these memories is performed by an address generation unit (AU) which supports address sequences such as block scan, bit reverse, and butterfly. The three parallel I/O units contain a data I/O port, an address generation unit, and a DMA control processor (DMAC).

The IDSP integrates 910,000 transistors in $15.2 \times 15.2 \text{ mm}^2$ using an 0.8 micron BiCMOS technology. For a full-CIF H.261 video codec four IDSP are required.

Another example of an SIMD-based video signal processor architecture based on identical parallel data paths is the HiPAR-DSP [44] (Fig. 59.13). The processor core consists of 16 RISC data paths, controlled by a common VLIW instruction word. The data paths contain a multiplier/accumulator unit, a shift/round unit, an ALU, and a 16×16 bit register file. Each data path is connected to a private data cache. To support the characteristic data access pattern of several image processing tasks efficiently, a shared memory with parallel data access is integrated on-chip and provides parallel and conflict-free access to the data stored in this memory. The supported access patterns are “matrix”, “vector” and “scalar”. Data exchange with external devices is supported by an on chip DMA unit and a hypercube interface.

At present, a prototype of the HiPAR-DSP, based on four parallel data paths, is implemented. This chip will be manufactured in a 0.6 micron CMOS technology and will require a silicon area of about 180 mm^2 . One processor chip is sufficient for realtime decoding of video signals, according to MPEG-2 Main Profile at Main Level. For encoding an external motion estimator is required.

In contrast to SIMD-based HiPAR-DSP architecture, the TMS320C80 (MVP) is based on an MIMD approach [43]. The MVP consists of four parallel processors (PP) and one master processor (Fig. 59.14). The processors are connected to 50-kbyte on-chip data memory via a global crossbar interconnection network. A DMA controller provides the data transfer to an external data memory and video I/O is supported by an on-chip video interface.

The master processor is a general-purpose RISC processor with an integral IEEE-compatible floating-point unit (FPU). The processor has a 32-bit instruction word and can load or store 8-, 16-, 32-, and 64-bit data sizes. The master processor includes a 32×32 -bit general purpose register file. The master processor is intended to operate as the main supervisor and distributor of tasks within the chip and is also responsible for the communication with external processors. Due to the integrated FPU, the master processor will perform tasks such as audio signal processing and 3-D graphics transformation.

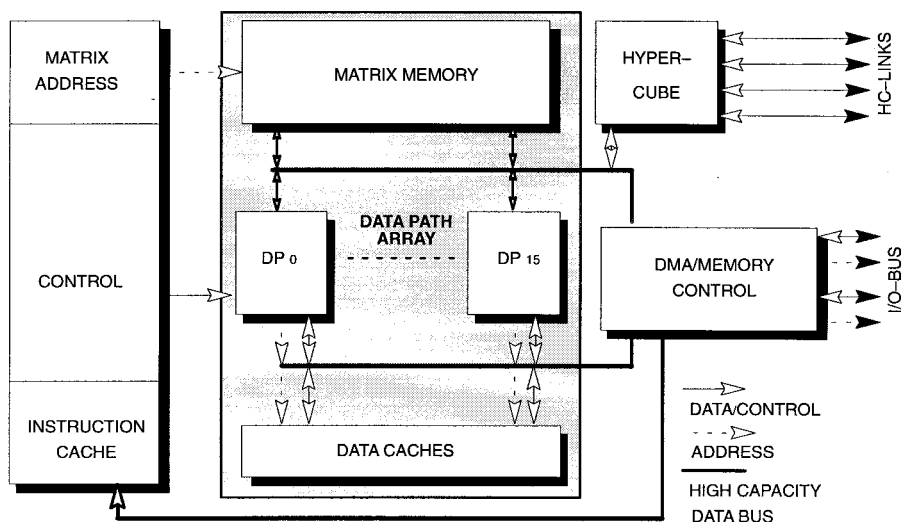

FIGURE 59.13: Architecture of the HiPAR-DSP [44].

The parallel processors architecture has been designed to perform typical DSP algorithms, e.g., filtering, DCT, and to support bit and pixel manipulations for graphics applications. The parallel processors contain two address units, a program flow control unit, and a data unit with 32-bit ALU, 16×16 -bit multiplier, and a barrel rotator.

The MVP has been designed using a 0.5 micron CMOS technology. Due to the supported flexibility, about four million transistors on a chip area of 324 mm^2 are required. A computational power of 2 GOPS is supported. A single MVP is able to encode CIF-30Hz video signals according to the MPEG-1 standard.

59.6.3 Coprocessor Concept

Most programmable architectures for video processing applications achieve an increase of processing power by an adaptation of the architecture to the algorithmic requirements. A feasible approach is the combination of a flexible programmable processor module with one or more adapted modules. This approach leads to an increase of processing power for specific algorithms and leads a significant decrease of required silicon area. The decrease of silicon area is caused by two effects. At first, the implementation of the required arithmetic operations can be optimized, which leads to an area reduction. Second, dedicated modules require significantly less hardware expense for module controlling, e.g., for program memory.

Typically, computation intensive tasks, such as DCT, block matching, or variable length coding, are candidates for an adapted or even dedicated implementation. Besides the adaptation to one specific task, mapping of several different tasks onto one adapted processor module might be advantageous. For example, mapping successive tasks, such as DCT, quantization, inverse quantization, IDCT, onto the same module reduces the internal communication overhead.

Coprocessor architectures that are based on highly adapted coprocessors achieve high computational power on a small chip area. The main disadvantage of these architectures is the limited flexibility. Changes of the envisaged applications might lead to an unbalanced utilization of the processor modules and therefore to a limitation of the effective processing power of the chip.

Applying the coprocessor concept opens up a variety of feasible architecture approaches, which

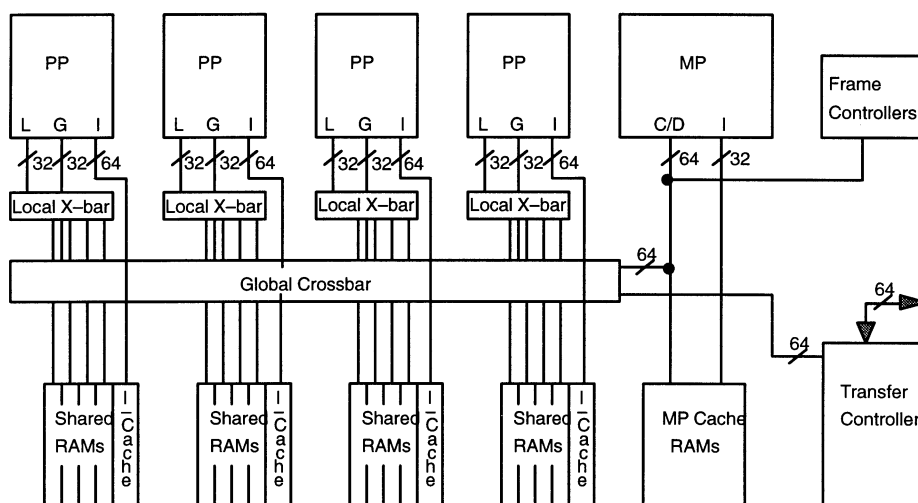

FIGURE 59.14: TMS320C80 (MVP) [43].

differ in achievable processing power and flexibility of the architecture. In the following several architectures are presented, which clarify the wide variety of sensible approaches for video compression based on a coprocessor concept. Most of these architectures aim at an efficient implementation of hybrid coding schemes. As a consequence, these architectures are based on highly adapted coprocessors.

A chip set for video coding has been proposed in [8]. This chip set consists of four devices: two encoder options (the AVP1300E and AVP1400E), the AVP1400D decoder, and the AVP1400C system controller. The AVP1300E has been designed for H.261 and MPEG-1 frame-based encoding. Full MPEG-1 encoding (I-frame, P-frame, and B-frame) is supported by the AVP1400E. In the following, the architecture of the encoder chips is presented in more detail.

The AVP1300E combines function oriented modules, mask programmable modules, and user programmable modules (Fig. 59.15). It consists of a dedicated motion estimator for exhaustive search block matching with a search area of ± 15 pels. The variable length encoder unit contains an ALU, a register array, a coefficient RAM, and a table ROM. Instructions for the VLE unit are stored in a program ROM. Special instructions for conditional switching, run-length coding, and variable-to-fixed-length conversion are supported. The remaining tasks of the encoder loop, i.e., DCT/IDCT, quantization, and inverse quantization, are performed in two modules called SIMD processor and quantization processor (QP). The SIMD processor consists of six parallel processors each with ALU, multiplier-accumulator units. Program information for this module is again stored in a ROM memory. The QP's instructions are stored in a 1024×28 -bit RAM. This module contains 16-bit ALU, a multiplier, and a register file of size 144×16 -bit. Data communication with external DRAMs is supported by a memory management unit (MMAFC). Additionally, the processor scheduling is performed by a global controller (GC).

Due to the adaptation of the architecture to specific tasks of the hybrid coding scheme, a single chip of size 132 mm^2 (at 0.9 micron CMOS technology) supports the encoding of CIF-30Hz video signals according to the H.261 standard, including the computation intensive exhaustive search motion estimation strategy. An overview of the complete chipset is given in [33].

The AxPe640V [37] is another typical example of the coprocessor approach (Fig. 59.16). To provide high flexibility for a broad range of video processing algorithms, the two processor modules are fully user programmable. A scalar RISC core supports the processing of tasks with data dependent control

FIGURE 59.15: AVP encoder architecture [8].

flow, whereas the typically more computation intensive low level tasks with data independent control flow can be executed by a parallel SIMD module.

The RISC core functions as a master processor for global control and for processing of tasks such as variable length encoding and quantization. To improve the performance for typical video coding schemes, the data path of the RISC core has been adapted to the requirements of quantization and variable length coding, by an extension of the basic instruction set. A program RAM of size is placed on-chip and can be loaded from an external PROM during start-up. The SIMD oriented arithmetic processing unit (APU) contains four parallel datapaths with a subtracter-complementer-multiplier pipeline. The intermediate results of the arithmetic pipelines are fed into a multi-operand accumulator with shift/limit circuitry. The results of the APU can be stored in the internal local memory or read out to the external data output bus.

Since both RISC core and APU include a private program RAM and address generation units, these processor modules are able to work in parallel on different tasks. This MIMD-like concept enables an execution of two tasks in parallel, e.g., DCT and quantization.

The AxPe640V is currently available in a 66-MHz version, designed in a 0.8 micron CMOS technology. A QCIF-10Hz H.261 codec can be realized with a single chip. To achieve higher computation power several AxPe640V can be combined to a multiprocessor system. For example, three AxPe640V are required for an implementation of a CIF-10Hz codec.

FIGURE 59.16: AxPe640V architecture [37].

The examples presented above clarify the wide range of architectural approaches for the VLSI implementation of video coding schemes. The applied strategies are influenced by several demands, especially the desired flexibility of the architecture and maximum cost for realization and manufacturing. Due to the high computational requirements of real time video coding, most of the presented architectures apply a coprocessor concept with flexible programmable modules in combination with

modules that are more or less adapted to specific tasks of the hybrid coding scheme. An overview of programmable architectures for video coding applications is given in [6].

Equations (59.4) and (59.5) can be applied for the comparison of programmable architectures. The result of this comparison is shown in Fig. 59.17, using the coding scheme according to ITU recommendation H.261 as a benchmark. Assuming a linear dependency between throughput rate

FIGURE 59.17: Normalized silicon area and throughput (frame rate) for adapted and flexible programmable architectures for a H.261 codec.

and silicon area, a linear relationship corresponds to constant architectural efficiency, indicated by the two grey lines in Fig. 59.17. According to these lines, two groups of architectural classes can be identified. The first group consists of adapted architectures, optimized for hybrid coding applications. The architectures contain one or more adapted modules for computation intensive tasks, such as DCT or block matching. It is obvious that the application field of these architectures is limited to a small range of applications. This limitation is avoided by the members of the second group of architectures. Most of these architectures do not contain function specific circuitry for specific tasks of the hybrid coding scheme. Thus, they can be applied for wider variety of applications without a significant loss of sustained computational power. On the other hand, these architectures are associated with a decreased architectural efficiency compared to the first group of proposed architectures: Adapted architectures achieve an efficiency gain of about 6 to 7.

For a typical video phone application a frame rate of 10 Hz can be assumed. For this application the required normalized silicon area of about 130 mm² is required for adapted programmable approaches and approximately 950 mm² are required for flexible programmable architectures. For a rough

estimation of the required silicon area for an MPEG-2 decoder, we assume that the algorithmic complexity of an MPEG-2 decoder for CCIR-601 signals is about half the complexity of an H.261 codec. Additionally, it has to be taken into account that the number of pixels per frame is about 5.3 times larger for CCIR signals than for CIF signals. From this the normalized implementation size of an MPEG-2 decoder for CCIR-601 signals and a frame rate of 25 Hz can be estimated to 870 mm² for an adapted architecture and 6333 mm² for flexible programmable architecture. Scaling these figures according to the defined scaling rules, a silicon area of about 71 mm² and 520 mm² can be estimated for an implementation based on an 0.5 μ m CMOS process. Thus, the realization of video coding hardware for TV or HDTV based on flexible programmable processors still requires several monolithic components.

59.7 Conclusion

The properties of recent hybrid coding schemes in terms of VLSI implementation have been presented. Architectural alternatives for the dedicated realization of the DCT and block matching have been discussed. Architectures of programmable video signal processors have been presented and compared in terms of architectural efficiency. It has been shown that adapted circuits achieve a six to seven times higher efficiency than flexible programmable circuits. This efficiency gap might decrease for future coding schemes associated with a higher amount of medium- and high-level algorithms. Due to their flexibility, programmable architectures will become more and more attractive for future VLSI implementations of video compression schemes.

A SENSOR ARRAY SYSTEM consists of a number of spatially-distributed elements, such as dipoles, hydrophones, geophones or microphones, followed by receivers and a processor. The array samples propagating wavefields in time and space. The receivers and the processor vary in mode of implementation and complexity according to the types of signals encountered, desired operation, and the adaptability of the array. For example, the array may be narrowband or wideband and the processor may be for determining the directions of the sources of signals or for beamforming to reject interfering signals and to enhance the quality of the desired signal in a communication system. The broad range of applications and the multifaceted nature of technical challenges for modern array signal processing have provided a fertile ground for contributions by and collaborations among researchers and practitioners from many disciplines, particularly those from the signal processing, statistics, and numerical linear algebra communities.

The following chapters present a sampling of the latest theory, algorithms, and applications related to array signal processing. The range of topics and algorithms include some which have been in use for more than a decade as well as some which are results of active current research. The sections on applications give examples of current areas of significant research and development.

Modern array signal processing often requires the use of the formalism of complex variables in modeling received signals and noise. Chapter 60 provides an introduction to complex random processes which are useful for bandpass communication systems and arrays. A classical use for arrays of sensors is to exploit the differences in the location (direction) of sources of transmitted signals to perform spatial filtering. Such techniques are reviewed in Chapter 61.

Another common use of arrays is the estimation of informative parameters about the wavefields impinging on the sensors. The most common parameter of interest is the direction of arrival (DOA) of a wave. Subspace techniques have been advanced as means of estimating the DOAs of sources, which are very close to each other, with high accuracy. The large number of developments in such techniques is reflected in the topics covered in Chapters 62 to 66. Chapter 62 gives a general overview of subspace processing for direction finding, while Chapter 63 discusses a particular type of subspace algorithm which is extended to sensing of azimuth and elevation angles with planar arrays. Most estimators assume knowledge of the needed statistical characteristics of the measurement noise. This requirement is relaxed in the approach given in Chapter 64. Chapter 65 extends the capabilities of traditional sensors to those which can measure the complete electric and magnetic field components and provides estimators which exploit such information. When signal sources move, or when computational requirements for real-time processing prohibit batch estimation of the subspaces, computationally efficient adaptive subspace updating techniques are called for. Chapter 66 presents many of the recent techniques which have been developed for this purpose. Before subspace methods are used for estimating the parameters of the waves received by an array, it is necessary to determine the number of sources which generate the waves. This aspect of the problem, often termed detection, is discussed in Chapter 67.

An important area of application for arrays is in the field of communications, particularly as it

pertains to emerging mobile and cellular systems. Chapter 68 gives an overview of a number of techniques for improving the reception of signals in mobile systems, while Chapter 69 considers problems which arise in beamforming in the presence of multipath signals—a common occurrence in mobile communications. Chapter 70 discusses radar systems which employ sensor arrays, thereby providing the opportunity for space-time signal processing for improved resolution and target detection.

60.1 Introduction

Much of modern digital signal processing is concerned with the extraction of information from signals which are noisy, or which behave randomly while still revealing some attribute or parameter of a system or environment under observation. The term in popular use now for this kind of computation is *statistical signal processing*, and much of this Handbook is devoted to this very subject. Statistical signal processing is classical statistical inference applied to problems of interest to electrical engineers, with the added twist that answers are often required in “real time”, perhaps seconds or less. Thus, computational algorithms are often studied hand-in-hand with statistics.

One thing that separates the phenomena electrical engineers study from that of agronomists, economists, or biologists, is that the data they process are very often *complex*; that is, the data points come in pairs of the form $x + jy$, where x is called the *real part*, y the *imaginary part*, and $j = \sqrt{-1}$. Complex numbers are entirely a human intellectual creation: there are no complex physical measurable quantities such as time, voltage, current, money, employment, crop yield, drug efficacy, or anything else. However, it is possible to attribute to physical phenomena an underlying mathematical model that associates complex causes with real results. Paradoxically, the introduction of a complex-number-based theory can often simplify mathematical models.

FIGURE 60.1: Quadrature demodulator.

Beyond their use in the development of analytical models, complex numbers often appear as actual data in some information processing systems. For representation and computation purposes, a complex number is nothing more than an ordered pair of real numbers. One just mentally attaches the “ j ” to one of the two numbers, then carries out the arithmetic or signal processing that this interpretation of the data implies.

One of the most well-known systems in electrical engineering that generates complex data from real measurements is the quadrature, or IQ, demodulator, shown in Fig. 60.1. The theory behind this system is as follows. A real bandpass signal, with bandwidth small compared to its center frequency, has the form

$$s(t) = A(t) \cos(\omega_c t + \phi(t)) \quad (60.1)$$

where ω_c is the center frequency, and $A(t)$ and $\phi(t)$ are the amplitude and angle modulation, respectively. By viewing $A(t)$ and $\phi(t)$ together as the polar coordinates for a complex function $g(t)$, i.e.,

$$g(t) = A(t)e^{j\phi(t)}, \quad (60.2)$$

we imagine that there is an underlying *complex modulation* driving the generation of $s(t)$, and thus

$$s(t) = \text{Re} \{ g(t)e^{j\omega_c t} \}. \quad (60.3)$$

Again, $s(t)$ is physically measurable, while $g(t)$ is a mathematical creation. However, the introduction of $g(t)$ does much to simplify and unify the theory of bandpass communication. It is often the case that information to be transmitted via an electronic communication channel can be mapped directly into the magnitude and phase, or the real and imaginary parts, of $g(t)$. Likewise, it is possible to *demodulate* $s(t)$, and thus “retrieve” the complex function $g(t)$ and the information it represents. This is the purpose of the quadrature demodulator shown in Fig. 60.1. In Section 60.2 we will examine in some detail the operation of this demodulator, but for now note that it has one real input and two real outputs, which are *interpreted* as the real and imaginary parts of an information-bearing complex signal.

Any application of statistical inference requires the development of a probabilistic model for the received or measured data. This means that we imagine the data to be a “realization” of a multivariate random variable, or a stochastic process, which is governed by some underlying probability space of which we have incomplete knowledge. Thus, the purpose of this section is to give an introduction to probabilistic models for complex data. The topics covered are 2nd-order stochastic processes and their complex representations, the multivariate complex Gaussian distribution, and related distributions which appear in statistical tests. Special attention will be paid to a particular class of random variables, called *circular* complex random variables. Circularity is a type of symmetry in the distributions of the real and imaginary parts of complex random variables and stochastic processes, which can be

physically motivated in many applications and is almost always assumed in the statistical signal processing literature. Complex representations for signals and the assumption of circularity are particularly useful in the processing of data or signals from an array of sensors, such as radar antennas. The reader will find them used throughout this chapter of the Handbook.

60.2 Complex Envelope Representations of Real Bandpass Stochastic Processes

60.2.1 Representations of Deterministic Signals

The motivation for using complex numbers to represent real phenomena, such as radar or communication signals, may be best understood by first considering the complex envelope of a real deterministic finite-energy signal.

Let $s(t)$ be a real signal with a well-defined Fourier transform $S(\omega)$. We say that $s(t)$ is *bandlimited* if the support of $S(\omega)$ is finite, that is,

$$\begin{aligned} S(\omega) &= 0 & \omega &\notin B \\ &\neq 0 & \omega &\in B \end{aligned} \quad (60.4)$$

where B is the *frequency band* of the signal, usually a finite union of intervals on the ω -axis such as

$$B = [-\omega_2, -\omega_1] \cup [\omega_1, \omega_2] . \quad (60.5)$$

The Fourier transform of such a signal is illustrated in Fig. 60.2.

FIGURE 60.2: Fourier transform of a bandpass signal.

Since $s(t)$ is real, the Fourier transform $S(\omega)$ exhibits conjugate symmetry, i.e., $S(-\omega) = S^*(\omega)$. This implies that knowledge of $S(\omega)$, for $\omega \geq 0$ only, is sufficient to uniquely identify $s(t)$.

The complex envelope of $s(t)$, which we denote $g(t)$, is a frequency-shifted version of the complex signal whose Fourier transform is $S(\omega)$ for positive ω , and 0 for negative ω . It is found by the operation indicated graphically by the diagram in Fig. 60.3, which could be written

$$g(t) = \text{LPF}\{2s(t)e^{-j\omega_c t}\} . \quad (60.6)$$

ω_c is the center frequency of the band B , and “LPF” represents an ideal lowpass filter whose bandwidth is greater than half the bandwidth of $s(t)$, but much less than $2\omega_c$. The Fourier transform of $g(t)$ is given by

$$\begin{aligned} G(\omega) &= 2S(\omega - \omega_c) & |\omega| < BW \\ &= 0 & \text{otherwise} . \end{aligned} \quad (60.7)$$

FIGURE 60.3: Quadrature demodulator.

FIGURE 60.4: Fourier transform of the complex representation.

The Fourier transform of $g(t)$, for $s(t)$ as given in Fig. 60.2, is shown in Fig. 60.4.

The inverse operation which gives $s(t)$ from $g(t)$ is

$$s(t) = \text{Re}\{g(t)e^{j\omega_c t}\}. \quad (60.8)$$

Our interest in $g(t)$ stems from the information it represents. Real bandpass processes can be written in the form

$$s(t) = A(t) \cos(\omega_c t + \phi(t)) \quad (60.9)$$

where $A(t)$ and $\phi(t)$ are slowly varying functions relative to the *unmodulated carrier* $\cos(\omega_c t)$, and carry information about the signal source. From the complex envelope representation (60.3), we know that

$$g(t) = A(t)e^{j\phi(t)} \quad (60.10)$$

and hence $g(t)$, in its polar form, is a direct representation of the information-bearing part of the signal.

In what follows we will outline a basic theory of complex representations for real stochastic processes, instead of the deterministic signals discussed above. We will consider representations of second-order stochastic processes, those with finite variances and correlations and well-defined spectral properties. Two classes of signals will be treated separately: those with finite energy (such as radar signals) and those with finite power (such as radio communication signals).

60.2.2 Finite-Energy Second-Order Stochastic Processes

Let $\mathbf{x}(t)$ be a real, second-order stochastic process, with the defining property

$$E\{\mathbf{x}^2(t)\} < \infty, \quad \text{all } t. \quad (60.11)$$

Furthermore, let $\mathbf{x}(t)$ be finite-energy, by which we mean

$$\int_{-\infty}^{\infty} E\{\mathbf{x}^2(t)\} dt < \infty. \quad (60.12)$$

The *autocorrelation function* for $\mathbf{x}(t)$ is defined as

$$R_{\mathbf{xx}}(t_1, t_2) = E\{\mathbf{x}(t_1)\mathbf{x}(t_2)\}, \quad (60.13)$$

and from (60.11) and the Cauchy-Schwartz inequality we know that $R_{\mathbf{xx}}$ is finite for all t_1, t_2 .

The *bi-frequency energy spectral density function* is

$$S_{\mathbf{xx}}(\omega_1, \omega_2) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{\mathbf{xx}}(t_1, t_2) e^{-j\omega_1 t_1} e^{+j\omega_2 t_2} dt_1 dt_2. \quad (60.14)$$

It is assumed that $S_{\mathbf{xx}}(\omega_1, \omega_2)$ exists and is well defined. In an advanced treatment of stochastic processes (e.g., Loeve [1]) it can be shown that $S_{\mathbf{xx}}(\omega_1, \omega_2)$ exists if and only if the Fourier transform of $\mathbf{x}(t)$ exists with probability 1; in this case, the process is said to be *harmonizable*.

If $\mathbf{x}(t)$ is the input to a linear time-invariant system \mathbf{H} , and $\mathbf{y}(t)$ is the output process, as shown in Fig. 60.5, then $\mathbf{y}(t)$ is also a second-order finite-energy stochastic process. The bi-frequency energy

FIGURE 60.5: LTI system with stochastic input and output.

spectral density of $\mathbf{y}(t)$ is

$$S_{\mathbf{yy}}(\omega_1, \omega_2) = H(\omega_1) H^*(\omega_2) S_{\mathbf{xx}}(\omega_1, \omega_2). \quad (60.15)$$

This last result aids in a natural interpretation of the function $S_{\mathbf{xx}}(\omega, \omega)$, which we denote as the *energy spectral density*. For any process, the total energy $E_{\mathbf{x}}$ is given by

$$E_{\mathbf{x}} = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{\mathbf{xx}}(\omega, \omega) d\omega. \quad (60.16)$$

If we pass $\mathbf{x}(t)$ through an ideal filter whose frequency response is 1 in the band B and 0 elsewhere, then the total energy in the output process is

$$E_{\mathbf{y}} = \frac{1}{2\pi} \int_B S_{\mathbf{xx}}(\omega, \omega) d\omega. \quad (60.17)$$

This says that the energy in the stochastic process $\mathbf{x}(t)$ can be partitioned into different frequency bands, and the energy in each band is found by integrating $S_{\mathbf{xx}}(\omega, \omega)$ over the band.

We can define a *bandpass* stochastic process, with band B , as one that passes undistorted through an ideal filter \mathbf{H} whose frequency response is 1 within the frequency band and 0 elsewhere. More precisely, if $\mathbf{x}(t)$ is the input to an ideal filter \mathbf{H} , and the output process $\mathbf{y}(t)$ is equivalent to $\mathbf{x}(t)$ in the mean-square sense, that is

$$E\{(\mathbf{x}(t) - \mathbf{y}(t))^2\} = 0 \quad \text{all } t, \quad (60.18)$$

then we say that $\mathbf{x}(t)$ is a bandpass process with frequency band equal to the passband of \mathbf{H} . This is equivalent to saying that the integral of $S_{\mathbf{xx}}(\omega_1, \omega_2)$ outside of the region $\omega_1, \omega_2 \in B$ is 0.

60.2.3 Second-Order Complex Stochastic Processes

A *complex* stochastic process $\mathbf{z}(t)$ is one given by

$$\mathbf{z}(t) = \mathbf{x}(t) + j\mathbf{y}(t) \quad (60.19)$$

where the real and imaginary parts, $\mathbf{x}(t)$ and $\mathbf{y}(t)$, respectively, are any two stochastic processes defined on a common probability space. A finite-energy, second-order complex stochastic process is one in which $\mathbf{x}(t)$ and $\mathbf{y}(t)$ are both finite-energy, second-order processes, and thus have all the properties given above. Furthermore, because the two processes have a joint distribution, we can define the *cross-correlation function*

$$R_{\mathbf{xy}}(t_1, t_2) = E\{\mathbf{x}(t_1)\mathbf{y}(t_2)\}. \quad (60.20)$$

By far the most widely used class of second-order complex processes in signal processing is the class of *circular* complex processes. A circular complex stochastic process is one with the following two defining properties:

$$R_{\mathbf{xx}}(t_1, t_2) = R_{\mathbf{yy}}(t_1, t_2) \quad (60.21)$$

and

$$R_{\mathbf{xy}}(t_1, t_2) = -R_{\mathbf{yx}}(t_1, t_2) \quad \text{all } t_1, t_2. \quad (60.22)$$

From Eqs. (60.21) and (60.22) we have that

$$E\{\mathbf{z}(t_1)\mathbf{z}^*(t_2)\} = 2R_{\mathbf{xx}}(t_1, t_2) + 2jR_{\mathbf{yx}}(t_1, t_2) \quad (60.23)$$

and furthermore

$$E\{\mathbf{z}(t_1)\mathbf{z}(t_2)\} = 0 \quad (60.24)$$

for all t_1, t_2 . This implies that all of the joint second-order statistics for the complex process $\mathbf{z}(t)$ are represented in the function

$$R_{\mathbf{zz}}(t_1, t_2) = E\{\mathbf{z}(t_1)\mathbf{z}^*(t_2)\} \quad (60.25)$$

which we define unambiguously as the *autocorrelation function* for $\mathbf{z}(t)$. Likewise, the *bi-frequency spectral density function* for $\mathbf{z}(t)$ is given by

$$S_{\mathbf{zz}}(\omega_1, \omega_2) = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} R_{\mathbf{zz}}(t_1, t_2) e^{-j\omega_1 t_1} e^{+j\omega_2 t_2} dt_1 dt_2. \quad (60.26)$$

The functions $R_{\mathbf{zz}}(t_1, t_2)$ and $S_{\mathbf{zz}}(\omega_1, \omega_2)$ exhibit Hermitian symmetry, i.e.,

$$R_{\mathbf{zz}}(t_1, t_2) = R_{\mathbf{zz}}^*(t_2, t_1) \quad (60.27)$$

and

$$S_{\mathbf{zz}}(\omega_1, \omega_2) = S_{\mathbf{zz}}^*(\omega_2, \omega_1). \quad (60.28)$$

However, there is no requirement that $S_{\mathbf{z}\mathbf{z}}(\omega_1, \omega_2)$ exhibit the conjugate symmetry for positive and negative frequencies, given in Eq. (60.6), as is the case for real stochastic processes.

Other properties of real second-order stochastic processes given above carry over to complex processes. Namely, if \mathbf{H} is a linear time-invariant system with arbitrary complex impulse response $h(t)$, frequency response $H(\omega)$, and complex input $\mathbf{z}(t)$, then the complex output $\mathbf{w}(t)$ satisfies

$$S_{\mathbf{w}\mathbf{w}}(\omega_1, \omega_2) = H(\omega_1)H^*(\omega_2)S_{\mathbf{z}\mathbf{z}}(\omega_1, \omega_2) . \quad (60.29)$$

A bandpass circular complex stochastic process is one with finite spectral support in some arbitrary frequency band B .

Complex stochastic processes undergo a frequency translation when multiplied by a deterministic complex exponential. If $\mathbf{z}(t)$ is circular, then

$$\mathbf{w}(t) = e^{j\omega_c t} \mathbf{z}(t) \quad (60.30)$$

is also circular, and has bi-frequency energy spectral density function

$$S_{\mathbf{w}\mathbf{w}}(\omega_1, \omega_2) = S_{\mathbf{z}\mathbf{z}}(\omega_1 - \omega_c, \omega_2 - \omega_c) . \quad (60.31)$$

60.2.4 Complex Representations of Finite-Energy Second-Order Stochastic Processes

Let $\mathbf{s}(t)$ be a bandpass finite-energy second-order stochastic process, as defined in Section 60.2.2. The complex representation of $\mathbf{s}(t)$ is found by the same down-conversion and filtering operation described for deterministic signals:

$$\mathbf{g}(t) = \text{LPF}\{2\mathbf{s}(t)e^{-j\omega_c t}\} . \quad (60.32)$$

The lowpass filter in Eq. (60.32) is an ideal filter that passes the baseband components of the frequency-shifted signal, and attenuates the components centered at frequency $-2\omega_c$.

The inverse operation for Eq. (60.32) is given by

$$\hat{\mathbf{s}}(t) = \text{Re}\{\mathbf{g}(t)e^{j\omega_c t}\} . \quad (60.33)$$

Because the operation in Eq. (60.32) involves the integral of a stochastic process, which we define using mean-square stochastic convergence, we cannot say that $\mathbf{s}(t)$ is identically equal to $\hat{\mathbf{s}}(t)$ in the manner that we do for deterministic signals. However, it can be shown that $\mathbf{s}(t)$ and $\hat{\mathbf{s}}(t)$ are equivalent in the mean-square sense, that is,

$$E\{(\mathbf{s}(t) - \hat{\mathbf{s}}(t))^2\} = 0 \quad \text{all } t . \quad (60.34)$$

With this interpretation, we say that $\mathbf{g}(t)$ is the unique complex envelope representation for $\mathbf{s}(t)$.

The assumption of circularity of the complex representation is widespread in many signal processing applications. There is an equivalent condition which can be placed on the real bandpass signal that guarantees its complex representation has this circularity property. This condition can be found indirectly by starting with a circular $\mathbf{g}(t)$ and looking at the $\mathbf{s}(t)$ which results.

Let $\mathbf{g}(t)$ be an arbitrary lowpass circular complex finite-energy second-order stochastic process. The frequency-shifted version of this process is

$$\mathbf{p}(t) = \mathbf{g}(t)e^{+j\omega_c t} \quad (60.35)$$

and the real part of this is

$$\mathbf{s}(t) = \frac{1}{2}(\mathbf{p}(t) + \mathbf{p}^*(t)) . \quad (60.36)$$

By the definition of circularity, $\mathbf{p}(t)$ and $\mathbf{p}^*(t)$ are orthogonal processes ($E\{\mathbf{p}(t_1)(\mathbf{p}^*(t_2))^* = 0\}$) and from this we have

$$\begin{aligned} S_{\mathbf{ss}}(\omega_1, \omega_2) &= \frac{1}{4}(S_{\mathbf{pp}}(\omega_1, \omega_2) + S_{\mathbf{p}^*\mathbf{p}^*}(\omega_1, \omega_2)) \\ &= \frac{1}{4}(S_{\mathbf{gg}}(\omega_1 - \omega_c, \omega_2 - \omega_c) + S_{\mathbf{gg}}^*(-\omega_1 - \omega_c, -\omega_2 - \omega_c)). \end{aligned} \quad (60.37)$$

Since $\mathbf{g}(t)$ is a baseband signal, the first term in Eq. (60.37) has spectral support in the first quadrant in the (ω_1, ω_2) plane, where both ω_1 and ω_2 are positive, and the second term has spectral support only for both frequencies negative. This situation is illustrated in Fig. 60.6.

FIGURE 60.6: Spectral support for bandpass process with circular complex representation.

It has been shown that a necessary condition for $\mathbf{s}(t)$ to have a circular complex envelope representation is that it have spectral support only in the first and third quadrants of the (ω_1, ω_2) plane. This condition is also sufficient: if $\mathbf{g}(t)$ is *not* circular, then the $\mathbf{s}(t)$ which results from the operation in Eq. (60.33) will have non-zero spectral components in the second and fourth quadrants of the (ω_1, ω_2) plane, and this contradicts the mean-square equivalence of $\mathbf{s}(t)$ and $\hat{\mathbf{s}}(t)$.

An interesting class of processes with spectral support only in the first and third quadrants is the class of processes whose autocorrelation function is separable in the following way:

$$R_{\mathbf{ss}}(t_1, t_2) = R_1(t_1 - t_2)R_2\left(\frac{t_1 + t_2}{2}\right). \quad (60.38)$$

For these processes, the bi-frequency energy spectral density separates in a like manner:

$$S_{\mathbf{ss}}(\omega_1, \omega_2) = S_1(\omega_1 - \omega_2)S_2\left(\frac{\omega_1 + \omega_2}{2}\right). \quad (60.39)$$

FIGURE 60.7: Spectral support for bandpass process with separable autocorrelation.

In fact, S_1 is the Fourier transform of R_2 and vice versa. If S_1 is a lowpass function, and S_2 is a bandpass function, then the resulting product has spectral support illustrated in Fig. 60.7.

The assumption of circularity in the complex representation can often be physically motivated. For example, in a radar system, if the reflected electromagnetic wave undergoes a phase shift, or if the reflector position cannot be resolved to less than a wavelength, or if the reflection is due to a sum of reflections at slightly different path lengths, then the absolute phase of the return signal is considered random and uniformly distributed. Usually it is not the absolute phase of the received signal which is of interest; rather, it is the *relative phase* of the signal value at two different points in time, or of two different signals at the same instance in time. In many radar systems, particularly those used for direction-of-arrival estimation or delay-Doppler imaging, this relative phase is central to the signal processing objective.

60.2.5 Finite-Power Stochastic Processes

The second major class of second-order processes we wish to consider is the class of finite power signals. A finite-power signal $\mathbf{x}(t)$ is one whose mean-square value exists, as in Eq. (60.4), but whose total energy, as defined in Eq. (60.12), is infinite. Furthermore, we require that the time-averaged mean-square value, given by

$$P_{\mathbf{x}} = \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T R_{\mathbf{x}\mathbf{x}}(t, t) dt, \quad (60.40)$$

exist and be finite. $P_{\mathbf{x}}$ is called the *power* of the process $\mathbf{x}(t)$.

The most commonly invoked stochastic process of this type in communications and signal processing is the *wide-sense-stationary* process, one whose autocorrelation function $R_{\mathbf{x}\mathbf{x}}(t_1, t_2)$ is a function of the time difference $t_1 - t_2$ only. In this case, the mean-square value is constant and is equal to the average power. Such a process is used to model a communication signal that transmits for a long period of time, and for which the beginning and end of transmission are considered unimportant.

A wide-sense-stationary (w.s.s.) process may be considered to be the limiting case of a particular type of finite-energy process, namely a process with separable autocorrelation as described by Eqs. (60.38) and (60.39). If in Eq. (60.38) the function $R_2\left(\frac{t_1+t_2}{2}\right)$ is equal to a constant, then the process is w.s.s. with second-order properties determined by the function $R_1(t_1 - t_2)$. The bi-frequency energy spectral density function is

$$S_{\mathbf{xx}}(\omega_1, \omega_2) = 2\pi\delta(\omega_1 - \omega_2)S_2\left(\frac{\omega_1 + \omega_2}{2}\right) \quad (60.41)$$

where

$$S_2(\omega) = \int_{-\infty}^{\infty} R_1(\tau)e^{-j\omega\tau}d\tau. \quad (60.42)$$

This last pair of equations motivates us to describe the second-order properties of $\mathbf{x}(t)$ with functions of one argument instead of two, namely the autocorrelation function $R_{\mathbf{xx}}(\tau)$ and its Fourier transform $S_{\mathbf{xx}}(\omega)$, known as the *power spectral density*. From basic Fourier transform properties we have

$$P_{\mathbf{x}} = \frac{1}{2\pi} \int_{-\infty}^{\infty} S_{\mathbf{xx}}(\omega)d\omega. \quad (60.43)$$

If w.s.s. $\mathbf{x}(t)$ is the input to a linear time-invariant system with frequency response $H(\omega)$ and output $\mathbf{y}(t)$, then it is not difficult to show that

1. $\mathbf{y}(t)$ is wide-sense-stationary, and
2. $S_{\mathbf{yy}}(\omega) = |H(\omega)|^2 S_{\mathbf{xx}}(\omega)$.

These last results, combined with Eq. (60.43), lead to a natural interpretation of the power spectral density function. If $\mathbf{x}(t)$ is the input to an ideal bandpass filter with passband B , then the total power of the filter output is

$$P_{\mathbf{y}} = \frac{1}{2\pi} \int_B S_{\mathbf{x}}(\omega)d\omega. \quad (60.44)$$

This shows how the total power in the process $\mathbf{x}(t)$ can be attributed to components in different spectral bands.

60.2.6 Complex Wide-Sense-Stationary Processes

Two real stochastic processes $\mathbf{x}(t)$ and $\mathbf{y}(t)$, defined on a common probability space, are said to be jointly wide-sense-stationary if:

1. Both $\mathbf{x}(t)$ and $\mathbf{y}(t)$ are w.s.s., and
2. The cross-correlation $R_{\mathbf{xy}}(t_1, t_2) = E\{\mathbf{x}(t_1)\mathbf{y}(t_2)\}$ is a function of $t_1 - t_2$ only.

For jointly w.s.s. processes, the cross-correlation function is normally written with a single argument, e.g., $R_{\mathbf{xy}}(\tau)$, with $\tau = t_1 - t_2$. From the definition we see that

$$R_{\mathbf{xy}}(\tau) = R_{\mathbf{yx}}(-\tau). \quad (60.45)$$

A complex wide-sense-stationary stochastic process $\mathbf{z}(t)$ is one that can be written

$$\mathbf{z}(t) = \mathbf{x}(t) + j\mathbf{y}(t) \quad (60.46)$$

where $\mathbf{x}(t)$ and $\mathbf{y}(t)$ are jointly wide-sense stationary. A *circular* complex w.s.s. process is one in which

$$R_{\mathbf{xx}}(\tau) = R_{\mathbf{yy}}(\tau) \quad (60.47)$$

and

$$R_{\mathbf{xy}}(\tau) = -R_{\mathbf{yx}}(\tau) \quad \text{all } \tau . \quad (60.48)$$

The reader is cautioned not to confuse the meanings of Eqs. (60.45) and (60.48).

For circular complex w.s.s. processes, it is easy to show that

$$E\{\mathbf{z}(t_1)\mathbf{z}(t_2)\} = 0 \quad (60.49)$$

for all t_1, t_2 , and therefore the function

$$\begin{aligned} R_{\mathbf{zz}}(t_1, t_2) &= E\{\mathbf{z}(t_1)\mathbf{z}^*(t_2)\} \\ &= 2R_{\mathbf{xx}}(t_1, t_2) + 2jR_{\mathbf{yx}}(t_1, t_2) \end{aligned} \quad (60.50)$$

defines all the second-order properties of $\mathbf{z}(t)$. All the quantities involved in Eq. (60.50) are functions of $\tau = t_1 - t_2$ only, and thus the single-argument function $R_{\mathbf{zz}}(\tau)$ is defined as the autocorrelation function for $\mathbf{z}(t)$.

The power spectral density for $\mathbf{z}(t)$ is

$$S_{\mathbf{zz}}(\omega) = \int_{-\infty}^{\infty} R_{\mathbf{zz}}(\tau) e^{-j\omega\tau} d\tau . \quad (60.51)$$

$R_{\mathbf{zz}}(\tau)$ exhibits conjugate symmetry ($R_{\mathbf{zz}}(\tau) = R_{\mathbf{zz}}^*(-\tau)$); $S_{\mathbf{zz}}(\omega)$ is non-negative but otherwise has no symmetry constraints.

If $\mathbf{z}(t)$ is the input to a complex linear time-invariant system with frequency response $H(\omega)$, then the output process $\mathbf{w}(t)$ is wide-sense-stationarity with power spectral density

$$S_{\mathbf{ww}}(\omega) = |H(\omega)|^2 S_{\mathbf{zz}}(\omega) . \quad (60.52)$$

A bandpass w.s.s. process is one with finite (possible asymmetric) support in frequency.

If $\mathbf{z}(t)$ is a circular w.s.s. process, then

$$\mathbf{w}(t) = e^{j\omega_c t} \mathbf{z}(t) \quad (60.53)$$

is also circular, and has power spectral density

$$S_{\mathbf{ww}}(\omega) = S_{\mathbf{zz}}(\omega - \omega_c) . \quad (60.54)$$

60.2.7 Complex Representations of Real Wide-Sense-Stationary Signals

Let $\mathbf{s}(t)$ be a real bandpass w.s.s. stochastic process. The complex representation for $\mathbf{s}(t)$ is given by the now-familiar expression

$$\mathbf{g}(t) = \text{LPF}\{2\mathbf{s}(t)e^{-j\omega_c t}\} \quad (60.55)$$

with inverse relationship

$$\hat{\mathbf{s}}(t) = \text{Re}\{\mathbf{g}(t)e^{j\omega_c t}\} . \quad (60.56)$$

In Eqs. (60.55) and (60.56), ω_c is the center frequency for the passband of $\mathbf{s}(t)$, and the lowpass filter has bandwidth greater than that of $\mathbf{s}(t)$ but much less than $2\omega_c$. $\mathbf{s}(t)$ and $\hat{\mathbf{s}}(t)$ are equivalent in the mean-square sense, implying that $\mathbf{g}(t)$ is the unique complex envelope representation for $\mathbf{s}(t)$.

For arbitrary real w.s.s. $\mathbf{s}(t)$, the circularity of the complex representation comes without any additional conditions like the ones imposed for finite-energy signals. If w.s.s. $\mathbf{s}(t)$ is the input to a quadrature demodulator, then the output signals $\mathbf{x}(t)$ and $\mathbf{y}(t)$ are jointly w.s.s., and the complex process

$$\mathbf{g}(t) = \mathbf{x}(t) + j\mathbf{y}(t) \quad (60.57)$$

is circular. There are various ways of showing this, with the simplest probably being a proof by contradiction. If $\mathbf{g}(t)$ is a complex process that is *not* circular, then the process $\text{Re}\{\mathbf{g}(t)e^{j\omega_c t}\}$ can be shown to have an autocorrelation function with nonzero terms which are a function of $t_1 + t_2$, and thus it cannot be w.s.s.

Communication signals are often modeled as w.s.s. stochastic processes. The stationarity results from the fact that the carrier phase, as seen at the receiver, is unknown and considered random, due to lack of knowledge about the transmitter and path length. This in turn leads to a circularity assumption on the complex modulation.

In many communication and surveillance systems, the quadrature demodulator is an actual electronic subsystem which generates a pair of signals interpreted directly as a complex representation of a bandpass signal. Often these signals are sampled, providing complex digital data for further digital signal processing. In array signal processing, there are multiple such receivers, one behind each sensor or antenna in a multi-sensor system. Data from an array of receivers is then modeled as a *vector* of complex random variables. In the next section, we consider multivariate distributions for such complex data.

60.3 The Multivariate Complex Gaussian Density Function

The discussions of Section 60.2 centered on the second-order (correlation) properties of real and complex stochastic processes, but to this point nothing has been said about joint probability distributions for these processes. In this section, we consider the distribution of samples from a complex process in which the real and imaginary parts are Gaussian distributed. The key concept of this section is that the assumption of circularity on a complex stochastic process (or any collection of complex random variables) leads to a compact form of the density function which can be written directly as a function of a complex argument z rather than its real and imaginary parts.

From a data processing point-of-view, a collection of N complex numbers is simply a collection of $2N$ real numbers, with a certain mathematical significance attached to the N numbers we call the “real parts” and the other N numbers we call the “imaginary parts”. Likewise, a collection of N complex random variables is really just a collection of $2N$ real random variables with some joint distribution in \mathbb{R}^{2N} . Because these random variables have an interpretation as real and imaginary parts of some complex numbers, and because the $2N$ -dimensional distribution may have certain symmetries such as those resulting from circularity, it is often natural and intuitive to express joint densities and distributions using a notation which makes explicit the complex nature of the quantities involved. In this section we develop such a density for the case where the random variables have a Gaussian distribution and are samples of a circular complex stochastic process.

Let $\mathbf{z}_i, i = 1..N$ be a collection of complex numbers that we wish to model probabilistically. Write

$$\mathbf{z}_i = \mathbf{x}_i + j\mathbf{y}_i \quad (60.58)$$

and consider the vector of numbers $[\mathbf{x}_1, \mathbf{y}_1, \dots, \mathbf{x}_N, \mathbf{y}_N]^T$ as a set of $2N$ random variables with a distribution over \mathbb{R}^{2N} . Suppose further that the vector $[\mathbf{x}_1, \mathbf{y}_1, \dots, \mathbf{x}_N, \mathbf{y}_N]^T$ is subject to the usual multivariate Gaussian distribution with $2N \times 1$ mean vector μ and $2N \times 2N$ covariance matrix \mathbf{R} . For compactness, denote the entire random vector with the symbol \mathbf{x} . The density function is

$$f_{\mathbf{x}}(x) = (2\pi)^{\frac{-2N}{2}} (\det \mathbf{R})^{\frac{-1}{2}} e^{-\frac{x^T \mathbf{R}^{-1} x}{2}}. \quad (60.59)$$

We seek a way of expressing the density function of Eq. (60.59) directly in terms of the complex variable z , i.e., a density of the form $f_z(z)$. In so doing it is important to keep in mind what such a density represents. $f_z(z)$ will be a non-negative real-valued function $f : \mathbb{C}^N \rightarrow \mathbb{R}^+$, with the

property that

$$\int_{\mathbb{C}^N} f_{\mathbf{z}}(z) dz = 1. \quad (60.60)$$

The probability that $\mathbf{z} \in A$, where A is some subset of \mathbb{C}^N , is given by

$$P(A) = \int_A f_{\mathbf{z}}(z) dz. \quad (60.61)$$

The differential element dz is understood to be

$$dz = dx_1 dy_1 dx_2 dy_2 \dots dx_N dy_N. \quad (60.62)$$

The most general form of the complex multivariate Gaussian density is in fact given by Eq. (60.59), and further simplification requires further assumptions. Circularity of the underlying complex process is one such key assumption, and it is now imposed. To keep the following development simple, it is assumed that the mean vector μ is 0. The results for nonzero μ are not difficult to obtain by extension.

Consider the four real random variables $\mathbf{x}_i, \mathbf{y}_i, \mathbf{x}_k, \mathbf{y}_k$. If these numbers represent the samples of a circular complex stochastic process, then we can express the 4×4 covariance as

$$E \left\{ \begin{bmatrix} \mathbf{x}_i \\ \mathbf{y}_i \\ \mathbf{x}_k \\ \mathbf{y}_k \end{bmatrix} [\mathbf{x}_i \mathbf{y}_i \mathbf{x}_k \mathbf{y}_k] \right\} = \frac{1}{2} \begin{bmatrix} \alpha_{ii} & 0 & | & \alpha_{ik} & -\beta_{ik} \\ 0 & \alpha_{ii} & | & \beta_{ik} & \alpha_{ik} \\ - & - & - & - & - \\ \alpha_{ki} & -\beta_{ki} & | & \alpha_{kk} & 0 \\ \beta_{ki} & \alpha_{ki} & | & 0 & \alpha_{kk} \end{bmatrix} \quad (60.63)$$

where

$$\alpha_{ik} = 2E\{\mathbf{x}_i \mathbf{x}_k\} = 2E\{\mathbf{y}_i \mathbf{y}_k\} \quad (60.64)$$

and

$$\beta_{ik} = -2E\{\mathbf{x}_i \mathbf{y}_k\} = +2E\{\mathbf{x}_k \mathbf{y}_i\}. \quad (60.65)$$

Extending this to the full $2N \times 2N$ covariance matrix \mathbf{R} , we have

$$\mathbf{R} = \frac{1}{2} \begin{bmatrix} \alpha_{11} & 0 & | & \alpha_{12} & -\beta_{12} & | & \cdot & \cdot & \cdot & | & \alpha_{1N} & -\beta_{1N} \\ 0 & \alpha_{11} & | & \beta_{12} & \alpha_{12} & | & \cdot & \cdot & \cdot & | & \beta_{1N} & \alpha_{1N} \\ - & - & - & - & - & - & - & - & - & - & - & - \\ \alpha_{21} & -\beta_{21} & | & \alpha_{22} & 0 & | & \cdot & \cdot & \cdot & | & \alpha_{2N} & -\beta_{2N} \\ \beta_{21} & \alpha_{21} & | & 0 & \alpha_{22} & | & \cdot & \cdot & \cdot & | & \beta_{2N} & \alpha_{2N} \\ - & - & - & - & - & - & - & - & - & - & - & - \\ \cdot & \cdot & | & \cdot & \cdot & | & \cdot & & & | & \cdot & \cdot \\ \cdot & \cdot & | & \cdot & \cdot & | & & \cdot & & | & \cdot & \cdot \\ \cdot & \cdot & | & \cdot & \cdot & | & & & \cdot & | & \cdot & \cdot \\ - & - & - & - & - & - & - & - & - & - & - & - \\ \alpha_{N1} & -\beta_{N1} & | & \alpha_{N2} & -\beta_{N2} & | & \cdot & \cdot & \cdot & | & \alpha_{NN} & 0 \\ \beta_{N1} & \alpha_{N1} & | & \beta_{N2} & \alpha_{N2} & | & \cdot & \cdot & \cdot & | & 0 & \alpha_{NN} \end{bmatrix}. \quad (60.66)$$

The key thing to notice about the matrix in Eq. (60.66) is that, because of its special structure, it is completely specified by N^2 real quantities: one for each of the 2×2 diagonal blocks, and two for each of the 2×2 upper off-diagonal blocks. This is in contrast to the $N(2N + 1)$ free parameters one finds in an unconstrained $2N \times 2N$ real Hermitian matrix.

Consider now the complex random variables \mathbf{z}_i and \mathbf{z}_k . We have that

$$\begin{aligned} E\{\mathbf{z}_i \mathbf{z}_i^*\} &= E\{(\mathbf{x}_i + j\mathbf{y}_i)(\mathbf{x}_i - j\mathbf{y}_i)\} \\ &= E\{\mathbf{x}_i^2 + \mathbf{y}_i^2\} = \alpha_{ii} \end{aligned} \quad (60.67)$$

and

$$\begin{aligned} E\{\mathbf{z}_i \mathbf{z}_k^*\} &= E\{(\mathbf{x}_i + j\mathbf{y}_i)(\mathbf{x}_k - j\mathbf{y}_k)\} \\ &= E\{\mathbf{x}_i \mathbf{x}_k + \mathbf{y}_i \mathbf{y}_k - j\mathbf{x}_i \mathbf{y}_k + j\mathbf{y}_i \mathbf{x}_k\} \\ &= \alpha_{ik} + j\beta_{ik} . \end{aligned} \quad (60.68)$$

Similarly

$$E\{\mathbf{z}_k \mathbf{z}_i^*\} = \alpha_{ik} - j\beta_{ik} \quad (60.69)$$

and

$$E\{\mathbf{z}_k \mathbf{z}_k^*\} = \alpha_{kk} . \quad (60.70)$$

Using Eqs. (60.66) through (60.70), it is possible to write the following $N \times N$ complex Hermitian matrix:

$$E\{\mathbf{z}\mathbf{z}^H\} = \begin{bmatrix} \alpha_{11} & \alpha_{12} + j\beta_{12} & \dots & \alpha_{1N} + j\beta_{1N} \\ \alpha_{21} + j\beta_{21} & \alpha_{22} & \dots & \alpha_{2N} + j\beta_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ \alpha_{N1} + j\beta_{N1} & \alpha_{N2} + j\beta_{N2} & \dots & \alpha_{NN} \end{bmatrix} . \quad (60.71)$$

Note that this complex matrix has exactly the same N^2 free parameters as did the $2N \times 2N$ real matrix \mathbf{R} in Eq. (60.66), and thus it tells us everything there is to know about the joint distribution of the real and imaginary components of \mathbf{z} . Under the symmetry constraints imposed on \mathbf{R} , we can define

$$\mathbf{C} = E\{\mathbf{z}\mathbf{z}^H\} \quad (60.72)$$

and call this matrix the covariance matrix for \mathbf{z} . In the 0-mean Gaussian case, this matrix parameter uniquely identifies the multivariate distribution for \mathbf{z} .

The derivation of the density function $f_{\mathbf{z}}(\mathbf{z})$ rests on a set of relationships between the $2N \times 1$ real vector \mathbf{x} , and its $N \times 1$ complex counterpart \mathbf{z} . We say that \mathbf{x} and \mathbf{z} are *isomorphic* to one another, and denote this with the symbol

$$\mathbf{z} \approx \mathbf{x} . \quad (60.73)$$

Likewise we say that the $2N \times 2N$ real matrix \mathbf{R} , given in Eq. (60.66), and the $N \times N$ complex matrix \mathbf{C} , given in Eq. (60.71) are isomorphic to one another, or

$$\mathbf{C} \approx \mathbf{R} . \quad (60.74)$$

The development of the complex Gaussian density function $f_{\mathbf{z}}(\mathbf{z})$ is based on three claims based on these isomorphisms.

Proposition 1. If $\mathbf{z} \approx \mathbf{x}$, and $\mathbf{R} \approx \mathbf{C}$, then

$$\mathbf{x}^T (2\mathbf{R}) \mathbf{x} = \mathbf{z}^H \mathbf{C} \mathbf{z} . \quad (60.75)$$

Proposition 2. If $\mathbf{R} \approx \mathbf{C}$, then

$$\frac{1}{4}\mathbf{R}^{-1} \approx \mathbf{C}^{-1} . \quad (60.76)$$

Proposition 3. If $\mathbf{R} \approx \mathbf{C}$, then

$$\det \mathbf{R} = |\det \mathbf{C}|^2 \left(\frac{1}{2}\right)^{2N} . \quad (60.77)$$

The density function $f_{\mathbf{z}}(z)$ is found by substituting the results from Propositions 1 through 3 directly into the density function $f_{\mathbf{x}}(x)$. This is possible because the mapping from \mathbf{z} to \mathbf{x} is one-to-one and onto, and the Jacobian is 1 [see Eq. (60.62)]. We have

$$f_{\mathbf{z}}(z) = (2\pi)^{\frac{-2N}{2}} (\det \mathbf{R})^{\frac{-1}{2}} e^{-\frac{\mathbf{x}^T \mathbf{R}^{-1} \mathbf{x}}{2}} \quad (60.78)$$

$$\begin{aligned} &= \left(\frac{1}{2}\right)^{-N} (2\pi)^{-N} (\det \mathbf{C})^{-1} e^{-z^H \mathbf{C}^{-1} z} . \\ &= \pi^{-N} (\det \mathbf{C})^{-1} e^{-z^H \mathbf{C}^{-1} z} . \end{aligned} \quad (60.79)$$

At this point it is straightforward to introduce a non-zero mean μ , which is the complex vector isomorphic to the mean of the real random vector \mathbf{x} . The resulting density is

$$f_{\mathbf{z}}(z) = \pi^{-N} (\det \mathbf{C})^{-1} e^{-(z-\mu)^H \mathbf{C}^{-1} (z-\mu)} . \quad (60.80)$$

The density function in Eq. (60.80) is commonly referred to as the *complex Gaussian density function*, although in truth one could be more general and have an arbitrary $2N$ -dimension Gaussian distribution on the real and imaginary components of \mathbf{z} . It is important to recognize that the use of Eq. (60.80) implies those symmetries in the real covariance of \mathbf{x} implied by circularity of the underlying complex process. This symmetry is expressed by some authors in the equation

$$E\{\mathbf{z}\mathbf{z}^T\} = \mathbf{0} \quad (60.81)$$

where the superscript “T” indicates transposition without complex conjugation. This comes directly from Eqs. (60.24) and (60.49).

For many, the functional form of the complex Gaussian density in Eq. (60.80) is actually simpler and cleaner than its N -dimensional real counterpart, due to elimination of the various factors of 2 which complicate it. This density is the starting point for virtually all of the multivariate analysis of complex data seen in the current signal and array processing literature.

60.4 Related Distributions

In many problems of interest in statistical signal processing, the raw data may be complex and subject to a complex Gaussian distribution described in the density function in Eq. (60.80). The processing may take the form of the computation of a test statistic for use in a hypothesis test. The density functions for these test statistics are then used to determine probabilities of false alarm and/or detection. Thus, it is worthwhile to study certain distributions that are closely related to the complex Gaussian in this way.

In this section we will describe and give the functional form for four densities related to the complex Gaussian: the complex χ^2 , the complex F , the complex β , and the complex t . Only the “central” versions of these distributions will be given, i.e., those based on 0-mean Gaussian data. The central distributions are usually associated with the null hypothesis in a detection problem and are used to compute probabilities of false alarm. The non-central densities, used in computing probabilities of detection, do not exist in closed form but can be easily tabulated.

60.4.1 Complex Chi-Squared Distribution

One very common type of detection problem in radar problems is the “signal present” vs. “signal absent” decision problem. Often under the “signal absent” hypothesis, the data is zero-mean complex Gaussian, with known covariance, whereas under the “signal present” hypothesis the mean is non-zero, but perhaps unknown or subject to some uncertainty. A common test under these circumstances is to compute the sum of squared magnitudes of the data points (after pre-whitening, if appropriate) and compare this to a threshold. The resulting test statistic has a χ^2 -squared distribution.

Let $\mathbf{z}_1 \dots \mathbf{z}_N$ be N complex Gaussian random variables, independent and identically distributed with mean 0 and variance 1 (meaning that the covariance matrix for the \mathbf{z} vector is \mathbf{I}). Define the real non-negative random variable \mathbf{q} according to

$$\mathbf{q} = \sum_i^N |\mathbf{z}_i|^2 . \quad (60.82)$$

Then the density function for \mathbf{q} is given by

$$f_{\mathbf{q}}(q) = \frac{1}{(N-1)!} q^{N-1} e^{-q} U(q) . \quad (60.83)$$

To establish this result, show that the density function for $|\mathbf{z}_i|^2$ is a simple exponential. Equation (60.83) is the N -fold convolution of this exponential density function with itself.

We often say that \mathbf{q} is χ^2 with N complex degrees of freedom. A “complex degree of freedom” is like two real degrees of freedom. Note, however, that Eq. (60.83) is not the usual χ^2 density function with $2N$ degrees of freedom. Each of the real variables going into the computation of \mathbf{q} has variance $\frac{1}{2}$, not 1. $f_{\mathbf{q}}(q)$ is a gamma density with an integer parameter N , and, like the complex Gaussian density in Eq. (60.60), it is cleaner and simpler than its real counterpart.

60.4.2 Complex F Distribution

In some “signal present” vs. “signal absent” problems, the variance or covariance of the noise is not known under the null hypothesis, and must be estimated from some auxiliary data. Then the test statistic becomes the ratio of the sum of square magnitudes of the test data to the sum of square magnitudes of the auxiliary data. The resulting test statistic is subject to a particular form of the F -distribution.

Let \mathbf{q}_1 and \mathbf{q}_2 be two independent random variables subject to the χ^2 distribution with N and M complex degrees of freedom, respectively. Define the real, nonnegative random variable \mathbf{f} according to

$$\mathbf{f} = \frac{\mathbf{q}_1}{\mathbf{q}_2} . \quad (60.84)$$

The density function for \mathbf{f} is

$$f_{\mathbf{f}}(f) = \frac{(N+M-1)!}{(N-1)!(M-1)!} \frac{f^{N-1}}{(1+f)^{N+M}} U(f) . \quad (60.85)$$

We say that \mathbf{f} is subject to an F -distribution with N and M complex degrees of freedom.

60.4.3 Complex Beta Distribution

An F -distributed random variable can be transformed in such a way that the resulting density has finite support. The random variable \mathbf{b} , defined by

$$\mathbf{b} = \frac{1}{(1 + \mathbf{f})}, \quad (60.86)$$

where \mathbf{f} is an F -distributed random variable, has this property. The density function is given by

$$f_{\mathbf{b}}(b) = \frac{(N + M - 1)!}{(N - 1)!(M - 1)!} b^{M-1} (1 - b)^{N-1} \quad (60.87)$$

on the interval $0 \leq b \leq 1$, and is 0 elsewhere.

The random variable \mathbf{b} is said to be beta-distributed, with N and M complex degrees of freedom.

60.4.4 Complex Student- t Distribution

In the “signal present” vs. “signal absent” problem, if the signal is known exactly (including phase) then the optimal detector is a pre-whitener followed by a matched filter. The resulting test statistic is complex Gaussian, and the detector partitions the complex plane into two half-planes which become the decision regions for the two hypotheses. Now it may be that the signal is known, but the variance of the noise is not. In this case, the Gaussian test statistic must be scaled by an estimate of the standard deviation, obtained as before from zero-mean auxiliary data. In this case the test statistic is said to have a complex t (or Student- t) distribution. Of the four distributions discussed in this section, this is the only one in which the random variables themselves are complex: the χ^2 , F , and β distributions all describe real random variables functionally dependent on complex Gaussians.

Let \mathbf{z} and \mathbf{q} be independent scalar random variables. \mathbf{z} is complex Gaussian with mean 0 and variance 1, and \mathbf{q} is χ^2 with N complex degrees of freedom. Define the random variable \mathbf{t} according to

$$\mathbf{t} = \frac{\mathbf{z}}{\sqrt{\mathbf{q}/N}}. \quad (60.88)$$

The density of \mathbf{t} is then given by

$$f_{\mathbf{t}}(t) = \frac{1}{\pi \left(1 + \frac{|t|^2}{N}\right)^{N+1}}. \quad (60.89)$$

This density is said to be “heavy-tailed” relative to the Gaussian, and this is a result in the uncertainty in the estimate of the standard deviation. Note that as $N \rightarrow \infty$, the denominator Eq. (60.88) approaches 1 (i.e., the estimate of the standard deviation approaches truth) and thus $f_{\mathbf{t}}(t)$ approaches the Gaussian density $\pi^{-1} e^{-|t|^2}$ as expected.

60.5 Conclusion

In this chapter we have outlined a basic theory of complex random variables and stochastic processes as they most often appear in statistical signal and array processing problems. The properties of complex representations for real bandpass signals were emphasized, since this is the most common application in electrical engineering where complex data appear. Models for both finite-energy signals, such as radar pulses, and finite-power signals, such as communication signals, were developed. The key notion of circularity of complex stochastic processes was explored, along with the conditions that

a real stochastic process must satisfy in order for it to have a circular complex representation. The complex multivariate Gaussian distribution was developed, again building on the circularity of the underlying complex stochastic process. Finally, related distributions which often appear in statistical inference problems with complex Gaussian data were introduced.

The general topic of random variables and stochastic processes is fundamental to modern signal processing, and many good textbooks are available. Those by Papoulis [2], Leon-Garcia [3], and Melsa and Sage [4] are recommended. The original short paper deriving the complex multivariate Gaussian density function is by Wooding [5]; another derivation and related statistical analysis is given in Goodman [6], whose name is more often cited in connection with complex random variables. The monograph by Miller [7] has a mathematical flavor, and covers complex stochastic processes, stochastic differential equations, parameter estimation, and least-squares problems. The paper by Neeser and Massey [8] treats circular (which they call “proper”) complex stochastic processes and their application in information theory. There is a good discussion of complex random variables in Kay [9], which includes Cramer-Rao lower bounds and optimization of functions of complex variables. Kelly and Forsythe [10] is an advanced treatment of inference problems for complex multivariate data, and contains a number of appendices with valuable background information, including one on distributions related to the complex Gaussian.

61.1 Introduction

Systems designed to receive spatially propagating signals often encounter the presence of interference signals. If the desired signal and interferers occupy the same temporal frequency band, then temporal filtering cannot be used to separate signal from interference. However, desired and interfering signals often originate from different spatial locations. This spatial separation can be exploited to separate signal from interference using a spatial filter at the receiver.

A beamformer is a processor used in conjunction with an array of sensors to provide a versatile form of spatial filtering. The term beamforming derives from the fact that early spatial filters were designed to form pencil beams (see polar plot in Fig. 61.5(c)) in order to receive a signal radiating from a specific location and attenuate signals from other locations. “Forming beams” seems to indicate radiation of energy; however, beamforming is applicable to either radiation or reception of energy. In this section we discuss formation of beams for reception, providing an overview of beamforming from a signal processing perspective. Data independent, statistically optimum, adaptive, and partially adaptive beamforming are discussed.

Implementing a temporal filter requires processing of data collected over a temporal aperture. Similarly, implementing a spatial filter requires processing of data collected over a spatial aperture. A single sensor such as an antenna, sonar transducer, or microphone collects impinging energy over a continuous aperture, providing spatial filtering by summing coherently waves that are in phase across the aperture while destructively combining waves that are not. An array of sensors provides a discrete sampling across its aperture. When the spatial sampling is discrete, the processor that performs the spatial filtering is termed a beamformer. Typically a beamformer linearly combines the spatially sampled time series from each sensor to obtain a scalar output time series in the same manner that an FIR filter linearly combines temporally sampled data. Two principal advantages of spatial sampling with an array of sensors are discussed below.

Spatial discrimination capability depends on the size of the spatial aperture; as the aperture increases, discrimination improves. The absolute aperture size is not important, rather its size in wavelengths is the critical parameter. A single physical antenna (continuous spatial aperture) capable of providing the requisite discrimination is often practical for high frequency signals because the wavelength is short. However, when low frequency signals are of interest, an array of sensors can often synthesize a much larger spatial aperture than that practical with a single physical antenna.

A second very significant advantage of using an array of sensors, relevant at any wavelength, is the spatial filtering versatility offered by discrete sampling. In many application areas, it is necessary to change the spatial filtering function in real time to maintain effective suppression of interfering signals. This change is easily implemented in a discretely sampled system by changing the way in which the beamformer linearly combines the sensor data. Changing the spatial filtering function of a continuous aperture antenna is impractical.

This section begins with the definition of basic terminology, notation, and concepts. Succeeding sections cover data-independent, statistically optimum, adaptive, and partially adaptive beamforming. We then conclude with a summary.

Throughout this section we use methods and techniques from FIR filtering to provide insight into various aspects of spatial filtering with beamformer. However, in some ways beamforming differs significantly from FIR filtering. For example, in beamforming a source of energy has several parameters that can be of interest: range, azimuth and elevation angles, polarization, and temporal frequency content. Different signals are often mutually correlated as a result of multipath propagation. The spatial sampling is often nonuniform and multidimensional. Uncertainty must often be included in characterization of individual sensor response and location, motivating development of robust beamforming techniques. These differences indicate that beamforming represents a more general problem than FIR filtering and, as a result, more general design procedures and processing structures are common.

61.2 Basic Terminology and Concepts

In this section we introduce terminology and concepts employed throughout. We begin by defining the beamforming operation and discussing spatial filtering. Next we introduce second order statistics of the array data, developing representations for the covariance of the data received at the array and discussing distinctions between narrowband and broadband beamforming. Last, we define various types of beamformers.

61.2.1 Beamforming and Spatial Filtering

Figure 61.1 depicts two beamformers. The first, which samples the propagating wave field in space, is typically used for processing narrowband signals. The output at time k , $y(k)$, is given by a linear

combination of the data at the J sensors at time k :

$$y(k) = \sum_{l=1}^J w_l^* x_l(k) \quad (61.1)$$

where $*$ represents complex conjugate. It is conventional to multiply the data by conjugates of the weights to simplify notation. We assume throughout that the data and weights are complex since in many applications a quadrature receiver is used at each sensor to generate in phase and quadrature (I and Q) data. Each sensor is assumed to have any necessary receiver electronics and an A/D converter if beamforming is performed digitally.

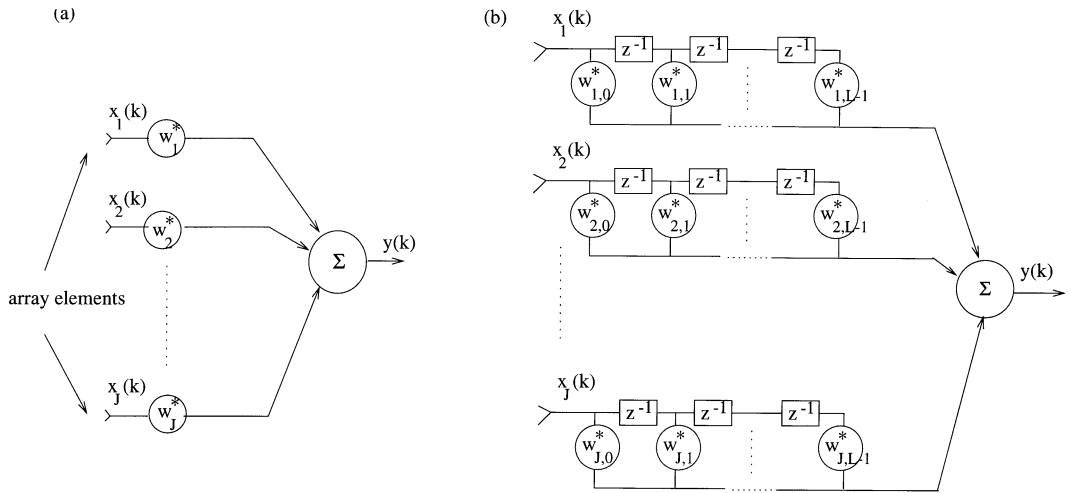

FIGURE 61.1: A beamformer forms a linear combination of the sensor outputs. In (a), sensor outputs are multiplied by complex weights and summed. This beamformer is typically used with narrowband signals. A common broadband beamformer is illustrated in (b).

The second beamformer in Fig. 61.1 samples the propagating wave field in both space and time and is often used when signals of significant frequency extent (broadband) are of interest. The output in this case can be expressed as

$$y(k) = \sum_{l=1}^J \sum_{p=0}^{K-1} w_{l,p}^* x_l(k-p) \quad (61.2)$$

where $K - 1$ is the number of delays in each of the J sensor channels. If the signal at each sensor is viewed as an input, then a beamformer represents a multi-input single output system.

It is convenient to develop notation that permits us to treat both beamformers in Fig. 61.1 simultaneously. Note that Eqs. (61.1) and (61.2) can be written as

$$y(k) = \mathbf{w}^H \mathbf{x}(k) \quad (61.3)$$

by appropriately defining a weight vector \mathbf{w} and data vector $\mathbf{x}(k)$. We use lower and upper case boldface to denote vector and matrix quantities, respectively, and let superscript H represent Hermitian

(complex conjugate) transpose. Vectors are assumed to be column vectors. Assume that \mathbf{w} and $\mathbf{x}(k)$ are N dimensional; this implies that $N = KJ$ when referring to Eq. (61.2) and $N = J$ when referring to Eq. (61.1). Except for Section 61.5 on adaptive algorithms, we will drop the time index and assume that its presence is understood throughout the remainder of the paper. Thus, Eq. (61.3) is written as $y = \mathbf{w}^H \mathbf{x}$. Many of the techniques described in this section are applicable to continuous time as well as discrete time beamforming.

The frequency response of an FIR filter with tap weights w_p^* , $1 \leq p \leq J$ and a tap delay of T seconds is given by

$$r(\omega) = \sum_{p=1}^J w_p^* e^{-j\omega T(p-1)}. \quad (61.4)$$

Alternatively

$$r(\omega) = \mathbf{w}^H \mathbf{d}(\omega) \quad (61.5)$$

where $\mathbf{w}^H = [w_1^* \ w_2^* \ \dots w_J^*]$ and $\mathbf{d}(\omega) = [1 \ e^{j\omega T} \ e^{j\omega 2T} \ \dots e^{j\omega(J-1)T}]^H$. $r(\omega)$ represents the response of the filter¹ to a complex sinusoid of frequency ω and $\mathbf{d}(\omega)$ is a vector describing the phase of the complex sinusoid at each tap in the FIR filter relative to the tap associated with w_1 .

Similarly, beamformer response is defined as the amplitude and phase presented to a complex plane wave as a function of location and frequency. Location is, in general, a three dimensional quantity, but often we are only concerned with one- or two-dimensional direction of arrival (DOA). Throughout the remainder of the section we do not consider range. Figure 61.2 illustrates the manner in which an array of sensors samples a spatially propagating signal. Assume that the signal is a complex plane wave with DOA θ and frequency ω . For convenience let the phase be zero at the first sensor. This implies $x_1(k) = e^{j\omega k}$ and $x_l(k) = e^{j\omega[k - \Delta_l(\theta)]}$, $2 \leq l \leq J$. $\Delta_l(\theta)$ represents the time delay due to propagation from the first to the l th sensor. Substitution into Eq. (61.2) results in the beamformer output

$$y(k) = e^{j\omega k} \sum_{l=1}^J \sum_{p=0}^{K-1} w_{l,p}^* e^{-j\omega[\Delta_l(\theta)+p]} = e^{j\omega k} r(\theta, \omega) \quad (61.6)$$

where $\Delta_1(\theta) = 0$. $r(\theta, \omega)$ is the beamformer response and can be expressed in vector form as

$$r(\theta, \omega) = \mathbf{w}^H \mathbf{d}(\theta, \omega). \quad (61.7)$$

The elements of $\mathbf{d}(\theta, \omega)$ correspond to the complex exponentials $e^{j\omega[\Delta_l(\theta)+p]}$. In general it can be expressed as

$$\mathbf{d}(\theta, \omega) = [1 \ e^{j\omega\tau_2(\theta)} \ e^{j\omega\tau_3(\theta)} \ \dots e^{j\omega\tau_N(\theta)}]^H. \quad (61.8)$$

where the $\tau_i(\theta)$, $2 \leq i \leq N$ are the time delays due to propagation and any tap delays from the zero phase reference to the point at which the i th weight is applied. We refer to $\mathbf{d}(\theta, \omega)$ as the array response vector. It is also known as the steering vector, direction vector, or array manifold vector. Nonideal sensor characteristics can be incorporated into $\mathbf{d}(\theta, \omega)$ by multiplying each phase shift by a function $a_i(\theta, \omega)$, which describes the associated sensor response as a function of frequency and direction.

The *beam pattern* is defined as the magnitude squared of $r(\theta, \omega)$. Note that each weight in \mathbf{w} affects both the temporal and spatial response of the beamformer. Historically, use of FIR filters has been viewed as providing frequency dependent weights in each channel. This interpretation is somewhat

¹ An FIR filter is by definition linear, so an input sinusoid produces at the output a sinusoid of the same frequency. The magnitude and argument of $r(\omega)$ are, respectively, the magnitude and phase responses.

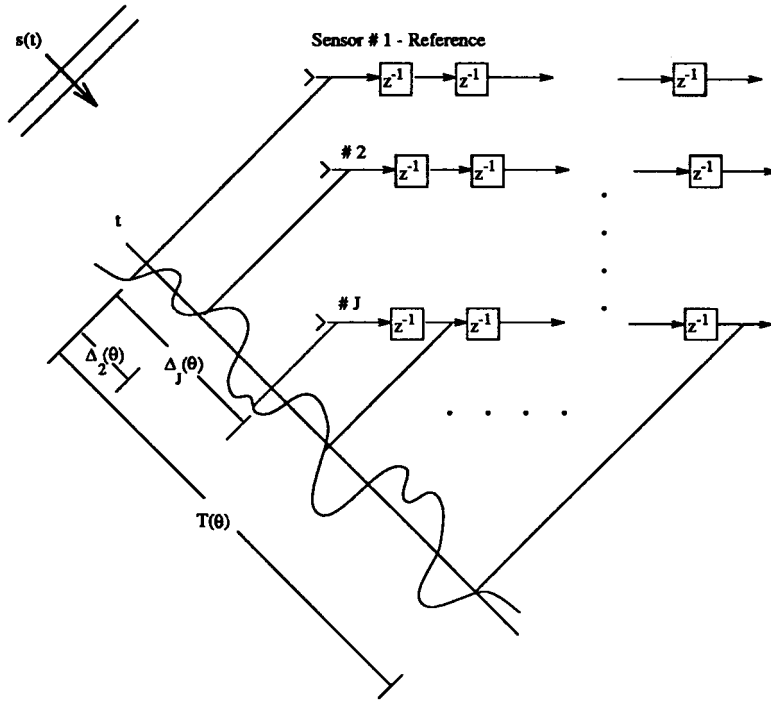

FIGURE 61.2: An array with attached delay lines provides a spatial/temporal sampling of propagating sources. This figure illustrates this sampling of a signal propagating in plane waves from a source located at DOA θ . With J sensors and K samples per sensor, at any instant in time the propagating source signal is sampled at JK nonuniformly spaced points. $T(\theta)$, the time duration from the first sample of the first sensor to the last sample of the last sensor, is termed the temporal aperture of the observation of the source at θ . As notation suggests, temporal aperture will be a function of DOA θ . Plane wave propagation implies that at any time k a propagating signal, received anywhere on a planar front perpendicular to a line drawn from the source to a point on the plane, has equal intensity. Propagation of the signal between two points in space is then characterized as pure delay. In this figure, $\Delta_i(\theta)$ represents the time delay due to plane wave propagation from the 1st (reference) to the i th sensor.

incomplete since the coefficients in each filter also influence the spatial filtering characteristics of the beamformer. As a multi-input single output system, the spatial and temporal filtering that occurs is a result of mutual interaction between spatial and temporal sampling.

The correspondence between FIR filtering and beamforming is closest when the beamformer operates at a single temporal frequency ω_o and the array geometry is linear and equi-spaced as illustrated in Fig. 61.3. Letting the sensor spacing be d , propagation velocity be c , and θ represent DOA relative to broadside (perpendicular to the array), we have $\tau_i(\theta) = (i - 1)(d/c)\sin\theta$. In this case we identify the relationship between temporal frequency ω in $\mathbf{d}(\omega)$ (FIR filter) and direction θ in $\mathbf{d}(\theta, \omega_o)$ (beamformer) as $\omega = \omega_o(d/c)\sin\theta$. Thus, temporal frequency in an FIR filter corresponds to the sine of direction in a narrowband linear equi-spaced beamformer. Complete interchange of beamforming and FIR filtering methods is possible for this special case provided the mapping between frequency and direction is accounted for.

The vector notation introduced in (61.3) suggests a vector space interpretation of beamforming. This point of view is useful both in beamformer design and analysis. We use it here in consideration

FIGURE 61.3: The analogy between an equi-spaced omni-directional narrowband line array and a single-channel FIR filter is illustrated in this figure.

of spatial sampling and array geometry. The weight vector \mathbf{w} and the array response vectors $\mathbf{d}(\theta, \omega)$ are vectors in an N -dimensional vector space. The angles between \mathbf{w} and $\mathbf{d}(\theta, \omega)$ determine the response $r(\theta, \omega)$. For example, if for some (θ, ω) the angle between \mathbf{w} and $\mathbf{d}(\theta, \omega)$ is 90° (i.e., if \mathbf{w} is orthogonal to $\mathbf{d}(\theta, \omega)$), then the response is zero. If the angle is close to 0° , then the response magnitude will be relatively large. The ability to discriminate between sources at different locations and/or frequencies, say (θ_1, ω_1) and (θ_2, ω_2) , is determined by the angle between their array response vectors, $\mathbf{d}(\theta_1, \omega_1)$ and $\mathbf{d}(\theta_2, \omega_2)$.

The general effects of spatial sampling are similar to temporal sampling. Spatial aliasing corresponds to an ambiguity in source locations. The implication is that sources at different locations have the same array response vector, e.g., for narrowband sources $\mathbf{d}(\theta_1, \omega_o)$ and $\mathbf{d}(\theta_2, \omega_o)$. This can occur if the sensors are spaced too far apart. If the sensors are too close together, spatial discrimination suffers as a result of the smaller than necessary aperture; array response vectors are not well dispersed in the N dimensional vector space. Another type of ambiguity occurs with broadband signals when a source at one location and frequency cannot be distinguished from a source at a different location and frequency, i.e., $\mathbf{d}(\theta_1, \omega_1) = \mathbf{d}(\theta_2, \omega_2)$. For example, this occurs in a linear equi-spaced array whenever $\omega_1 \sin \theta_1 = \omega_2 \sin \theta_2$. (The addition of temporal samples at one sensor prevents this particular ambiguity.)

A primary focus of this section is on designing response via weight selection; however, (61.7) indicates that response is also a function of array geometry (and sensor characteristics if the ideal omnidirectional sensor model is invalid). In contrast with single channel filtering where A/D converters provide a uniform sampling in time, there is no compelling reason to space sensors regularly. Sensor locations provide additional degrees of freedom in designing a desired response and can be selected so that over the range of (θ, ω) of interest the array response vectors are unambiguous and well dispersed in the N dimensional vector space. Utilization of these degrees of freedom can become very complicated due to the multidimensional nature of spatial sampling and the nonlinear relationship between $r(\theta, \omega)$ and sensor locations.

61.2.2 Second Order Statistics

Evaluation of beamformer performance usually involves power or variance, so the second order statistics of the data play an important role. We assume the data received at the sensors are zero mean throughout this section. The variance or expected power of the beamformer output is given by $E\{|y|^2\} = \mathbf{w}^H E\{\mathbf{x} \mathbf{x}^H\} \mathbf{w}$. If the data are wide sense stationary, then $\mathbf{R}_x = E\{\mathbf{x} \mathbf{x}^H\}$, the data

covariance matrix, is independent of time. Although we often encounter nonstationary data, the wide sense stationary assumption is used in developing statistically optimal beamformers and in evaluating steady state performance.

Suppose \mathbf{x} represents samples from a uniformly sampled time series having a power spectral density $S(\omega)$ and no energy outside of the spectral band $[\omega_a, \omega_b]$. \mathbf{R}_x can be expressed in terms of the power spectral density of the data using the Fourier transform relationship as

$$\mathbf{R}_x = \frac{1}{2\pi} \int_{\omega_a}^{\omega_b} S(\omega) \mathbf{d}(\omega) \mathbf{d}^H(\omega) d\omega \quad (61.9)$$

with $\mathbf{d}(\omega)$ as defined for (61.5). Now assume the array data \mathbf{x} is due to a source located at direction θ . In like manner to the time series case we can obtain the covariance matrix of the array data as

$$\mathbf{R}_x = \frac{1}{2\pi} \int_{\omega_a}^{\omega_b} S(\omega) \mathbf{d}(\theta, \omega) \mathbf{d}^H(\theta, \omega) d\omega \quad (61.10)$$

A source is said to be narrowband of frequency ω_o if \mathbf{R}_x can be represented as the rank one outer product

$$\mathbf{R}_x = \sigma_s^2 \mathbf{d}(\theta, \omega_o) \mathbf{d}^H(\theta, \omega_o) \quad (61.11)$$

where σ_s^2 is the source variance or power.

The conditions under which a source can be considered narrowband depend on both the source bandwidth and the time over which the source is observed. To illustrate this, consider observing an amplitude modulated sinusoid or the output of a narrowband filter driven by white noise on an oscilloscope. If the signal bandwidth is small relative to the center frequency (i.e., if it has small fractional bandwidth), and the time intervals over which the signal is observed are short relative to the inverse of the signal bandwidth, then each observed waveform has the shape of a sinusoid. Note that as the observation time interval is increased, the bandwidth must decrease for the signal to remain sinusoidal in appearance. It turns out, based on statistical arguments, that the observation time bandwidth product (TBWP) is the fundamental parameter that determines whether a source can be viewed as narrowband (see Buckley [2]).

An array provides an effective temporal aperture over which a source is observed. Figure 61.2 illustrates this temporal aperture $T(\theta)$ for a source arriving from direction θ . Clearly the TBWP is dependent on the source DOA. An array is considered narrowband if the observation TBWP is much less than one for all possible source directions.

Narrowband beamforming is conceptually simpler than broadband since one can ignore the temporal frequency variable. This fact, coupled with interest in temporal frequency analysis for some applications, has motivated implementation of broadband beamformers with a narrowband decomposition structure, as illustrated in Fig. 61.4. The narrowband decomposition is often performed by taking a discrete Fourier transform (DFT) of the data in each sensor channel using an FFT algorithm. The data across the array at each frequency of interest are processed by their own beamformer. This is usually termed frequency domain beamforming. The frequency domain beamformer outputs can be made equivalent to the DFT of the broadband beamformer output depicted in Fig. 61.1(b) with proper selection of beamformer weights and careful data partitioning.

61.2.3 Beamformer Classification

Beamformers can be classified as either data independent or statistically optimum, depending on how the weights are chosen. The weights in a data independent beamformer do not depend on the array data and are chosen to present a specified response for all signal/interference scenarios. The weights in a statistically optimum beamformer are chosen based on the statistics of the array data to “optimize”

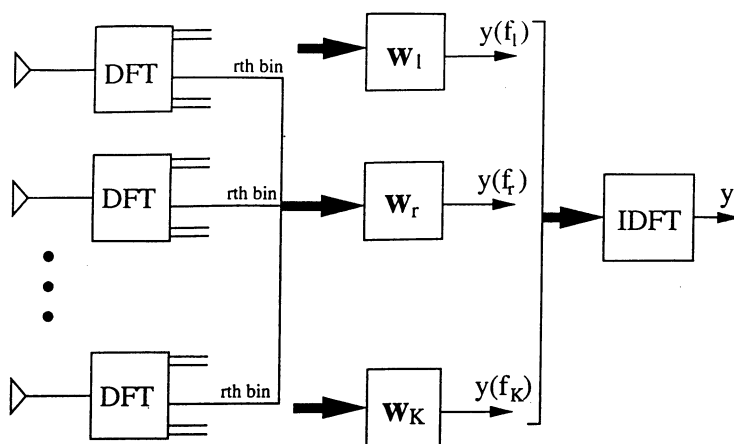

FIGURE 61.4: Beamforming is sometimes performed in the frequency domain when broadband signals are of interest. This figure illustrates transformation of the data at each sensor into the frequency domain. Weighted combinations of data at each frequency (bin) are performed. An inverse discrete Fourier transform produces the output time series.

the array response. In general, the statistically optimum beamformer places nulls in the directions of interfering sources in an attempt to maximize the signal-to-noise ratio at the beamformer output. A comparison between data independent and statistically optimum beamformers is illustrated in Fig. 61.5.

The next four sections cover data independent, statistically optimum, adaptive, and partially adaptive beamforming. Data independent beamformer design techniques are often used in statistically optimum beamforming (e.g., constraint design in linearly constrained minimum variance beamforming). The statistics of the array data are not usually known and may change over time so adaptive algorithms are typically employed to determine the weights. The adaptive algorithm is designed so the beamformer response converges to a statistically optimum solution. Partially adaptive beamformers reduce the adaptive algorithm computational load at the expense of a loss (designed to be small) in statistical optimality.

61.3 Data Independent Beamforming

The weights in a data independent beamformer are designed so the beamformer response approximates a desired response independent of the array data or data statistics. This design objective — approximating a desired response — is the same as that for classical FIR filter design (see, for example, Parks and Burrus [8]). We shall exploit the analogies between beamforming and FIR filtering where possible in developing an understanding of the design problem. We also discuss aspects of the design problem specific to beamforming.

The first part of this section discusses forming beams in a classical sense, i.e., approximating a desired response of unity at a point of direction and zero elsewhere. Methods for designing beamformers having more general forms of desired response are presented in the second part.

61.3.1 Classical Beamforming

Consider the problem of separating a single complex frequency component from other frequency components using the J tap FIR filter illustrated in Fig. 61.3. If frequency ω_o is of interest, then the

desired frequency response is unity at ω_o and zero elsewhere. A common solution to this problem is to choose \mathbf{w} as the vector $\mathbf{d}(\omega_o)$. This choice can be shown to be optimal in terms of minimizing the squared error between the actual response and desired response. The actual response is characterized by a main lobe (or beam) and many sidelobes. Since $\mathbf{w} = \mathbf{d}(\omega_o)$, each element of \mathbf{w} has unit magnitude. Tapering or windowing the amplitudes of the elements of \mathbf{w} permits trading of main lobe or beam width against sidelobe levels to form the response into a desired shape. Let \mathbf{T} be a J by J diagonal matrix with the real-valued taper weights as diagonal elements. The tapered FIR filter weight vector is given by $\mathbf{T} \mathbf{d}(\omega_o)$. A detailed comparison of a large number of tapering functions is given in [5].

In spatial filtering one is often interested in receiving a signal arriving from a known location point θ_o . Assuming the signal is narrowband (frequency ω_o), a common choice for the beamformer weight vector is the array response vector $\mathbf{d}(\theta_o, \omega_o)$. The resulting array and beamformer is termed a phased array because the output of each sensor is phase shifted prior to summation. Figure 61.5(b) depicts the magnitude of the actual response when $\mathbf{w} = \mathbf{T} \mathbf{d}(\theta_o, \omega_o)$, where \mathbf{T} implements a common Dolph-Chebyshev tapering function. As in the FIR filter discussed above, beam width and sidelobe levels are the important characteristics of the response. Amplitude tapering can be used to control the shape of the response, i.e., to form the beam. The equivalence of the narrowband linear equi-spaced array and FIR filter (see Fig. 61.3) implies that the same techniques for choosing taper functions are applicable to either problem. Methods for choosing tapering weights also exist for more general array configurations.

61.3.2 General Data Independent Response Design

The methods discussed in this section apply to design of beamformers that approximate an arbitrary desired response. This is of interest in several different applications. For example, we may wish to receive any signal arriving from a range of directions, in which case the desired response is unity over the entire range. As another example, we may know that there is a strong source of interference arriving from a certain range of directions, in which case the desired response is zero in this range. These two examples are analogous to bandpass and bandstop FIR filtering. Although we are no longer “forming beams”, it is conventional to refer to this type of spatial filter as a beamformer.

Consider choosing \mathbf{w} so the actual response $r(\theta, \omega) = \mathbf{w}^H \mathbf{d}(\theta, \omega)$ approximates desired response $r_d(\theta, \omega)$. Ad hoc techniques similar to those employed in FIR filter design can be used for selecting \mathbf{w} . Alternatively, formal optimization design methods can be employed (see, for example, Parks and Burrus [8]). Here, to illustrate the general optimization design approach, we only consider choosing \mathbf{w} to minimize the weighted averaged square of the difference between desired and actual response.

Consider minimizing the squared error between the actual and desired response at P points (θ_i, ω_i) , $1 < i < P$. If $P > N$, then we obtain the overdetermined least squares problem

$$\min_{\mathbf{w}} |\mathbf{A}^H \mathbf{w} - \mathbf{r}_d|^2 \quad (61.12)$$

where

$$\mathbf{A} = [\mathbf{d}(\theta_1, \omega_1), \mathbf{d}(\theta_2, \omega_2) \dots \mathbf{d}(\theta_P, \omega_P)] ; \quad (61.13)$$

$$\mathbf{r}_d = [r_d(\theta_1, \omega_1), r_d(\theta_2, \omega_2) \dots r_d(\theta_P, \omega_P)]^H . \quad (61.14)$$

Provided $\mathbf{A} \mathbf{A}^H$ is invertible (i.e., \mathbf{A} is full rank), then the solution to Eq. (61.12) is given as

$$\mathbf{w} = \mathbf{A}^+ \mathbf{r}_d \quad (61.15)$$

where $\mathbf{A}^+ = (\mathbf{A} \mathbf{A}^H)^{-1} \mathbf{A}$ is the pseudo-inverse of \mathbf{A} .

A note of caution is in order at this point. The white noise gain of a beamformer is defined as the output power due to unit variance white noise at the sensors. Thus, the norm squared of the weight

FIGURE 61.5: Beamformers come in both data independent and statistically optimum varieties. In (a) through (e) of this figure we consider an equi-spaced narrowband array of 16 sensors spaced at one-half wavelength. In (a), (b), and (c) the magnitude of the weights, the beam pattern, and the beam pattern, in polar coordinates are shown, respectively, for a Dolph-Chebyshev beamformer with -30 dB sidelobes. In (d) and (e) beam patterns are shown of statistically optimum beamformers which were designed to minimize output power subject to a constraint that the response be unity for an arrival angle of 18° . Energy is assumed to arrive at the array from several interference sources. In (d) several interferers are located between -20° and -23° , each with power of 30 dB relative to the uncorrelated noise power at a single sensor. Deep nulls are formed in the interferer directions. The interferers in (e) are located between 20° and 23° , again with relative power of 30 dB. Again deep nulls are formed at the interferer directions; however, the sidelobe levels are significantly higher at other directions. (f) depicts the broadband LCMV beamformer magnitude response at eight frequencies on the normalized frequency interval $[2\pi/5, 4\pi/5]$ when two interferers arrive from directions -5.75°

FIGURE 61.5: *(continued)* The interferers have a white spectrum on $[2\pi/5, 4\pi/5]$ and have powers of 40 dB and 30 dB relative to the white noise, respectively. The constraints are designed to present a unit gain and linear phase over $[2\pi/5, 4\pi/5]$ at a DOA of 18° . The array is linear equi-spaced with 16 sensors spaced at one-half wavelength for frequency $4\pi/5$ and five tap FIR filters are used in each sensor channel.

TABLE 61.1 Summary of Optimum Beamformers

Type	MSC	Reference signal	Max SNR	LCMV
Definitions	\mathbf{x}_a — auxiliary data \mathbf{y}_m — primary data $\mathbf{r}_{ma} = E\{\mathbf{x}_a \mathbf{y}_m^*\}$ $\mathbf{R}_a = E\{\mathbf{x}_a \mathbf{x}_a^H\}$ output: $\mathbf{y} = \mathbf{y}_m - \mathbf{w}_a^H \mathbf{x}_a$	\mathbf{x} — array data \mathbf{y}_d — desired signal $\mathbf{r}_{xd} = E\{\mathbf{x} \mathbf{y}_d^*\}$ $\mathbf{R}_x = E\{\mathbf{x} \mathbf{x}^H\}$ output: $\mathbf{y} = \mathbf{w}^H \mathbf{x}$	$\mathbf{x} = \mathbf{s} + \mathbf{n}$ — array data \mathbf{s} — signal component \mathbf{n} — noise component $\mathbf{R}_s = E\{\mathbf{s} \mathbf{s}^H\}$ $\mathbf{R}_n = E\{\mathbf{n} \mathbf{n}^H\}$ output: $\mathbf{y} = \mathbf{w}^H \mathbf{x}$	\mathbf{x} — array data \mathbf{C} — constraint matrix \mathbf{f} — response vector $\mathbf{R}_x = E\{\mathbf{x} \mathbf{x}^H\}$ output: $\mathbf{y} = \mathbf{w}^H \mathbf{x}$
Criterion	$\min_{\mathbf{w}_a} E\{ \mathbf{y}_m - \mathbf{w}_a^H \mathbf{x}_a ^2\}$	$\min_{\mathbf{w}} E\{ \mathbf{y} - \mathbf{y}_d ^2\}$	$\max_{\mathbf{w}} \frac{\mathbf{w}^H \mathbf{R}_s \mathbf{w}}{\mathbf{w}^H \mathbf{R}_n \mathbf{w}}$	$\min_{\mathbf{w}} \{\mathbf{w}^H \mathbf{R}_x \mathbf{w}\} \text{ s.t. } \mathbf{C}^H \mathbf{w} = \mathbf{f}$
Optimum weights	$\mathbf{w}_a = \mathbf{R}_a^{-1} \mathbf{r}_{ma}$	$\mathbf{w}_a = \mathbf{R}_x^{-1} \mathbf{r}_{rd}$	$\mathbf{R}_n^{-1} \mathbf{R}_s \mathbf{w} = \lambda_{\max} \mathbf{w}$	$\mathbf{w} = \mathbf{R}_x^{-1} \mathbf{C} [\mathbf{C}^H \mathbf{R}_x^{-1} \mathbf{C}]^{-1} \mathbf{f}$
Advantages	Simple	Direction of desired signal can be unknown	True maximization of SNR	Flexible and general constraints
Disadvantages	Requires absence of desired signal from auxiliary channels for weight determination	Must generate reference signal	Must know \mathbf{R}_s and \mathbf{R}_n Solve generalized eigenproblem for weights	Computation of constrained weight vector

vector, $\mathbf{w}^H \mathbf{w}$, represents the white noise gain. If the white noise gain is large, then the accuracy by which \mathbf{w} approximates the desired response is a moot point because the beamformer output will have a poor SNR due to white noise contributions. If \mathbf{A} is ill-conditioned, then \mathbf{w} can have a very large norm and still approximate the desired response. The matrix \mathbf{A} is ill-conditioned when the effective numerical dimension of the space spanned by the $\mathbf{d}(\theta_i, \omega_i)$, $1 \leq i \leq P$, is less than N . For example, if only one source direction is sampled, then the numerical rank of \mathbf{A} is approximately given by the TBWP for that direction. Low rank approximates of \mathbf{A} and \mathbf{A}^+ should be used whenever the numerical rank is less than N . This ensures that the norm of \mathbf{w} will not be unnecessarily large.

Specific directions and frequencies can be emphasized in Eq. (61.12) by selection of the sample points (θ_i, ω_i) and/or unequally weighting of the error at each (θ_i, ω_i) . Parks and Burrus [8] discuss this in the context of FIR filtering.

61.4 Statistically Optimum Beamforming

In statistically optimum beamforming, the weights are chosen based on the statistics of the data received at the array. Loosely speaking, the goal is to “optimize” the beamformer response so the output contains minimal contributions due to noise and interfering signals. We discuss several different criteria for choosing statistically optimum beamformer weights. Table 61.1 summarizes these different approaches. Where possible, equations describing the criteria and weights are confined to Table 61.1. Throughout the section we assume that the data is wide-sense stationary and that its second order statistics are known. Determination of weights when the data statistics are unknown or time varying is discussed in the following section on adaptive algorithms.

61.4.1 Multiple Sidelobe Canceller

The multiple sidelobe canceller (MSC) is perhaps the earliest statistically optimum beamformer. An MSC consists of a “main channel” and one or more “auxiliary channels” as depicted in Fig. 61.6(a). The main channel can be either a single high gain antenna or a data independent beamformer (see Section 61.3). It has a highly directional response, which is pointed in the desired signal direction. Interfering signals are assumed to enter through the main channel sidelobes. The auxiliary channels also receive the interfering signals. The goal is to choose the auxiliary channel weights to cancel the

main channel interference component. This implies that the responses to interferers of the main channel and linear combination of auxiliary channels must be identical. The overall system then has a response of zero as illustrated in Fig. 61.6(b). In general, requiring zero response to all interfering signals is either not possible or can result in significant white noise gain. Thus, the weights are usually chosen to trade off interference suppression for white noise gain by minimizing the expected value of the total output power as indicated in Table 61.1.

Choosing the weights to minimize output power can cause cancellation of the desired signal because it also contributes to total output power. In fact, as the desired signal gets stronger it contributes to a larger fraction of the total output power and the percentage cancellation increases. Clearly this is an undesirable effect. The MSC is very effective in applications where the desired signal is very weak (relative to the interference), since the optimum weights will not pay any attention to it, or when the desired signal is known to be absent during certain time periods. The weights can then be adapted in the absence of the desired signal and frozen when it is present.

FIGURE 61.6: The multiple sidelobe canceller (MSC) consists of a main channel and several auxiliary channels as illustrated in (a). The auxiliary channel weights are chosen to “cancel” interference entering through sidelobes of the main channel. (b) Depicts the main channel, auxiliary branch, and overall system response when an interferer arrives from direction θ_I .

61.4.2 Use of a Reference Signal

If the desired signal were known, then the weights could be chosen to minimize the error between the beamformer output and the desired signal. Of course, knowledge of the desired signal eliminates the need for beamforming. However, for some applications, enough may be known about the desired signal to generate a signal that closely represents it. This signal is called a reference signal. As indicated in Table 61.1, the weights are chosen to minimize the mean square error between the beamformer output and the reference signal.

The weight vector depends on the cross covariance between the unknown desired signal present in \mathbf{x} and the reference signal. Acceptable performance is obtained provided this approximates the covariance of the unknown desired signal with itself. For example, if the desired signal is amplitude modulated, then acceptable performance is often obtained by setting the reference signal equal to the carrier. It is also assumed that the reference signal is uncorrelated with interfering signals in \mathbf{x} . The fact that the direction of the desired signal does not need to be known is a distinguishing feature of the reference signal approach. For this reason it is sometimes termed “blind” beamforming. Other closely related blind beamforming techniques choose weights by exploiting properties of the desired signal such as constant modulus, cyclostationarity, or third and higher order statistics.

61.4.3 Maximization of Signal-to-Noise Ratio

Here the weights are chosen to directly maximize the signal-to-noise ratio (SNR) as indicated in Table 61.1. A general solution for the weights requires knowledge of both the desired signal, \mathbf{R}_s , and noise, \mathbf{R}_n , covariance matrices. The attainability of this knowledge depends on the application. For example, in an active radar system \mathbf{R}_n can be estimated during the time that no signal is being transmitted and \mathbf{R}_s can be obtained from knowledge of the transmitted pulse and direction of interest. If the signal component is narrowband, of frequency ω , and direction θ , then $\mathbf{R}_s = \sigma^2 \mathbf{d}(\theta, \omega) \mathbf{d}^H(\theta, \omega)$ from the results in Section 61.2. In this case, the weights are obtained as

$$\mathbf{w} = \alpha \mathbf{R}_n^{-1} \mathbf{d}(\theta, \omega) \quad (61.16)$$

where the α is some non-zero complex constant. Substitution of Eq. (61.16) into the SNR expression shows that the SNR is independent of the value chosen for α .

61.4.4 Linearly Constrained Minimum Variance Beamforming

In many applications none of the above approaches is satisfactory. The desired signal may be of unknown strength and may always be present, resulting in signal cancellation with the MSC and preventing estimation of signal and noise covariance matrices in the maximum SNR processor. Lack of knowledge about the desired signal may prevent utilization of the reference signal approach. These limitations can be overcome through the application of linear constraints to the weight vector. Use of linear constraints is a very general approach that permits extensive control over the adapted response of the beamformer. In this section we illustrate how linear constraints can be employed to control beamformer response, discuss the optimum linearly constrained beamforming problem, and present the generalized sidelobe canceller structure.

The basic idea behind linearly constrained minimum variance (LCMV) beamforming is to constrain the response of the beamformer so signals from the direction of interest are passed with specified gain and phase. The weights are chosen to minimize output variance or power subject to the response constraint. This has the effect of preserving the desired signal while minimizing contributions to the output due to interfering signals and noise arriving from directions other than the direction of interest. The analogous FIR filter has the weights chosen to minimize the filter output power subject to the constraint that the filter response to signals of frequency ω_o be unity.

In Section 61.2 we saw that the beamformer response to a source at angle θ and temporal frequency ω is given by $\mathbf{w}^H \mathbf{d}(\theta, \omega)$. Thus, by linearly constraining the weights to satisfy $\mathbf{w}^H \mathbf{d}(\theta, \omega) = g$ where g is a complex constant, we ensure that any signal from angle θ and frequency ω is passed to the output with response g . Minimization of contributions to the output from interference (signals not arriving from θ with frequency ω) is accomplished by choosing the weights to minimize the output power or variance $E\{|y|^2\} = \mathbf{w}^H \mathbf{R}_x \mathbf{w}$. The LCMV problem for choosing the weights is thus written

$$\min_{\mathbf{w}} \quad \mathbf{w}^H \mathbf{R}_x \mathbf{w} \quad \text{subject to} \quad \mathbf{d}^H(\theta, \omega) \mathbf{w} = g^* \quad (61.17)$$

The method of Lagrange multipliers can be used to solve Eq. (61.17) resulting in

$$\mathbf{w} = g^* \frac{\mathbf{R}_x^{-1} \mathbf{d}(\theta, \omega)}{\mathbf{d}^H(\theta, \omega) \mathbf{R}_x^{-1} \mathbf{d}(\theta, \omega)} . \quad (61.18)$$

Note that, in practice, the presence of uncorrelated noise will ensure that \mathbf{R}_x is invertible. If $g = 1$, then Eq. (61.18) is often termed the minimum variance distortionless response (MVDR) beamformer. It can be shown that Eq. (61.18) is equivalent to the maximum SNR solution given in Eq. (61.16) by substituting $\sigma^2 \mathbf{d}(\theta, \omega) \mathbf{d}^H(\theta, \omega) + \mathbf{R}_n$ for \mathbf{R}_x in Eq. (61.18) and applying the matrix inversion lemma.

The single linear constraint in Eq. (61.17) is easily generalized to multiple linear constraints for added control over the beampattern. For example, if there is fixed interference source at a known direction ϕ , then it may be desirable to force zero gain in that direction in addition to maintaining the response g to the desired signal. This is expressed as

$$\begin{bmatrix} \mathbf{d}^H(\theta, \omega) \\ \mathbf{d}^H(\phi, \omega) \end{bmatrix} \mathbf{w} = \begin{bmatrix} g^* \\ 0 \end{bmatrix} . \quad (61.19)$$

If there are $L < N$ linear constraints on \mathbf{w} , we write them in the form $\mathbf{C}^H \mathbf{w} = \mathbf{f}$ where the N by L matrix \mathbf{C} and L dimensional vector \mathbf{f} are termed the constraint matrix and response vector. The constraints are assumed to be linearly independent so \mathbf{C} has rank L . The LCMV problem and solution with this more general constraint equation are given in Table 61.1.

Several different philosophies can be employed for choosing the constraint matrix and response vector. Specifically point, derivative, and eigenvector constraint approaches are popular. Each linear constraint uses one degree of freedom in the weight vector so with L constraints there are only $N - L$ degrees of freedom available for minimizing variance. See Van Veen and Buckley [11] or Van Veen [12] for a more in-depth discussion on this topic.

Generalized Sidelobe Canceller. The generalized sidelobe canceller (GSC) represents an alternative formulation of the LCMV problem, which provides insight, is useful for analysis, and can simplify LCMV beamformer implementation. It also illustrates the relationship between MSC and LCMV beamforming. Essentially, the GSC is a mechanism for changing a constrained minimization problem into unconstrained form.

Suppose we decompose the weight vector \mathbf{w} into two orthogonal components \mathbf{w}_o and $-\mathbf{v}$ (i.e., $\mathbf{w} = \mathbf{w}_o - \mathbf{v}$) that lie in the range and null spaces of \mathbf{C} , respectively. The range and null spaces of a matrix span the entire space so this decomposition can be used to represent any \mathbf{w} . Since $\mathbf{C}^H \mathbf{v} = \mathbf{0}$, we must have

$$\mathbf{w}_o = \mathbf{C}(\mathbf{C}^H \mathbf{C})^{-1} \mathbf{f} \quad (61.20)$$

if \mathbf{w} is to satisfy the constraints. Equation (61.20) is the minimum L_2 norm solution to the underdetermined equivalent of Eq. (61.12). The vector \mathbf{v} is a linear combination of the columns of an N by M ($M = N - L$) matrix \mathbf{C}_n (i.e., $\mathbf{v} = \mathbf{C}_n \mathbf{w}_M$) provided the columns of \mathbf{C}_n form a basis for the null space of \mathbf{C} . \mathbf{C}_n can be obtained from \mathbf{C} using any of several orthogonalization procedures such as Gram-Schmidt, QR decomposition, or singular value decomposition. The weight vector $\mathbf{w} = \mathbf{w}_o - \mathbf{C}_n \mathbf{w}_M$ is depicted in block diagram form in Fig. 61.7. The choice for \mathbf{w}_o and \mathbf{C}_n implies that \mathbf{w} satisfies the constraints independent of \mathbf{w}_M and reduces the LCMV problem to the unconstrained problem

$$\min_{\mathbf{w}_M} [\mathbf{w}_o - \mathbf{C}_n \mathbf{w}_M]^H \mathbf{R}_x [\mathbf{w}_o - \mathbf{C}_n \mathbf{w}_M] . \quad (61.21)$$

The solution is

$$\mathbf{w}_M = (\mathbf{C}_n^H \mathbf{R}_x \mathbf{C}_n)^{-1} \mathbf{C}_n^H \mathbf{R}_x \mathbf{w}_o . \quad (61.22)$$

The primary implementation advantages of this alternate but equivalent formulation stem from the facts that the weights \mathbf{w}_M are unconstrained and a data independent beamformer \mathbf{w}_o is implemented as an integral part of the optimum beamformer. The unconstrained nature of the adaptive weights permits much simpler adaptive algorithms to be employed and the data independent beamformer is useful in situations where adaptive signal cancellation occurs (see Section 61.4.5).

FIGURE 61.7: The generalized sidelobe canceller (GSC) represents an implementation of the LCMV beamformer in which the adaptive weights are unconstrained. It consists of a preprocessor composed of a fixed beamformer \mathbf{w}_o and a blocking matrix \mathbf{C}_n , and a standard adaptive filter with unconstrained weight vector \mathbf{w}_M .

As an example, assume the constraints are as given in Eq. (61.17). Equation (61.20) implies $\mathbf{w}_o = g^* \mathbf{d}(\theta, \omega) / [\mathbf{d}^H(\theta, \omega) \mathbf{d}(\theta, \omega)]$. \mathbf{C}_n satisfies $\mathbf{d}^H(\theta, \omega) \mathbf{C}_n = \mathbf{0}$ so each column $[\mathbf{C}_n]_i$; $1 < i < N - L$, can be viewed as a data independent beamformer with a null in direction θ at frequency ω : $\mathbf{d}^H(\theta, \omega) [\mathbf{C}_n]_j = 0$. Thus, a signal of frequency ω and direction θ arriving at the array will be blocked or nulled by the matrix \mathbf{C}_n . In general, if the constraints are designed to present a specified response to signals from a set of directions and frequencies, then the columns of \mathbf{C}_n will block those directions and frequencies. This characteristic has led to the term “blocking matrix” for describing \mathbf{C}_n . These signals are only processed by \mathbf{w}_o and since \mathbf{w}_o satisfies the constraints, they are presented with the desired response independent of \mathbf{w}_M . Signals from directions and frequencies over which the response is not constrained will pass through the upper branch in Fig. 61.7 with some response determined by \mathbf{w}_o . The lower branch chooses \mathbf{w}_M to estimate the signals at the output of \mathbf{w}_o as a linear combination of the data at the output of the blocking matrix. This is similar to the operation of the MSC, in which weights are applied to the output of auxiliary sensors in order to estimate the primary channel output (see Fig. 61.6).

61.4.5 Signal Cancellation in Statistically Optimum Beamforming

Optimum beamforming requires some knowledge of the desired signal characteristics, either its statistics (for maximum SNR or reference signal methods), its direction (for the MSC), or its response vector $\mathbf{d}(\theta, \omega)$ (for the LCMV beamformer). If the required knowledge is inaccurate, the optimum beamformer will attenuate the desired signal as if it were interference. Cancellation of the desired signal is often significant, especially if the SNR of the desired signal is large. Several approaches have been suggested to reduce this degradation (e.g., Cox et al. [3]).

A second cause of signal cancellation is correlation between the desired signal and one or more interference signals. This can result either from multipath propagation of a desired signal or from smart (correlated) jamming. When interference and desired signals are uncorrelated, the beamformer attenuates interferers to minimize output power. However, with a correlated interferer the beamformer minimizes output power by processing the interfering signal in such a way as to cancel

the desired signal. If the interferer is partially correlated with the desired signal, then the beamformer will cancel the portion of the desired signal that is correlated with the interferer. Methods for reducing signal cancellation due to correlated interference have been suggested (e.g., Widrow et al. [13], Shan and Kailath [10]).

61.5 Adaptive Algorithms for Beamforming

The optimum beamformer weight vector equations listed in Table 61.1 require knowledge of second order statistics. These statistics are usually not known, but with the assumption of ergodicity, they (and therefore the optimum weights) can be estimated from available data. Statistics may also change over time, e.g., due to moving interferers. To solve these problems, weights are typically determined by adaptive algorithms.

There are two basic adaptive approaches: (1) block adaptation, where statistics are estimated from a temporal block of array data and used in an optimum weight equation; and (2) continuous adaptation, where the weights are adjusted as the data is sampled such that the resulting weight vector sequence converges to the optimum solution. If a nonstationary environment is anticipated, block adaptation can be used, provided that the weights are recomputed periodically. Continuous adaptation is usually preferred when statistics are time-varying or, for computational reasons, when the number of adaptive weights M is moderate to large; values of $M > 50$ are common.

Among notable adaptive algorithms proposed for beamforming are the Howells-Applebaum adaptive loop developed in the late 1950s and reported by Howells [7] and Applebaum [1], and the Frost LCMV algorithm [4]. Rather than recapitulating adaptive algorithms for each optimum beamformer listed in Table 61.1, we take a unifying approach using the standard adaptive filter configuration illustrated on the right side of Fig. 61.7.

In Fig. 61.7 the weight vector \mathbf{w}_M is chosen to estimate the desired signal y_d as linear combination of the elements of the data vector \mathbf{u} . We select \mathbf{w}_M to minimize the MSE

$$J(\mathbf{w}_M) = E\{|y_d - \mathbf{w}_M^H \mathbf{u}|^2\} = \sigma_d^2 - \mathbf{w}_M^H \mathbf{r}_{ud} - \mathbf{r}_{ud}^H \mathbf{w}_M + \mathbf{w}_M^H \mathbf{R}_u \mathbf{w}_M, \quad (61.23)$$

where $\sigma_d^2 = E\{|y_d|^2\}$, $\mathbf{r}_{ud} = E\{\mathbf{u} y_d^*\}$ and $\mathbf{R}_u = E\{\mathbf{u} \mathbf{u}^H\}$. $J(\mathbf{w}_M)$ is minimized by

$$\mathbf{w}_{opt} = \mathbf{R}_u^{-1} \mathbf{r}_{ud}. \quad (61.24)$$

Comparison of (61.23) and the criteria listed in Table 61.1 indicates that this standard adaptive filter problem is equivalent to both the MSC beamformer problem (with $y_d = y_m$ and $\mathbf{u} = \mathbf{x}_a$) and the reference signal beamformer problem (with $\mathbf{u} = \mathbf{x}$). The LCMV problem is apparently different. However closer examination of Fig. 61.7 and Eqs. (61.22), and (61.24) reveals that the standard adaptive filter problem is equivalent to the LCMV problem implemented with the GSC structure. Setting $\mathbf{u} = \mathbf{C}_n^H \mathbf{x}$ and $y_d = \mathbf{w}_o^H \mathbf{x}$ implies $\mathbf{R}_u = \mathbf{C}_n^H \mathbf{R}_x \mathbf{C}_n$ and $\mathbf{r}_{ud} = \mathbf{C}_n^H \mathbf{R}_x \mathbf{w}_o$. The maximum SNR beamformer cannot in general be represented by Fig. 61.7 and Eq. (61.24). However, it was noted after (61.18) that if the desired signal is narrowband, then the maximum SNR and the LCMV beamformers are equivalent.

The block adaptation approach solves (61.24) using estimates of \mathbf{R}_u and \mathbf{r}_{ud} formed from K samples of \mathbf{u} and y_d : $\mathbf{u}(k)$, $y_d(k)$; $0 < k < K - 1$. The most common are the sample covariance matrix

$$\hat{\mathbf{R}}_u = \frac{1}{K} \sum_{k=0}^{K-1} \mathbf{u}(k) \mathbf{u}^H(k) \quad (61.25)$$

and sample cross-covariance vector

$$\hat{\mathbf{r}}_{ud} = \frac{1}{K} \sum_{k=0}^{K-1} \mathbf{u}(k) y_d^*(k). \quad (61.26)$$

TABLE 61.2 Comparison of the LMS and RLS Weight Adaptation Algorithms

Algorithm	LMS	RLS
Initialization	$\mathbf{w}_M(0) = 0$ $\mathbf{y}(0) = \mathbf{y}_d(0)$ $0 < \mu < \frac{1}{\text{Trace}[\mathbf{R}_u]}$	$\mathbf{w}_M(0) = 0$ $\mathbf{P}(0) = \delta^{-1} \mathbf{I}$ δ small, \mathbf{I} identity matrix
Update	$\mathbf{w}_M(k) = \mathbf{w}_M(k-1) + \mu \mathbf{u}(k-1) y^*(k-1)$	$\mathbf{v}(k) = \mathbf{P}(k-1) \mathbf{u}(k)$
Equations	$y(k) = y_d(k) - \mathbf{w}_M^H(k) \mathbf{u}(k)$	$\mathbf{k}(k) = \frac{\lambda^{-1} \mathbf{v}(k)}{1 + \lambda^{-1} \mathbf{u}^H(k) \mathbf{v}(k)}$ $\alpha(k) = y_d(k) - \mathbf{w}_M^H(k) \mathbf{u}(k)$ $\mathbf{w}_M(k) = \mathbf{w}_M(k-1) + \mathbf{k}(k) \alpha^*(k)$ $\mathbf{P}(k) = \lambda^{-1} \mathbf{P}(k-1) - \lambda^{-1} \mathbf{k}(k) \mathbf{v}^H(k)$
Multiplies per up-date	$2M$	$4M^2 + 4M + 2$
Performance Characteristics	Under certain conditions, convergence of $\mathbf{w}_M(k)$ to the statistically optimum weight vector \mathbf{w}_{opt} in the mean-square sense is guaranteed if μ is chosen as indicated above. The convergence rate is governed by the eigenvalue spread of \mathbf{R}_u . For large eigenvalue spread, convergence can be very slow.	The $\mathbf{w}_M(k)$ represents the least squares solution at each instant k and are optimum in a deterministic sense. Convergence to the statistically optimum weight vector \mathbf{w}_{opt} is often faster than that obtained using the LMS algorithm because it is independent of the eigenvalue spread of \mathbf{R}_u .

Performance analysis and guidelines for selecting the block size K are provided in Reed et al. [9].

Continuous adaptation algorithms are easily developed in terms of Fig. 61.7 and Eq. (61.23). Note that $J(\mathbf{w}_M)$ is a quadratic error surface. Since the quadratic surface's "Hessian" \mathbf{R}_u is the covariance matrix of noisy data, it is positive definite. This implies that the error surface is a "bowl". The shape of the bowl is determined by the eigenstructure of \mathbf{R}_u . The optimum weight vector \mathbf{w}_{opt} corresponds to the bottom of the bowl.

One approach to adaptive filtering is to envision a point on the error surface that corresponds to the present weight vector $\mathbf{w}_M(k)$. We select a new weight vector $\mathbf{w}_M(k+1)$ so as to descend on the error surface. The gradient vector

$$\nabla_{\mathbf{w}_M(k)} = \left. \frac{\partial}{\partial \mathbf{w}_M} J(\mathbf{w}_M) \right|_{\mathbf{w}_M = \mathbf{w}_M(k)} = -2\mathbf{r}_{ud} + 2\mathbf{R}_u \mathbf{w}_M(k) \quad (61.27)$$

tells us the direction in which to adjust the weight vector. Steepest descent, i.e., adjustment in the negative gradient direction, leads to the popular least mean-square (LMS) adaptive algorithm. The LMS algorithm replaces $\nabla_{\mathbf{w}_M(k)}$ with the instantaneous gradient estimate $\hat{\nabla}_{\mathbf{w}_M(k)} = -2[\mathbf{u}(k)y_d^*(k) - \mathbf{u}(k)\mathbf{u}^H(k)\mathbf{w}_M(k)]$. Denoting $y(k) = y_d(k) - \mathbf{w}_M^H(k)\mathbf{u}(k)$, we have

$$\mathbf{w}_M(k+1) = \mathbf{w}_M(k) + \mu \mathbf{u}(k) y^*(k). \quad (61.28)$$

The gain constant μ controls convergence characteristics of the random vector sequence $\mathbf{w}_M(k)$. Table 61.2 provides guidelines for its selection.

The primary virtue of the LMS algorithm is its simplicity. Its performance is acceptable in many applications; however, its convergence characteristics depend on the shape of the error surface and therefore the eigenstructure of \mathbf{R}_u . When the eigenvalues are widely spread, convergence can be slow and other adaptive algorithms with better convergence characteristics should be considered. Alternative procedures for searching the error surface have been proposed in addition to algorithms based on least squares and Kalman filtering. Roughly speaking, these algorithms trade-off computational requirements with speed of convergence to \mathbf{w}_{opt} . We refer you to texts on adaptive filtering for detailed descriptions and analysis (Widrow and Stearns [14], Haykin [6], and others).

One alternative to LMS is the exponentially weighted recursive least squares (RLS) algorithm. At

the K th time step, $\mathbf{w}_M(K)$ is chosen to minimize a weighted sum of past squared errors

$$\min_{\mathbf{w}_M(K)} \sum_{k=0}^K \lambda^{K-k} |y_d(k) - \mathbf{w}_M^H(K) \mathbf{u}(k)|^2 . \quad (61.29)$$

λ is a positive constant less than one which determines how quickly previous data are deemphasized. The RLS algorithm is obtained from (61.29) by expanding the magnitude squared and applying the matrix inversion lemma. Table 61.2 summarizes both the LMS and RLS algorithms.

61.6 Interference Cancellation and Partially Adaptive Beamforming

The computational requirements of each update in adaptive algorithms are proportional to either the weight vector dimension M (e.g., LMS) or dimension squared M^2 (e.g., RLS). If M is large, this requirement is quite severe and for practical real time implementation it is often necessary to reduce M . Furthermore, the rate at which an adaptive algorithm converges to the optimum solution may be very slow for large M . Adaptive algorithm convergence properties can be improved by reducing M .

The concept of “degrees of freedom” is much more relevant to this discussion than the number of weights. The expression degrees of freedom refers to the number of unconstrained or “free” weights in an implementation. For example, an LCMV beamformer with L constraints on N weights has $N - L$ degrees of freedom; the GSC implementation separates these as the unconstrained weight vector \mathbf{w}_M . There are M degrees of freedom in the structure of Fig. 61.7. A fully adaptive beamformer uses all available degrees of freedom and a partially adaptive beamformer uses a reduced set of degrees of freedom. Reducing degrees of freedom lowers computational requirements and often improves adaptive response time. However, there is a performance penalty associated with reducing degrees of freedom. A partially adaptive beamformer cannot generally converge to the same optimum solution as the fully adaptive beamformer. The goal of partially adaptive beamformer design is to reduce degrees of freedom without significant degradation in performance.

The discussion in this section is general, applying to different types of beamformers although we borrow much of the notation from the GSC. We assume the beamformer is described by the adaptive structure of Fig. 61.7 where the desired signal y_d is obtained as $y_d = \mathbf{w}_o^H \mathbf{x}$ and the data vector \mathbf{u} as $\mathbf{u} = \mathbf{T}^H \mathbf{x}$. Thus, the beamformer output is $y = \mathbf{w}^H \mathbf{x}$ where $\mathbf{w} = \mathbf{w}_o - \mathbf{T} \mathbf{w}_M$. In order to distinguish between fully and partially adaptive implementations, we decompose \mathbf{T} into a product of two matrices $\mathbf{C}_n \mathbf{T}_M$. The definition of \mathbf{C}_n depends on the particular beamformer and \mathbf{T}_M represents the mapping which reduces degrees of freedom. The MSC and GSC are obtained as special cases of this representation. In the MSC \mathbf{w}_o is an N vector that selects the primary sensor, \mathbf{C}_n is an N by $N - 1$ matrix that selects the $N - 1$ possible auxiliary sensors from the complete set of N sensors, and \mathbf{T}_M is an $N - 1$ by M matrix that selects the M auxiliary sensors actually utilized. In terms of the GSC, \mathbf{w}_o and \mathbf{C}_n are defined as in Section 61.4.4 and \mathbf{T}_M is an $N - L$ by M matrix that reduces degrees of freedom ($M < N - L$).

The goal of partially adaptive beamformer design is to choose \mathbf{T}_M (or \mathbf{T}) such that good interference cancellation properties are retained even though M is small. To see that this is possible in principle, consider the problem of simultaneously cancelling two narrowband sources from direction θ_1 and θ_2 at frequency ω_o . Perfect cancellation of these sources requires $\mathbf{w}^H \mathbf{d}(\theta_1, \omega_o) = 0$ and $\mathbf{w}^H \mathbf{d}(\theta_2, \omega_o) = 0$ so we must choose \mathbf{w}_M to satisfy

$$\mathbf{w}_M^H [\mathbf{T}^H \mathbf{d}(\theta_1, \omega_o) \quad \mathbf{T}^H \mathbf{d}(\theta_2, \omega_o)] = [g_1, g_2] \quad (61.30)$$

where $g_i = \mathbf{w}_o^H \mathbf{d}(\theta_i, \omega_o)$ is the response of the \mathbf{w}_o branch to the i th interferer. Assuming $\mathbf{T}^H \mathbf{d}(\theta_1, \omega_o)$ and $\mathbf{T}^H \mathbf{d}(\theta_2, \omega_o)$ are linearly independent and nonzero, and provided $M \geq 2$, then at least one \mathbf{w}_M exists that satisfies (61.30). Extending this reasoning, we see that \mathbf{w}_M can be chosen to cancel M narrowband interferers (assuming the $\mathbf{T}^H \mathbf{d}(\theta_i, \omega_o)$ are linearly independent and nonzero), independent of \mathbf{T} . Total cancellation occurs if \mathbf{w}_M is chosen so the response of $\mathbf{T} \mathbf{w}_M$ perfectly matches the \mathbf{w}_o branch response to the interferers. In general, M narrowband interferers can be cancelled using M adaptive degrees of freedom with relatively mild restrictions on \mathbf{T} .

No such rule exists in the broadband case. Here complete cancellation of a single interferer requires choosing $\mathbf{T} \mathbf{w}_M$ so that the response of the adaptive branch, $\mathbf{w}_M^H \mathbf{T}^H \mathbf{d}(\theta_1, \omega)$, matches the response of the \mathbf{w}_o branch, $\mathbf{w}_o^H \mathbf{d}(\theta_1, \omega)$, over the entire frequency band of the interferer. In this case, the degree of cancellation depends on how well these two responses match and is critically dependent on the interferer direction, frequency content, and \mathbf{T} . Good cancellation can be obtained in some situations when $M = 1$, while in others even large values of M result in poor cancellation.

A variety of intuitive and optimization-based techniques have been proposed for designing \mathbf{T}_M that achieve good interference cancellation with relatively small degrees of freedom. See Van Veen and Buckley [11] and Van Veen [12] for further review and discussion.

61.7 Summary

A beamformer forms a scalar output signal as a weighted combination of the data received at an array of sensors. The weights determine the spatial filtering characteristics of the beamformer and enable separation of signals having overlapping frequency content if they originate from different locations. The weights in a data independent beamformer are chosen to provide a fixed response independent to the received data. Statistically optimum beamformers select the weights to optimize the beamformer response based on the statistics of the data. The data statistics are often unknown and may change with time so adaptive algorithms are used to obtain weights that converge to the statistically optimum solution. Computational and response time considerations dictate the use of partially adaptive beamformers with arrays composed of large numbers of sensors.

61.8 Defining Terms

Beamformer: A device used in conjunction with an array of sensors to separate signals and interference on the basis of their spatial characteristics. The beamformer output is usually given by a weighted combination of the sensor outputs.

Array response vector: Vector describing the amplitude and phase relationships between propagating wave components at each sensor as a function of spatial direction and temporal frequency. Forms the basis for determining the beamformer response.

Beampattern: The magnitude squared of the beamformer's spatial filtering response as a function of spatial direction and possibly temporal frequency.

Data independent, statistically optimum, adaptive, and partially adaptive beamformers: The weights in a data independent beamformer are chosen independent of the statistics of the data. A statistically optimum beamformer chooses its weights to optimize some statistical function of the beamformer output, such as signal-to-noise ratio. An adaptive beamformer adjusts its weights in response to the data to accommodate unknown or time varying statistics. A partially adaptive beamformer uses only a subset of the available adaptive degrees of freedom to reduce the computational burden or improve the adaptive convergence rate.

Multiple sidelobe canceller: Adaptive beamformer structure in which the data received at low

gain auxiliary sensors is used to adaptively cancel the interference arriving in the mainlobe or sidelobes of a spatially high gain sensor.

Linearly constrained minimum variance (LCMV) beamformer: Beamformer in which the weights are chosen to minimize the output power subject to a linear response constraint. The constraint preserves the signal of interest while power minimization optimally attenuates noise and interference.

Minimum variance distortionless response (MVDR) beamformer: A form of LCMV beamformer employing a single constraint designed to pass a signal of given direction and frequency with unit gain.

Generalized sidelobe canceller: Structure for implementing LCMV beamformers that separates the constrained and unconstrained components of the adaptive weight vector. The unconstrained components adaptively cancel interference that leaks through the sidelobes of a data independent beamformer designed to satisfy the constraints.

62.1 Introduction

Estimating bearings of multiple narrowband signals from measurements collected by an array of sensors has been a very active research problem for the last two decades. Typical applications of this problem are radar, communication, and underwater acoustics. Many algorithms have been proposed to solve the bearing estimation problem. One of the first techniques that appeared was beamforming which has a resolution limited by the array structure. Spectral estimation techniques were also applied to the problem. However, these techniques fail to resolve closely spaced arrival angles for low signal-to-noise ratios. Another approach is the maximum-likelihood (ML) solution. This approach has been well documented in the literature. In the stochastic ML method [29], the signals are assumed to be Gaussian whereas they are regarded as arbitrary and deterministic in the deterministic ML method [37]. The sensor noise is modeled as Gaussian in both methods, which is a reasonable assumption due to the central limit theorem. The stochastic ML estimates of the bearings achieve the Cramer-Rao bound (CRB). On the other hand, this does not hold for deterministic ML estimates [32]. The common problem with the ML methods in general is the necessity of solving a nonlinear multidimensional optimization problem which has a high computational cost and for which there is no guarantee of global convergence. *Subspace-based* (or, super-resolution) approaches have attracted much attention, after the work of [29], due to their computational simplicity as compared to the ML approach, and their possibility of overcoming the Rayleigh bound on the resolution power of classical direction finding methods. Subspace-based direction finding methods are summarized in this section.

62.2 Formulation of the Problem

Consider an array of M antenna elements receiving a set of plane waves emitted by P ($P < M$) sources in the far field of the array. We assume a narrow-band propagation model, i.e., the signal envelopes do not change during the time it takes for the wavefronts to travel from one sensor to another. Suppose that the signals have a common frequency of f_0 ; then, the wavelength $\lambda = c/f_0$ where c is the speed of propagation. The received M -vector $\mathbf{r}(t)$ at time t is

$$\mathbf{r}(t) = \mathbf{A}\mathbf{s}(t) + \mathbf{n}(t) \quad (62.1)$$

where $\mathbf{s}(t) = [s_1(t), \dots, s_P(t)]^T$ is the P -vector of sources; $\mathbf{A} = [\mathbf{a}(\theta_1), \dots, \mathbf{a}(\theta_P)]$ is the $M \times P$ steering matrix in which $\mathbf{a}(\theta_i)$, the i th steering vector, is the response of the array to the i th source arriving from θ_i ; and, $\mathbf{n}(t) = [n_1(t), \dots, n_M(t)]^T$ is an additive noise process.

We assume: (1) the source signals may be statistically independent, partially correlated, or completely correlated (i.e., coherent); the distributions are unknown; (2) the array may have an arbitrary shape and response; and, (3) the noise process is independent of the sources, zero-mean, and it may be either partially white or colored; its distribution is unknown. These assumptions will be relaxed, as required by specific methods, as we proceed.

The direction finding problem is to estimate the bearings [i.e., directions of arrival (DOA)] $\{\theta_i\}_{i=1}^P$ of the sources from the snapshots $\mathbf{r}(t)$, $t = 1, \dots, N$.

In applications, the Rayleigh criterion sets a bound on the resolution power of classical direction finding methods. In the next sections we summarize some of the so-called super-resolution direction finding methods which may overcome the Rayleigh bound. We divide these methods into two classes, those that use second-order and those that use second- and higher-order statistics.

62.3 Second-Order Statistics-Based Methods

The second-order methods use the sample estimate of the array spatial covariance matrix $\hat{\mathbf{R}} = E\{\mathbf{r}(t)\mathbf{r}(t)^H\} = \mathbf{A}\mathbf{R}_s\mathbf{A}^H + \mathbf{R}_n$, where $\mathbf{R}_s = E\{\mathbf{s}(t)\mathbf{s}(t)^H\}$ is the $P \times P$ signal covariance matrix and $\mathbf{R}_n = E\{\mathbf{n}(t)\mathbf{n}(t)^H\}$ is the $M \times M$ noise covariance matrix. For the time being, let us assume that the noise is spatially white, i.e., $\mathbf{R}_n = \sigma^2\mathbf{I}$. If the noise is colored and its covariance matrix is known or can be estimated, the measurements can be “whitened” by multiplying the measurements from the left by the matrix $\Lambda^{-1/2}\mathbf{E}_n^H$ obtained by the orthogonal eigendecomposition $\mathbf{R}_n = \mathbf{E}_n\Lambda\mathbf{E}_n^H$. The array spatial covariance matrix is estimated as $\hat{\mathbf{R}} = \sum_{t=1}^N \mathbf{r}(t)\mathbf{r}(t)^H / N$.

Some spectral estimation approaches to the direction finding problem are based on optimization. Consider the *minimum variance* algorithm, for example. The received signal is processed by a beamforming vector \mathbf{w}_θ which is designed such that the output power is minimized subject to the constraint that a signal from a desired direction is passed to the output with unit gain. Solving this optimization problem, we obtain the array output power as a function of the arrival angle θ as

$$P_{mv}(\theta) = \frac{1}{\mathbf{a}^H(\theta)\mathbf{R}^{-1}\mathbf{a}(\theta)}.$$

The arrival angles are obtained by scanning the range $[-90^\circ, 90^\circ]$ of θ and locating the peaks of $P_{mv}(\theta)$. At low signal-to-noise ratios the conventional methods, such as minimum variance, fail to resolve closely spaced arrival angles. The resolution of conventional methods are limited by signal-to-noise ratio even if exact \mathbf{R} is used, whereas in subspace methods, there is no resolution limit; hence, the latter are also referred to as *super-resolution* methods. The limit comes from the sample estimate of \mathbf{R} .

The subspace-based methods exploit the eigendecomposition of the estimated array covariance matrix $\hat{\mathbf{R}}$. To see the implications of the eigendecomposition of $\hat{\mathbf{R}}$, let us first state the properties

of \mathbf{R} : (1) If the source signals are independent or partially correlated, $\text{rank}(\mathbf{R}_s) = P$. If there are coherent sources, $\text{rank}(\mathbf{R}_s) < P$. In the methods explained in Sections 62.3.1 and 62.3.2, except for the WSF method (see Search-Based Methods), it will be assumed that there are no coherent sources. The coherent signals case is described in Section 62.3.3. (2) If the columns of \mathbf{A} are independent, which is generally true when the source bearings are different, then \mathbf{A} is of full-rank P . (3) Properties 1 and 2 imply $\text{rank}(\mathbf{A}\mathbf{R}_s\mathbf{A}^H) = P$; therefore, $\mathbf{A}\mathbf{R}_s\mathbf{A}^H$ must have P nonzero eigenvalues and $M - P$ zero eigenvalues. Let the eigendecomposition of $\mathbf{A}\mathbf{R}_s\mathbf{A}^H$ be $\mathbf{A}\mathbf{R}_s\mathbf{A}^H = \sum_{i=1}^M \alpha_i \mathbf{e}_i \mathbf{e}_i^H$; then $\alpha_1 \geq \alpha_2 \geq \dots \geq \alpha_P \geq \alpha_{P+1} = \dots = \alpha_M = 0$ are the rank-ordered eigenvalues, and $\{\mathbf{e}_i\}_{i=1}^M$ are the corresponding eigenvectors. (4) Because $\mathbf{R}_n = \sigma^2 \mathbf{I}$, the eigenvectors of \mathbf{R} are the same as those of $\mathbf{A}\mathbf{R}_s\mathbf{A}^H$, and its eigenvalues are $\lambda_i = \alpha_i + \sigma^2$, if $1 \leq i \leq P$, or $\lambda_i = \sigma^2$, if $P + 1 \leq i \leq M$. The eigenvectors can be partitioned into two sets: $\mathbf{E}_s \triangleq [\mathbf{e}_1, \dots, \mathbf{e}_P]$ forms the *signal subspace*, whereas $\mathbf{E}_n \triangleq [\mathbf{e}_{P+1}, \dots, \mathbf{e}_M]$ forms the *noise subspace*. These subspaces are orthogonal. The signal eigenvalues $\Lambda_s \triangleq \text{diag}\{\lambda_1, \dots, \lambda_P\}$, and the noise eigenvalues $\Lambda_n \triangleq \text{diag}\{\lambda_{P+1}, \dots, \lambda_M\}$. (5) The eigenvectors corresponding to zero eigenvalues satisfy $\mathbf{A}\mathbf{R}_s\mathbf{A}^H \mathbf{e}_i = \mathbf{0}$, $i = P + 1, \dots, M$; hence, $\mathbf{A}^H \mathbf{e}_i = \mathbf{0}$, $i = P + 1, \dots, M$, because \mathbf{A} and \mathbf{R}_s are full rank. This last equation means that *steering vectors are orthogonal to noise subspace eigenvectors*. It further implies that because of the orthogonality of signal and noise subspaces, *spans of signal eigenvectors and steering vectors are equal*. Consequently there exists a nonsingular $P \times P$ matrix \mathbf{T} such that $\mathbf{E}_s = \mathbf{A}\mathbf{T}$.

Alternatively, the signal and noise subspaces can also be obtained by performing a singular value decomposition directly on the received data without having to calculate the array covariance matrix. Li and Vaccaro [17] state that the properties of the bearing estimates do not depend on which method is used; however, singular value decomposition must then deal with a data matrix that increases in size as the new snapshots are received. In the sequel, we assume that the array covariance matrix is estimated from the data and an eigendecomposition is performed on the estimated covariance matrix.

The eigenvalue decomposition of the spatial array covariance matrix, and the eigenvector partitionment into signal and noise subspaces, leads to a number of subspace-based direction finding methods. The signal subspace contains information about where the signals are whereas the noise subspace informs us where they are not. Use of either subspace results in better resolution performance than conventional methods. In practice, the performance of the subspace-based methods is limited fundamentally by the accuracy of separating the two subspaces when the measurements are noisy [18]. These methods can be broadly classified into signal subspace and noise subspace methods. A summary of direction-finding methods based on both approaches follows next.

62.3.1 Signal Subspace Methods

In these methods, only the signal subspace information is retained. Their rationale is that by discarding the noise subspace we effectively enhance the SNR because the contribution of the noise power to the covariance matrix is eliminated. Signal subspace methods are divided into search-based and algebraic methods, which are explained next.

Search-Based Methods

In search-based methods, it is assumed that the response of the array to a single source, the *array manifold* $\mathbf{a}(\theta)$, is either known analytically as a function of arrival angle, or is obtained through the calibration of the array. For example, for an M -element uniform linear array, the array response to a signal from angle θ is analytically known and is given by

$$\mathbf{a}(\theta) = \left[1, e^{-j2\pi \frac{d}{\lambda} \sin(\theta)}, \dots, e^{-j2\pi (M-1) \frac{d}{\lambda} \sin(\theta)} \right]^T$$

where d is the separation between the elements, and λ is the wavelength.

In search-based methods to follow (except for the subspace fitting methods), which are spatial versions of widely known power spectral density estimators, the estimated array covariance matrix is approximated by its signal subspace eigenvectors, or its *principal components*, as $\hat{\mathbf{R}} \approx \sum_{i=1}^P \lambda_i \mathbf{e}_i \mathbf{e}_i^H$. Then the arrival angles are estimated by locating the peaks of a function, $S(\theta)$ ($-90^\circ \leq \theta \leq 90^\circ$), which depends on the particular method. Some of these methods and the associated function $S(\theta)$ are summarized in the following [13, 18, 20]:

Correlogram method: In this method, $S(\theta) = \mathbf{a}(\theta)^H \hat{\mathbf{R}} \mathbf{a}(\theta)$. The resolution obtained from the Correlogram method is lower than that obtained from the MV and AR methods.

Minimum variance (MV) [1] method: In this method, $S(\theta) = 1/\mathbf{a}(\theta)^H \hat{\mathbf{R}}^{-1} \mathbf{a}(\theta)$. The MV method is known to have a higher resolution than the correlogram method, but lower resolution and variance than the AR method.

Autoregressive (AR) method: In this method, $S(\theta) = 1/|\mathbf{u}^T \hat{\mathbf{R}}^{-1} \mathbf{a}(\theta)|^2$ where $\mathbf{u} = [1, 0, \dots, 0]^T$. This method is known to have a better resolution than the previous ones.

Subspace fitting (SSF) and weighted subspace fitting (WSF) methods: In Section 62.2 we saw that the spans of signal eigenvectors and steering vectors are equal; therefore, bearings can be solved from the best least-squares fit of the two spanning sets when the array is calibrated [35]. In the Subspace Fitting Method the criterion $[\hat{\theta}, \hat{\mathbf{T}}] = \argmin ||\mathbf{E}_s \mathbf{W}^{1/2} - \mathbf{A}(\theta) \mathbf{T}||^2$ is used, where $||\cdot||$ denotes the Frobenius norm, \mathbf{W} is a positive definite weighting matrix, \mathbf{E}_s is the matrix of signal subspace eigenvectors, and the notation for the steering matrix is changed to show its dependence on the bearing vector θ . This criterion can be minimized directly with respect to \mathbf{T} , and the result for \mathbf{T} can then be substituted back into it, so that

$$\hat{\theta} = \argmin Tr\{(\mathbf{I} - \mathbf{A}(\theta)\mathbf{A}(\theta)^\#)\mathbf{E}_s \mathbf{W} \mathbf{E}_s^H\},$$

where $\mathbf{A}^\# = (\mathbf{A}^H \mathbf{A})^{-1} \mathbf{A}^H$.

Viberg and Ottersten have shown that a class of direction finding algorithms can be approximated by this subspace fitting formulation for appropriate choices of the weighting matrix \mathbf{W} . For example, for the deterministic ML method $\mathbf{W} = \Lambda_s - \sigma^2 \mathbf{I}$, which is implemented using the empirical values of the signal eigenvalues, Λ_s , and the noise eigenvalue σ^2 . TLS-ESPRIT, which is explained in the next section, can also be formulated in a similar but more involved way. Viberg and Ottersten have also derived an optimal Weighted Subspace Fitting (WSF) Method, which yields the smallest estimation error variance among the class of subspace fitting methods. In WSF, $\mathbf{W} = (\Lambda_s - \sigma^2 \mathbf{I})^2 \Lambda_s^{-1}$. The WSF method works regardless of the source covariance (including coherence) and has been shown to have the same asymptotic properties as the stochastic ML method; hence, it is asymptotically efficient for Gaussian signals (i.e., it achieves the stochastic CRB). Its behavior in the finite sample case may be different from the asymptotic case [34]. Viberg and Ottersten have also shown that the asymptotic properties of the WSF estimates are identical for both cases of Gaussian and non-Gaussian sources. They have also developed a consistent detection method for arbitrary signal correlation, and an algorithm for minimizing the WSF criterion. They do point out several practical implementation problems of their method, such as the need for accurate calibrations of the array manifold and knowledge of the derivative of the steering vectors w.r.t θ . For nonlinear and nonuniform arrays, multidimensional search methods are required for SSF, hence it is computationally expensive.

Algebraic Methods

Algebraic methods do not require a search procedure and yield DOA estimates directly.

ESPRIT (Estimation of Signal Parameters via Rotational Invariance Techniques) [23]: The ESPRIT algorithm requires “translationally invariant” arrays, i.e., an array with its *identical copy* displaced in space. The geometry and response of the arrays do not have to be known; only the measurements

from these arrays and the displacement between the identical arrays are required. The computational complexity of ESPRIT is less than that of the search-based methods.

Let $\mathbf{r}^1(t)$ and $\mathbf{r}^2(t)$ be the measurements from these arrays. Due to the displacement of the arrays the following holds:

$$\mathbf{r}^1(t) = \mathbf{A}\mathbf{s}(t) + \mathbf{n}_1(t) \text{ and } \mathbf{r}^2(t) = \mathbf{A}\Phi\mathbf{s}(t) + \mathbf{n}_2(t),$$

where $\Phi = \text{diag}\{e^{-j2\pi\frac{d}{\lambda}\sin\theta_1}, \dots, e^{-j2\pi\frac{d}{\lambda}\sin\theta_P}\}$ in which d is the separation between the identical arrays, and the angles $\{\theta_i\}_{i=1}^P$ are measured with respect to the normal to the displacement vector between the identical arrays. Note that the auto covariance of $\mathbf{r}^1(t)$, \mathbf{R}^{11} , and the cross covariance between $\mathbf{r}^1(t)$ and $\mathbf{r}^2(t)$, \mathbf{R}^{21} , are given by

$$\mathbf{R}^{11} = \mathbf{A}\mathbf{D}\mathbf{A}^H + \mathbf{R}_{n_1}$$

and

$$\mathbf{R}^{21} = \mathbf{A}\Phi\mathbf{D}\mathbf{A}^H + \mathbf{R}_{n_2n_1},$$

where \mathbf{D} is the covariance matrix of the sources, and \mathbf{R}_{n_1} and $\mathbf{R}_{n_2n_1}$ are the noise auto- and cross-covariance matrices.

The ESPRIT algorithm solves for Φ , which then gives the bearing estimates. Although the subspace separation concept is not used in ESPRIT, its LS and TLS versions are based on a signal subspace formulation. The LS and TLS versions are more complicated, but are more accurate than the original ESPRIT, and are summarized in the next subsection. Here we summarize the original ESPRIT:

(1) Estimate the autocovariance of $\mathbf{r}^1(t)$ and cross covariance between $\mathbf{r}^1(t)$ and $\mathbf{r}^2(t)$, as

$$\mathbf{R}^{11} = \frac{1}{N} \sum_{t=1}^N \mathbf{r}^1(t)\mathbf{r}^1(t)^H$$

and

$$\mathbf{R}^{21} = \frac{1}{N} \sum_{t=1}^N \mathbf{r}^2(t)\mathbf{r}^1(t)^H.$$

(2) Calculate $\hat{\mathbf{R}}^{11} = \mathbf{R}^{11} - \mathbf{R}_{n_1}$ and $\hat{\mathbf{R}}^{21} = \mathbf{R}^{21} - \mathbf{R}_{n_2n_1}$ where \mathbf{R}_{n_1} and $\mathbf{R}_{n_2n_1}$ are the estimated noise covariance matrices. (3) Find the singular values λ_i of the matrix pencil $\hat{\mathbf{R}}^{11} - \lambda_i \hat{\mathbf{R}}^{21}$, $i = 1, \dots, P$. (4) The bearings, θ_i ($i = 1, \dots, P$), are readily obtained by solving the equation

$$\lambda_i = e^{j2\pi\frac{d}{\lambda}\sin\theta_i}$$

for θ_i . In the above steps, it is assumed that the noise is spatially and temporally white or the covariance matrices \mathbf{R}_{n_1} and $\mathbf{R}_{n_2n_1}$ are known.

LS and TLS ESPRIT [28]: (1) Follow Steps 1 and 2 of ESPRIT; (2) stack $\hat{\mathbf{R}}^{11}$ and $\hat{\mathbf{R}}^{21}$ into a $2M \times M$ matrix \mathbf{R} , as $\mathbf{R} \triangleq \begin{bmatrix} \hat{\mathbf{R}}^{11T} & \hat{\mathbf{R}}^{21T} \end{bmatrix}^T$, and perform an SVD of \mathbf{R} , keeping the first $2M \times P$ submatrix of the left singular vectors of \mathbf{R} . Let this submatrix be \mathbf{E}_s ; (3) partition \mathbf{E}_s into two $M \times P$ matrices \mathbf{E}_{s1} and \mathbf{E}_{s2} such that

$$\mathbf{E}_s = \begin{bmatrix} \mathbf{E}_{s1}^T & \mathbf{E}_{s2}^T \end{bmatrix}^T.$$

(4) For LS-ESPRIT, calculate the eigendecomposition of $(\mathbf{E}_{s1}^H \mathbf{E}_{s1})^{-1} \mathbf{E}_{s1}^H \mathbf{E}_{s2}$. The eigenvalue matrix gives

$$\Phi = \text{diag}\{e^{-j2\pi\frac{d}{\lambda}\sin\theta_1}, \dots, e^{-j2\pi\frac{d}{\lambda}\sin\theta_P}\}$$

from which the arrival angles are readily obtained. For TLS-ESPRIT, proceed as follows: (5) Perform an SVD of the $M \times 2P$ matrix $[\mathbf{E}_{s1}, \mathbf{E}_{s2}]$, and stack the last P right singular vectors of $[\mathbf{E}_{s1}, \mathbf{E}_{s2}]$ into a $2P \times P$ matrix denoted \mathbf{F} ; (6) Partition \mathbf{F} as

$$\mathbf{F} \triangleq \begin{bmatrix} \mathbf{F}_x^T & \mathbf{F}_y^T \end{bmatrix}^T$$

where \mathbf{F}_x and \mathbf{F}_y are $P \times P$; (7) Perform the eigendecomposition of $-\mathbf{F}_x \mathbf{F}_y^{-1}$. The eigenvalue matrix gives

$$\Phi = \text{diag}\{e^{-j2\pi \frac{d}{\lambda} \sin \theta_1}, \dots, e^{-j2\pi \frac{d}{\lambda} \sin \theta_P}\}$$

from which the arrival angles are readily obtained.

Different versions of ESPRIT have different statistical properties. The Toeplitz Approximation Method (TAM) [16], in which the array measurement model is represented as a state-variable model, although different in implementation from LS-ESPRIT, is equivalent to LS-ESPRIT; hence, it has the same error variance as LS-ESPRIT.

Generalized Eigenvalues Utilizing Signal Subspace Eigenvectors (GEESE) [24]: (1) Follow Steps 1 through 3 of TLS ESPRIT. (2) Find the singular values λ_i of the pencil

$$\mathbf{E}_{s1} - \lambda_i \mathbf{E}_{s2}, i = 1, \dots, P;$$

(3) The bearings, θ_i ($i = 1, \dots, P$), are readily obtained from

$$\lambda_i = e^{j2\pi \frac{d}{\lambda} \sin \theta_i}.$$

The GEESE method is claimed to be better than ESPRIT [24].

62.3.2 Noise Subspace Methods

These methods, in which only the noise subspace information is retained, are based on the property that the steering vectors are orthogonal to any linear combination of the noise subspace eigenvectors. Noise subspace methods are also divided into search-based and algebraic methods, which are explained next.

Search-Based Methods

In search-based methods, the array manifold is assumed to be known, and the arrival angles are estimated by locating the peaks of the function $S(\theta) = 1/\mathbf{a}(\theta)^H \mathbf{N} \mathbf{a}(\theta)$ where \mathbf{N} is a matrix formed using the noise space eigenvectors.

Pisarenko method: In this method, $\mathbf{N} = \mathbf{e}_M \mathbf{e}_M^H$, where \mathbf{e}_M is the eigenvector corresponding to the minimum eigenvalue of \mathbf{R} . If the minimum eigenvalue is repeated, any unit-norm vector which is a linear combination of the eigenvectors corresponding to the minimum eigenvalue can be used as \mathbf{e}_M . The basis of this method is that when the search angle θ corresponds to an actual arrival angle, the denominator of $S(\theta)$ in the Pisarenko method, $|\mathbf{a}(\theta)^H \mathbf{e}_M|^2$, becomes small due to orthogonality of steering vectors and noise subspace eigenvectors; hence, $S(\theta)$ will peak at an arrival angle.

MUSIC (Multiple Signal Classification) [29] method: In this method, $\mathbf{N} = \sum_{i=P+1}^M \mathbf{e}_i \mathbf{e}_i^H$. The idea is similar to that of the Pisarenko method; the inner product $|\mathbf{a}(\theta)^H \sum_{i=P+1}^M \mathbf{e}_i|^2$ is small when θ is an actual arrival angle. An obvious signal-subspace formulation of MUSIC is also possible. The MUSIC spectrum is equivalent to the MV method using the exact covariance matrix when SNR is infinite, and therefore performs better than the MV method.

Asymptotic properties of MUSIC are well established [32, 33], e.g., MUSIC is known to have the same asymptotic variance as the deterministic ML method for uncorrelated sources. It is shown by Xu

and Buckley [38] that although, asymptotically, bias is insignificant compared to standard deviation, it is an important factor limiting the performance for resolving closely spaced sources when they are correlated.

In order to overcome the problems due to finite sample effects and source correlation, a multidimensional (MD) version of MUSIC has been proposed [29, 28]; however, this approach involves a computationally involved search, as in the ML method. MD MUSIC can be interpreted as a norm minimization problem, as shown in [8]; using this interpretation, strong consistency of MD MUSIC has been demonstrated. An optimally weighted version of MD MUSIC, which outperforms the deterministic ML method, has also been proposed in [35].

Eigenvector (EV) method: In this method,

$$\mathbf{N} = \sum_{i=P+1}^M \frac{1}{\lambda_i} \mathbf{e}_i \mathbf{e}_i^H.$$

The only difference between the EV method and MUSIC is the use of inverse eigenvalue (the λ_i are the noise subspace eigenvalues of \mathbf{R}) weighting in EV and unity weighting in MUSIC, which causes EV to yield fewer spurious peaks than MUSIC [13]. The EV Method is also claimed to shape the noise spectrum better than MUSIC.

Method of direction estimation (MODE): MODE is equivalent to WSF when there are no coherent sources. Viberg and Ottersten [35] claim that, for coherent sources, only WSF is asymptotically efficient. A minimum norm interpretation and proof of strong consistency of MODE for ergodic and stationary signals, has also been reported [8]. The norm measure used in that work involves the source covariance matrix. By contrasting this norm with the Frobenius norm that is used in MD MUSIC, Ephraim et al. relate MODE and MD MUSIC.

Minimum-norm [15] method: In this method, the matrix \mathbf{N} is obtained as follows [12]:

1. Form $\mathbf{E}_n = [\mathbf{e}_{P+1}, \dots, \mathbf{e}_M]$;
2. partition \mathbf{E}_n as $\mathbf{E}_n = [\mathbf{c} \ \mathbf{C}^T]^T$, to establish \mathbf{c} and \mathbf{C} ;
3. compute $\mathbf{d} = [\mathbf{1} \ (\mathbf{c}^H \mathbf{c})^{-1} \mathbf{C}^* \mathbf{c}]^T$, and, finally, $\mathbf{N} = \mathbf{d} \mathbf{d}^H$.

For two closely spaced, equal power signals, the Minimum Norm Method has been shown to have a lower SNR threshold (i.e., the minimum SNR required to separate the two sources) than MUSIC [14]. [17] derive and compare the mean-squared errors of the DOA estimates from Minimum Norm and MUSIC algorithms due to finite sample effects, calibration errors, and noise modeling errors for the case of finite samples and high SNR. They show that mean-squared errors for DOA estimates produced by the MUSIC algorithm are always lower than the corresponding mean-squared errors for the Minimum Norm algorithm.

Algebraic Methods

When the array is uniform linear, so that

$$\mathbf{a}(\theta) = \left[1, e^{-j2\pi \frac{d}{\lambda} \sin(\theta)}, \dots, e^{-j2\pi (M-1) \frac{d}{\lambda} \sin(\theta)} \right]^T,$$

the search in $S(\theta) = 1/\mathbf{a}(\theta)^H \mathbf{N} \mathbf{a}(\theta)$ for the peaks can be replaced by a root-finding procedure which yields the arrival angles. So doing results in better resolution than the search-based alternative because the root-finding procedure can give distinct roots corresponding to each source whereas the search function may not have distinct maxima for closely spaced sources. In addition, the computational complexity of algebraic methods is lower than that of the search-based ones. The algebraic version of

MUSIC (Root-MUSIC) is given next; for algebraic versions of Pisarenko, EV, and Minimum-Norm, the matrix \mathbf{N} in Root-Music is replaced by the corresponding \mathbf{N} in each of these methods.

Root-MUSIC Method: In Root-MUSIC, the array is required to be uniform linear, and the search procedure in MUSIC is converted into the following root-finding approach:

1. Form the $M \times M$ matrix $\mathbf{N} = \sum_{i=P+1}^M \mathbf{e}_i \mathbf{e}_i^H$.
2. Form a polynomial $p(z)$ of degree $2M - 1$ which has for its i th coefficient $c_i = \text{tr}_i[\mathbf{N}]$, where tr_i denotes the trace of the i th diagonal, and $i = -(M-1), \dots, 0, \dots, M-1$. Note that tr_0 denotes the main diagonal, tr_1 denotes the first super-diagonal, and tr_{-1} denotes the first sub-diagonal.
3. The roots of $p(z)$ exhibit inverse symmetry with respect to the unit circle in the z -plane. Express $p(z)$ as the product of two polynomials $p(z) = h(z)h^*(z^{-1})$.
4. Find the roots z_i ($i = 1, \dots, M$) of $h(z)$. The angles of roots that are very close to (or, ideally on) the unit circle yield the direction of arrival estimates, as

$$\theta_i = \sin^{-1}\left(\frac{\lambda}{2\pi d} \angle z_i\right), \text{ where } i = 1, \dots, P.$$

The Root-MUSIC algorithm has been shown to have better resolution power than MUSIC [27]; however, as mentioned previously, Root-MUSIC is restricted to uniform linear arrays. Steps (2) through (4) make use of this knowledge. Li and Vaccaro show that algebraic versions of the MUSIC and Minimum Norm algorithms have the same mean-squared errors as their search-based versions for finite samples and high SNR case. The advantages of Root-MUSIC over search-based MUSIC is increased resolution of closely spaced sources and reduced computations.

62.3.3 Spatial Smoothing [9, 31]

When there are coherent (completely correlated) sources, $\text{rank}(\mathbf{R}_s)$, and consequently $\text{rank}(\mathbf{R})$, is less than P , and hence the above described subspace methods fail. If the array is uniform linear, then by applying the spatial smoothing method, described below, a new rank- P matrix is obtained which can be used in place of \mathbf{R} in any of the subspace methods described earlier.

Spatial smoothing starts by dividing the M -vector $\mathbf{r}(t)$ of the ULA into $K = M - S + 1$ overlapping subvectors of size S , $\mathbf{r}_{S,k}^f$ ($k = 1, \dots, K$), with elements $\{r_k, \dots, r_{k+S-1}\}$, and $\mathbf{r}_{S,k}^b$ ($k = 1, \dots, K$), with elements $\{r_{M-k+1}^*, \dots, r_{M-S-k+2}^*\}$. Then, a forward and backward spatially smoothed matrix \mathbf{R}^{fb} is calculated as

$$\mathbf{R}^{fb} = \sum_{t=1}^N \sum_{k=1}^K (\mathbf{r}_{S,k}^f(t) \mathbf{r}_{S,k}^{fH}(t) + \mathbf{r}_{S,k}^b(t) \mathbf{r}_{S,k}^{bH}(t)) / KN.$$

The rank of \mathbf{R}^{fb} is P if there are at most $2M/3$ coherent sources. S must be selected such that

$$P_c + 1 \leq S \leq M - P_c/2 + 1$$

in which P_c is the number of coherent sources. Then, any subspace-based method can be applied to \mathbf{R}^{fb} to determine the directions of arrival. It is also possible to do spatial smoothing based only on $\mathbf{r}_{S,k}^f$ or $\mathbf{r}_{S,k}^b$, but in this case at most $M/2$ coherent sources can be handled.

62.3.4 Discussion

The application of all the subspace-based methods requires exact knowledge of the number of signals, in order to separate the signal and noise subspaces. The number of signals can be estimated from

the data using either the Akaike Information Criterion (AIC) [36] or Minimum Descriptive Length (MDL) [37] methods. The effect of underestimating the number of sources is analyzed by [26], whereas the case of overestimating the number of signals can be treated as a special case of the analysis in [32].

The second-order methods described above have the following disadvantages:

1. Except for ESPRIT (which requires a special array structure), all of the above methods require calibration of the array which means that the response of the array for every possible combination of the source parameters should be measured and stored; or, analytical knowledge of the array response is required. However, at any time, the antenna response can be different from when it was last calibrated due to environmental effects such as weather conditions for radar, or water waves for sonar. Even if the analytical response of the array elements is known, it may be impossible to know or track the precise locations of the elements in some applications (e.g., towed array). Consequently, these methods are sensitive to errors and perturbations in the array response. In addition, physically identical sensors may not respond identically in practice due to lack of synchronization or imbalances in the associated electronic circuitry.
2. In deriving the above methods, it was assumed that the noise covariance structure is known; however, it is often unrealistic to assume that the noise statistics are known due to several reasons. In practice, the noise is not isolated; it is often observed along with the signals. Moreover, as [33] state, there are noise phenomena effects that cannot be modeled accurately, e.g., channel crosstalk, reverberation, near-field, wide-band, and distributed sources.
3. None of the methods in Sections 62.3.1 and 62.3.2, except for the WSF method and other multidimensional search-based approaches, which are computationally very expensive, work when there are coherent (completely correlated) sources. Only if the array is uniform linear, can the spatial smoothing method in Section 62.3.3 be used. On the other hand, higher-order statistics of the received signals can be exploited to develop direction finding methods which have less restrictive requirements.

62.4 Higher-Order Statistics-Based Methods

The higher-order statistical direction finding methods use the spatial cumulant matrices of the array. They require that the source signals be non-Gaussian so that their higher than second order statistics convey extra information. Most communication signals (e.g., QAM) are *complex circular* (a signal is complex circular if its real and imaginary parts are independent and symmetrically distributed with equal variances) and hence their third-order cumulants vanish; therefore, even-order cumulants are used, and usually fourth-order cumulants are employed. The fourth-order cumulant of the source signals must be nonzero in order to use these methods. One important feature of cumulant-based methods is that they can suppress Gaussian noise regardless of its coloring. Consequently, the requirement of having to estimate the noise covariance, as in second-order statistical processing methods, is avoided in cumulant-based methods. It is also possible to suppress non-Gaussian noise [6], and, when properly applied, cumulants extend the aperture of an array [5, 30], which means that more sources than sensors can be detected. As in the second-order statistics-based methods, it is assumed that the number of sources is known or is estimated from the data.

The fourth-order moments of the signal $\mathbf{s}(t)$ are

$$E\{s_i s_j^* s_k s_l^*\} \quad 1 \leq i, j, k, l \leq P$$

and the fourth-order cumulants are defined as

$$\begin{aligned} c_{4,s}(i, j, k, l) &\triangleq \text{cum}(s_i, s_j^*, s_k, s_l^*) \\ &= E\{s_i s_j^* s_k s_l^*\} - E\{s_i s_j^*\} E\{s_k s_l^*\} \\ &\quad - E\{s_i s_l^*\} E\{s_k s_j^*\} - E\{s_i s_j\} E\{s_k^* s_l^*\}, \end{aligned}$$

where $1 \leq i, j, k, l \leq P$. Note that two arguments in the above fourth-order moments and cumulants are conjugated and the other two are unconjugated. For circularly symmetric signals, which is often the case in communication applications, the last term in $c_{4,s}(i, j, k, l)$ is zero.

In practice, sample estimates of the cumulants are used in place of the theoretical cumulants, and these sample estimates are obtained from the received signal vector $\mathbf{r}(t)$ ($t = 1, \dots, N$), as:

$$\begin{aligned} \hat{c}_{4,r}(i, j, k, l) &= \sum_{t=1}^N r_i(t) r_j^*(t) r_k(t) r_l^*(t) / N \\ &\quad - \sum_{t=1}^N r_i(t) r_j^*(t) \sum_{t=1}^N r_k(t) r_l^*(t) / N^2 \\ &\quad - \sum_{t=1}^N r_i(t) r_l^*(t) \sum_{t=1}^N r_k(t) r_j^*(t) / N^2, \end{aligned}$$

where $1 \leq i, j, k, l \leq M$. Note that the last term in $c_{4,r}(i, j, k, l)$ is zero and, therefore, it is omitted.

Higher-order statistical subspace methods use fourth-order spatial cumulant matrices of the array output, which can be obtained in a number of ways by suitably selecting the arguments i, j, k, l of $c_{4,r}(i, j, k, l)$. Existing methods for the selection of the cumulant matrix, and their associated processing schemes are summarized next.

Pan-Nikias [22] and Cardoso-Moulines [2] method: In this method, the array needs to be calibrated, or its response must be known in analytical form. The source signals are assumed to be independent or partially correlated (i.e., there are no coherent signals). The method is as follows:

1. An estimate of an $M \times M$ fourth-order cumulant matrix \mathbf{C} is obtained from the data. The following two selections for \mathbf{C} are possible [22, 2]:

$$c_{ij} = c_{4,r}(i, j, j, j) \quad 1 \leq i, j \leq M,$$

or

$$c_{ij} = \sum_{m=1}^M c_{4,r}(i, j, m, m) \quad 1 \leq i, j \leq M.$$

Using cumulant properties [19], and (62.1), and a_{ij} for the ij th element of \mathbf{A} , it is easy to verify that

$$c_{4,r}(i, j, j, j) = \sum_{p=1}^P a_{ip} \sum_{q,r,s=1}^P a_{jq}^* a_{jr} a_{js}^* c_{4,s}(p, q, r, s)$$

which, in matrix format, is $\mathbf{C} = \mathbf{A}\mathbf{B}$ where \mathbf{A} is the steering matrix and \mathbf{B} is a $P \times M$ matrix with elements

$$b_{ij} = \sum_{q,r,s=1}^P a_{jq}^* a_{jr} a_{js}^* c_{4,s}(i, q, r, s).$$

Similarly,

$$\sum_{m=1}^M c_{4,r}(i, j, m, m) = \sum_{p,q=1}^P a_{ip} \left(\sum_{r,s=1}^P \sum_{m=1}^M a_{mr} a_{ms}^* c_{4,s}(p, q, r, s) \right) a_{jq}^*, 1 \leq i, j \leq M$$

which, in matrix form, can be expressed as $\mathbf{C} = \mathbf{A}\mathbf{D}\mathbf{A}^H$, where \mathbf{D} is a $P \times P$ matrix with elements

$$d_{ij} = \sum_{r,s=1}^P \sum_{m=1}^M a_{mr} a_{ms}^* c_{4,s}(i, j, r, s).$$

Note that additive Gaussian noise is suppressed in both \mathbf{C} matrices because higher than second-order statistics of a Gaussian process are zero.

2. The P left singular vectors of $\mathbf{C} = \mathbf{A}\mathbf{B}$, corresponding to nonzero singular values or the P eigenvectors of $\mathbf{C} = \mathbf{A}\mathbf{D}\mathbf{A}^H$ corresponding to nonzero eigenvalues form the signal subspace. The orthogonal complement of the signal subspace gives the noise subspace. Any of the Section 62.3 covariance-based search and algebraic DF methods (except for the EV method and ESPRIT) can now be applied (in exactly the same way as described in Section 62.3) either by replacing the signal and noise subspace eigenvectors and eigenvalues of the array covariance matrix by the corresponding subspace eigenvectors and eigenvalues of $\mathbf{A}\mathbf{D}\mathbf{A}^H$, or by the corresponding subspace singular vectors and singular values of $\mathbf{A}\mathbf{B}$. A cumulant-based analog of the EV method does not exist because the eigenvalues and singular values of $\mathbf{A}\mathbf{D}\mathbf{A}^H$ and $\mathbf{A}\mathbf{B}$ corresponding to the noise subspace are theoretically zero. The cumulant-based analog of ESPRIT is explained later.

The same assumptions and restrictions for the covariance-based methods apply to their analogs in the cumulant domain. The advantage of using the cumulant-based analogs of these methods is that there is no need to know or estimate the noise-covariance matrix.

The asymptotic covariance of the DOA estimates obtained by MUSIC based on the above fourth-order cumulant matrices are derived in [2] for the case of Gaussian measurement noise with arbitrary spatial covariance, and are compared to the asymptotic covariance of the DOA estimates from the covariance-based MUSIC algorithm. Cardoso and Moulines show that covariance- and fourth-order cumulant-based MUSIC have similar performance for the high SNR case, and as SNR decreases below a certain SNR threshold, the variances of the fourth-order cumulant-based MUSIC DOA estimates increase with the fourth power of the reciprocal of the SNR, whereas the variances of covariance-based MUSIC DOA estimates increase with the square of the reciprocal of the SNR. They also observe that for high SNR and uncorrelated sources, the covariance-based MUSIC DOA estimates are uncorrelated, and the asymptotic variance of any particular source depends only on the power of that source (i.e., it is independent of the powers of the other sources). They observe, on the other hand, that DOA estimates from cumulant-based MUSIC, for the same case, are correlated, and the variance of the DOA estimate of a weak source increases in the presence of strong sources. This observation limits the use of cumulant-based MUSIC when the sources have a high dynamic range, even for the case of high SNR. Cardoso and Moulines state that this problem may be alleviated when the source of interest has a large fourth-order cumulant.

Porat and Friedlander [25] method: In this method, the array also needs to be calibrated, or its response is required in analytical form. The model used in this method divides the sources into groups that are partially correlated (but not coherent) within each group, but are statistically independent

across the groups, i.e.,

$$\mathbf{r}(t) = \sum_{g=1}^G \mathbf{A}_g \mathbf{s}_g + \mathbf{n}(t)$$

where G is the number of groups each having p_g sources ($\sum_{g=1}^G p_g = P$). In this model, the p_g sources in the g th group are partially correlated, and they are received from different directions. The method is as follows:

1. Estimate the fourth-order cumulant matrix, \mathbf{C}_r , of $\mathbf{r}(t) \otimes \mathbf{r}(t)^*$ where \otimes denotes the Kronecker product. It can be verified that

$$\mathbf{C}_r = \sum_{g=1}^G (\mathbf{A}_g \otimes \mathbf{A}_g^*) \mathbf{C}_{s_g} (\mathbf{A}_g \otimes \mathbf{A}_g^*)^H$$

where \mathbf{C}_{s_g} is the fourth-order cumulant matrix of \mathbf{s}_g . The rank of \mathbf{C}_r is $\sum_{g=1}^G p_g^2$, and since \mathbf{C}_r is $M^2 \times M^2$, it has $M^2 - \sum_{g=1}^G p_g^2$ zero eigenvalues which correspond to the noise subspace. The other eigenvalues correspond to the signal subspace.

2. Compute the SVD of \mathbf{C}_r and identify the signal and noise subspace singular vectors. Now, second-order subspace-based search methods can be applied, using the signal or noise subspaces, by replacing the array response vector $\mathbf{a}(\theta)$ by $\mathbf{a}(\theta) \otimes \mathbf{a}^*(\theta)$.

The eigendecomposition in this method has computational complexity $O(M^6)$ due to the Kronecker product, whereas the second-order statistics-based methods (e.g., MUSIC) have complexity $O(M^3)$.

Chiang-Nikias [4] method: This method uses the ESPRIT algorithm and requires an array with its entire identical copy displaced in space by distance d ; however, no calibration of the array is required. The signals

$$\mathbf{r}^1(t) = \mathbf{A}\mathbf{s}(t) + \mathbf{n}_1(t)$$

and

$$\mathbf{r}^2(t) = \mathbf{A}\Phi\mathbf{s}(t) + \mathbf{n}_2(t).$$

Two $M \times M$ matrices \mathbf{C}^1 and \mathbf{C}^2 are generated as follows:

$$c_{ij}^1 = \text{cum}(r_i^1, r_j^{1*}, r_k^1, r_k^{1*}), 1 \leq i, j, k \leq M$$

and

$$c_{ij}^2 = \text{cum}(r_i^2, r_j^{1*}, r_k^1, r_k^{1*}), 1 \leq i, j, k \leq M.$$

It can be shown that $\mathbf{C}^1 = \mathbf{A}\mathbf{E}\mathbf{A}^H$ and $\mathbf{C}^2 = \mathbf{A}\Phi\mathbf{E}\mathbf{A}^H$, where

$$\Phi = \text{diag}\{e^{-j2\pi\frac{d}{\lambda}\sin\theta_1}, \dots, e^{-j2\pi\frac{d}{\lambda}\sin\theta_P}\}$$

in which d is the separation between the identical arrays, and \mathbf{E} is a $P \times P$ matrix with elements

$$e_{ij} = \sum_{q,r=1}^P a_{kq} a_{kr}^* c_{4,s}(i, q, r, j).$$

Note that these equations are in the same form as those for covariance-based ESPRIT (the noise cumulants do not appear in \mathbf{C}^1 and \mathbf{C}^2 because the fourth-order cumulants of Gaussian noises are zero); therefore, any version of ESPRIT or GEESE can be used to solve for Φ by replacing \mathbf{R}^{11} and \mathbf{R}^{21} by \mathbf{C}^1 and \mathbf{C}^2 , respectively.

Virtual cross correlation computer (VC^3) [5]: In VC^3 , the source signals are assumed to be statistically independent. The idea of VC^3 can be demonstrated as follows: Suppose we have three identical sensors as in Fig. 62.1, where $r_1(t)$, $r_2(t)$, and $r_3(t)$ are measurements, and \vec{d}_1 , \vec{d}_2 , and \vec{d}_3 ($\vec{d}_3 = \vec{d}_1 + \vec{d}_2$) are the vectors joining these sensors. Let the response of each sensor to a signal from

FIGURE 62.1: Demonstration of VC^3 .

θ be $a(\theta)$. A *virtual* sensor is one at which no measurement is actually made. Suppose that we wish to compute the correlation between the virtual sensor $v_1(t)$ and $r_2(t)$, which (using the plane wave assumption) is

$$E\{r_2^*(t)v_1(t)\} = \sum_{p=1}^P |a(\theta_p)|^2 \sigma_p^2 e^{-j\vec{k}_p \cdot \vec{d}_3}.$$

Consider the following cumulant

$$\begin{aligned} \text{cum}(r_2^*(t), r_1(t), r_2^*(t), r_3(t)) &= \sum_{p=1}^P |a(\theta_p)|^4 \gamma_p e^{-j\vec{k}_p \cdot \vec{d}_1} e^{-j\vec{k}_p \cdot \vec{d}_2} \\ &= \sum_{p=1}^P |a(\theta_p)|^4 \gamma_p e^{-j\vec{k}_p \cdot \vec{d}_3}. \end{aligned}$$

This cumulant carries the same angular information as the cross correlation $E\{r_2^*(t)v_1(t)\}$, but for sources having different powers.

The fact that we are interested only in the directional information carried by correlations between the sensors therefore let us interpret a cross correlation as a vector (e.g., \vec{d}_3), and a fourth-order cumulant as the addition of two vectors (e.g., $\vec{d}_1 + \vec{d}_2$). This interpretation leads to the idea of decomposing the computation of a cross correlation into that of computing a cumulant. Doing this means that the directional information that would be obtained from the cross correlation between nonexistent sensors (or between an actual sensor and a nonexistent sensor) at certain virtual locations in the space can be obtained from a suitably defined cumulant that uses the real sensor measurements.

One advantage of virtual cross correlation computation is that it is possible to obtain a larger aperture than would be obtained by using only second-order statistics. This means that more sources than sensors can be detected using cumulants. For example, given an M element uniform linear array, VC^3 lets its aperture be extended from M to $2M - 1$ sensors, so that $2M - 2$ targets can

be detected (rather than $M - 1$) just by using the array covariance matrix obtained by VC^3 in any of the subspace-based search methods explained earlier. This use of VC^3 requires the array to be calibrated. Another advantage of VC^3 is a fault tolerance capability. If sensors at certain locations in a given array fail to operate properly, these sensors can be replaced using VC^3 .

Virtual ESPRIT (VESPA) [5]: For VESPA, the array only needs two identical sensors; the rest of the array may have arbitrary and unknown geometry and response. The sources are assumed to be statistically independent. VESPA uses the ESPRIT solution applied to cumulant matrices. By choosing a suitable pair of cumulants in VESPA, the need for a copy of the entire array, as required in ESPRIT, is totally eliminated. VESPA preserves the computational advantage of ESPRIT over search-based algorithms. An example array configuration is given in Fig. 62.2.

Without loss of generality, let the signals received by the identical sensor pair be r_1 and r_2 . The sensors r_1 and r_2 are collectively referred to as the *guiding sensor pair*. The VESPA algorithm is

1. Two $M \times M$ matrices, \mathbf{C}^1 and \mathbf{C}^2 , are generated as follows:

$$c^1_{ij} = \text{cum}(r_1, r_1^*, r_i, r_j^*), 1 \leq i, j \leq M$$

$$c^2_{ij} = \text{cum}(r_2, r_1^*, r_i, r_j^*), 1 \leq i, j \leq M.$$

It can be shown that these relations can be expressed as $\mathbf{C}^1 = \mathbf{AFA}^H$ and $\mathbf{C}^2 = \mathbf{A}\Phi\mathbf{FA}^H$, where the $P \times P$ matrix

$$\mathbf{F} \triangleq \text{diag}\{\gamma_{4,s_1}|a_{11}|^2, \dots, \gamma_{4,s_P}|a_{1P}|^2\}, \{\gamma_{4,s_P}\}_{p=1}^P,$$

and Φ has been defined before.

2. Note that these equations are in the same form as ESPRIT and Chiang and Nikias's ESPRIT-like method; however, as opposed to these methods, there is no need for an identical copy of the array; only an identical response sensor pair is necessary for VESPA. Consequently, any version of ESPRIT or GEESE can be used to solve for Φ by replacing \mathbf{R}^{11} and \mathbf{R}^{21} by \mathbf{C}^1 and \mathbf{C}^2 , respectively.

FIGURE 62.2: The main array and its virtual copy.

Note, also, that there exists a very close link between VC^3 and VESPA. Although the way we chose \mathbf{C}^1 and \mathbf{C}^2 above seems to be not very obvious, there is a unique geometric interpretation to it. According to VC^3 , as far as the bearing information is concerned, \mathbf{C}^1 is equivalent to the autocorrelation matrix of the array, and \mathbf{C}^2 is equivalent to the cross-correlation matrix between the

array and its virtual copy (which is created by displacing the array by the vector that connects the second and the first sensors).

If the noise component of the signal received by one of the guiding sensor pair elements is independent of the noises at the other sensors, VESPA suppresses the noise regardless of its distribution [6]. In practice, the noise does affect the standard deviations of results obtained from VESPA.

An iterative version of VESPA has also been developed for cases where the source powers have a high dynamic range [11]. Iterative VESPA has the same hardware requirements and assumptions as in VESPA.

Extended VESPA [10]: When there are coherent (or completely correlated) sources, all of the above second- and higher-order statistics methods, except for the WSF method and other multidimensional search-based approaches, fail. For the WSF and other multidimensional methods, however, the array must be calibrated accurately and the computational load is expensive. The coherent signals case arises in practice when there are multipaths. Porat and Friedlander present a modified version of their algorithm to handle the case of coherent signals; however, their method is not practical because it requires selection of a highly redundant subset of fourth-order cumulants that contains $O(N^4)$ elements, and no guidelines exist for its selection and 2nd-, 4th-, 6th-, and 8th-order moments of the data are required. If the array is *uniform linear*, coherence can be handled using spatial smoothing as a preprocessor to the usual second- or higher-order [3, 39] methods; however, the array aperture is reduced. Extended VESPA can handle coherence and provides increased aperture. Additionally, the array does not have to be completely uniform linear or calibrated; however, a uniform linear subarray is still needed. An example array configuration is shown in Figure 62.3.

FIGURE 62.3: An example array configuration. There are M sensors, L of which are uniform linearly positioned; $r_1(t)$ and $r_2(t)$ are identical guiding sensors. Linear subarray elements are separated by Δ .

Consider a scenario in which there are G statistically independent narrowband sources, $\{u_g(t)\}_{g=1}^G$. These source signals undergo multipath propagation, and each produces p_i coherent wavefronts

$$\{s_{1,1}, \dots, s_{1,p_1}, \dots, s_{G,1}, \dots, s_{G,p_G}\} \left(\sum_{i=1}^G p_i = P \right)$$

that impinge on an M element sensor array from directions

$$\{\theta_{1,1}, \dots, \theta_{1,p_1}, \dots, \theta_{G,1}, \dots, \theta_{G,p_G}\},$$

where $\theta_{m,p}$ represents the angle-of-arrival of the wavefront $s_{g,p}$ that is the p th coherent signal in the g th group. The collection of p_i coherent wavefronts, which are scaled and delayed replicas of the i th source, are referred to as the i th *group*. The wavefronts are represented by the P -vector $\mathbf{s}(t)$. The problem is to estimate the DOAs $\{\theta_{1,1}, \dots, \theta_{1,p_1}, \dots, \theta_{G,1}, \dots, \theta_{G,p_G}\}$.

When the multipath delays are insignificant compared to the bit durations of signals, then the signals received from different paths differ by only amplitude and phase shifts, thus the coherence among the received wavefronts can be expressed by the following equation:

$$\mathbf{s}(t) = \begin{bmatrix} \mathbf{s}_1(t) \\ \mathbf{s}_2(t) \\ \vdots \\ \mathbf{s}_G(t) \end{bmatrix} = \begin{bmatrix} \mathbf{c}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{c}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{c}_G \end{bmatrix} \begin{bmatrix} u_1(t) \\ u_2(t) \\ \vdots \\ u_G(t) \end{bmatrix} \triangleq \mathbf{Q}\mathbf{u}(t) \quad (62.2)$$

where $\mathbf{s}_i(t)$ is a $p_i \times 1$ signal vector representing the coherent wavefronts from the i th independent source $u_i(t)$, \mathbf{c}_i is a $p_i \times 1$ complex attenuation vector for the i th source ($1 \leq i \leq G$), and \mathbf{Q} is $P \times G$. The elements of \mathbf{c}_i account for the attenuation and phase differences among the multipaths due to different arrival times. The received signal can then be written in terms of the independent sources as follows:

$$\mathbf{r}(t) = \mathbf{A}\mathbf{s}(t) + \mathbf{n}(t) = \mathbf{A}\mathbf{Q}\mathbf{u}(t) + \mathbf{n}(t) = \mathbf{B}\mathbf{u}(t) + \mathbf{n}(t) \quad (62.3)$$

where $\mathbf{B} \triangleq \mathbf{A}\mathbf{Q}$. The columns of $M \times G$ matrix \mathbf{B} are known as the *generalized steering vectors*.

Extended VESPA has three major steps:

Step 1: Use Step (1) of VESPA by choosing $r_1(t)$ and $r_2(t)$ as any two sensor measurements. In this case $\mathbf{C}^1 = \mathbf{B}\mathbf{G}\mathbf{B}^H$ and $\mathbf{C}^2 = \mathbf{B}\mathbf{C}\mathbf{G}\mathbf{B}^H$, where

$$\mathbf{G} \triangleq \text{diag}(\gamma_{4,u_1}|b_{11}|^2, \dots, \gamma_{4,u_G}|b_{1G}|^2), \{\gamma_{4,u_g}\}_{g=1}^G$$

$$\mathbf{C} \triangleq \text{diag}\left(\frac{b_{21}}{b_{11}}, \dots, \frac{b_{2G}}{b_{1G}}\right).$$

Due to the coherence, the DOAs cannot be obtained at this step from just \mathbf{C}^1 and \mathbf{C}^2 because the columns of \mathbf{B} depend on a vector of DOAs (all those within a group). In the independent sources case, the columns of \mathbf{A} depend only on a single DOA. Fortunately, the columns of \mathbf{B} can be solved for as follows: (1.1) Follow Steps 2 through 5 of TLS ESPRIT by replacing \mathbf{R}^{11} and \mathbf{R}^{21} by \mathbf{C}^1 and \mathbf{C}^2 , respectively, and using appropriate matrix dimensions; (1.2) determine the eigenvectors and eigenvalues of $-\mathbf{F}_x\mathbf{F}_y^{-1}$; Let the eigenvector and eigenvalue matrices of $-\mathbf{F}_x\mathbf{F}_y^{-1}$ be \mathbf{E} and \mathbf{D} , respectively; and, (1.3) obtain an estimate of \mathbf{B} to within a diagonal matrix, as $\mathbf{B} = (\mathbf{U}_{11}\mathbf{E} + \mathbf{U}_{12}\mathbf{E}\mathbf{D}^{-1})/2$, for use in Step 2.

Step 2: Partition the matrices \mathbf{B} and \mathbf{A} as $\mathbf{B} = [\mathbf{b}_1, \dots, \mathbf{b}_G]$ and $\mathbf{A} = [\mathbf{A}_1, \dots, \mathbf{A}_G]$, where the steering vector for the i th group \mathbf{b}_i is $M \times 1$, $\mathbf{A}_i \triangleq [\mathbf{a}(\theta_{i,1}), \dots, \mathbf{a}(\theta_{i,p_i})]$ is $M \times p_i$, and $\theta_{i,m}$ is the angle-of-arrival of the m th source in the i th coherent group ($1 \leq m \leq p_i$). Using the fact that the i th column of \mathbf{Q} has p_i nonzero elements, express \mathbf{B} as $\mathbf{B} = \mathbf{A}\mathbf{Q} = [\mathbf{A}_1\mathbf{c}_1, \dots, \mathbf{A}_G\mathbf{c}_G]$; therefore, the i th column of \mathbf{B} , \mathbf{b}_i , is $\mathbf{b}_i = \mathbf{A}_i\mathbf{c}_i$ where $i = 1, \dots, G$. Now, the problem of solving for the steering vectors is transformed into the problem of solving for the steering vectors from *each* coherent group *separately*. To solve this new problem, each generalized steering vector \mathbf{b}_i can be interpreted as

a received signal for an array illuminated by p_i coherent signals having a steering matrix \mathbf{A}_i , and covariance matrix $\mathbf{c}_i \mathbf{c}_i^H$. The DOAs could then be solved for by using a second-order-statistics-based high-resolution method such as MUSIC, if the array was calibrated, and the rank of $\mathbf{c}_i \mathbf{c}_i^H$ was p_i ; however, the array is not calibrated and $\text{rank}(\mathbf{c}_i \mathbf{c}_i^H) = 1$. The solution is to keep the portion of each \mathbf{b}_i that corresponds to the uniform linear part of the array, $\mathbf{b}_{L,i}$, and to then apply the Section 62.3.3 spatial smoothing technique to a pseudocovariance matrix $\mathbf{b}_{L,i} \mathbf{b}_{L,i}^H$ for $i = 1, \dots, G$. Doing this restores the rank of $\mathbf{c}_i \mathbf{c}_i^H$ to p_i . In the Section 62.3.3 spatial smoothing technique, we must replace $\mathbf{r}(t)$ by $\mathbf{b}_{L,i}$ and set $N = 1$.

The conditions on the length of the linear subarray and the parameter S under which the rank of $\mathbf{b}_{S,i} \mathbf{b}_{S,i}^H$ is restored to p_i are [11]: (a) $L \geq 3p_i/2$, which means that the linear subarray must have at least $3p_{\max}/2$ elements, where p_{\max} is the maximum number of multipaths in anyone of the G groups; and (b) given L and p_{\max} , the parameter S must be selected such that $p_{\max} + 1 \leq S \leq L - p_{\max}/2 + 1$. **Step 3:** Apply any second-order-statistics-based subspace technique (e.g., root-MUSIC, etc.) to \mathbf{R}_i^{fb} ($i = 1, \dots, G$) to estimate DOAs of up to $2L/3$ coherent signals in each group.

Note that the matrices \mathbf{C} and \mathbf{G} in \mathbf{C}^1 and \mathbf{C}^2 are not used; however, if the received signals are independent, choosing $r_1(t)$ and $r_2(t)$ from the linear subarray lets DOA estimates be obtained from \mathbf{C} in Step 1 because, in that case,

$$\mathbf{C} = \text{diag}\{e^{-j2\pi \frac{d}{\lambda} \sin \theta_1}, \dots, e^{-j2\pi \frac{d}{\lambda} \sin \theta_P}\};$$

hence, extended VESPA can also be applied to the case of independent sources.

62.4.1 Discussion

One advantage of using higher-order statistics-based methods over second-order methods is that the covariance matrix of the noise is not needed when the noise is Gaussian. The fact that higher-order statistics have more arguments than covariances leads to more practical algorithms that have less restrictions on the array structure (for instance, the requirement of maintaining identical arrays for ESPRIT is reduced to only maintaining two identical sensors for VESPA). Another advantage is more sources than sensors can be detected, i.e., the array aperture is increased when higher-order statistics are properly applied; or, depending on the array geometry, unreliable sensor measurements can be replaced by using the VC^3 idea. One disadvantage of using higher-order statistics-based methods is that sample estimates of higher-order statistics require longer data lengths than covariances; hence, computational complexity is increased. In their recent study, Cardoso and Moulines [2] present a comparative performance analysis of second- and fourth-order statistics-based MUSIC methods. Their results indicate that dynamic range of the sources may be a factor limiting the performance of the fourth-order statistics-based MUSIC. A comprehensive performance analysis of the above higher-order statistical methods is still lacking; therefore, a detailed comparison of these methods remains as a very important research topic.

62.5 Flowchart Comparison of Subspace-Based Methods

Clearly, there are many subspace-based direction finding methods. In order to see the forest from the trees, to know when to use a second-order or a higher-order statistics-based method, we present Figs. 62.4 through 62.9. These figures provide a comprehensive summary of the existing subspace-based methods for direction finding and constitute guidelines to selection of a proper direction-finding method for a given application.

Note that: Fig. 62.4 depicts independent sources and ULA, Fig. 62.5 depicts independent sources and NL/mixed array, Fig. 62.6 depicts coherent and correlated sources and ULA, and Fig. 62.7 depicts coherent and correlated sources and NL/mixed array.

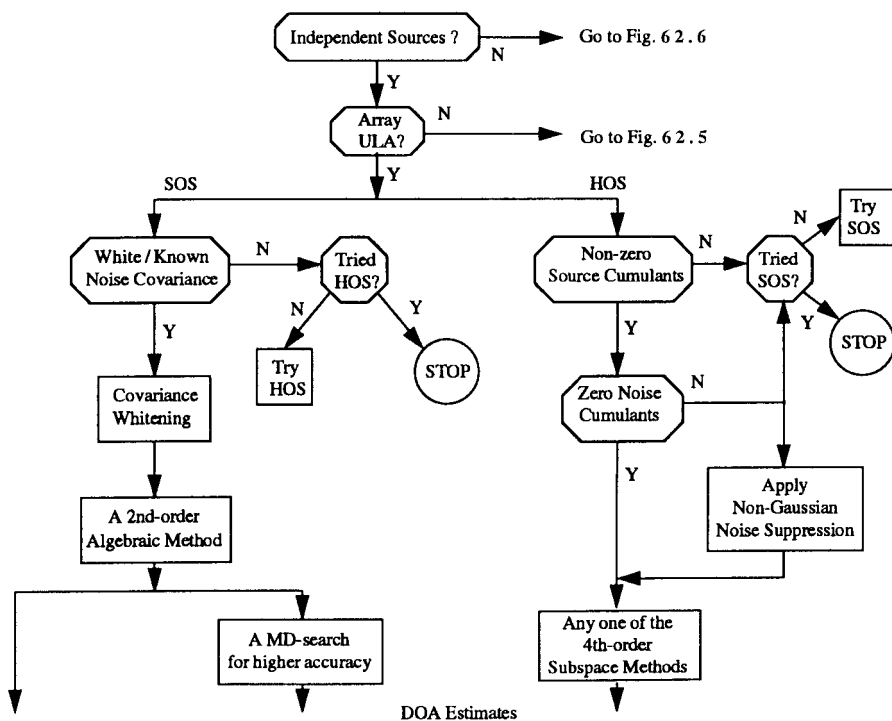

FIGURE 62.4: Second- or higher-order statistics-based subspace DF algorithm. Independent sources and ULA.

All four figures show two paths: SOS (second-order statistics) and HOS (higher-order statistics). Each path terminates in one or more method boxes, each of which may contain a multitude of methods. Figures 62.8 and 62.9 summarize the pros and cons of all the methods we have considered in this chapter.

Using Fig. 62.4 through 62.9, it is possible for a potential user of a subspace-based direction finding method to decide which method(s) is (are) most likely to give best results for his/her application.

Second-Order Statistics based Subspace Methods for Direction Finding

Signal Subspace Methods

> SNR is enhanced effectively by retaining the signal subspace only

Search Based Methods

> Select if array is calibrated or response is known analytically

Correlogram

> Lower resolution than MV and AR

Minimum Variance (MV)

> Narrower mainlobe and smoother sidelobes than conventional beamformers
> Higher resolution than Correlogram
> Lower resolution than AR
> Lower variance than AR

Autoregressive (AR)

> Higher resolution than MV and Correlogram

Subspace Fitting (SF)

> Weighted SF works regardless of source correlation, and has the same asymptotic properties as the stochastic ML method, i.e., it achieves CRB.
> Requires accurate calibration of the manifold and its derivative with respect to arrival angle

Algebraic Methods

> Select if the array is ULA or its identical copy exists
> Computationally simpler than search-based methods.

ESPRIT

> Select if the array has an identical copy
> Computationally simple as compared to search based methods
> Sensitive to perturbations in the sensor response and array geometry
> LS and TLS versions are best. They have the same asymptotic performance, but TLS converges faster and is better than LS for low SNR and short data lengths

Toeplitz Approximation Method (TAM)

> Equivalent to LS-ESPRIT

GEESE

> Better than ESPRIT

Noise Subspace Methods

> Methods are based on the orthogonality of steering vectors and noise subspace eigenvectors

Search Based Methods

> Select if array is calibrated or response is known analytically

Eigenvector (EV)

> Produces fewer spurious peaks than MUSIC
> Shapes the noise spectrum better than MUSIC

Pisarenko

> Performance with short data is poor

MUSIC

> Better than MV
> Same asymptotic performance as the deterministic ML for uncorrelated sources

Minimum Norm

> Select if the array is ULA
> Lower SNR threshold than MUSIC for resolution of closely spaced sources

Method of Direction Estimation (MODE)

> Consistent for ergodic and stationary signals

Algebraic Methods

> Select if the array is ULA
> Algebraic versions of EV, Pisarenko, MUSIC and Minimum Norm are possible
> Better resolution than search-based versions

Root MUSIC

> Lower SNR threshold than MUSIC for resolution of closely spaced sources
> Simple root-finding procedure

FIGURE 62.8: Pros and cons of all the methods considered.

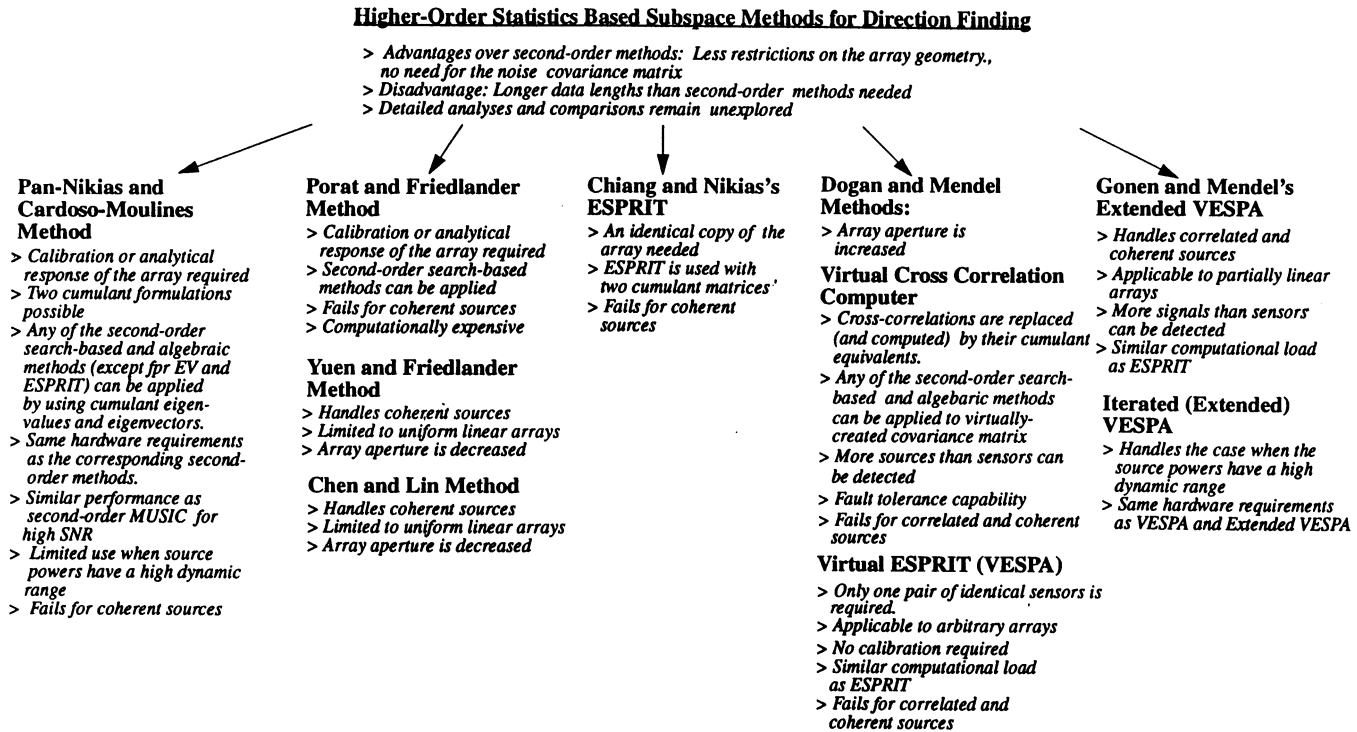

FIGURE 62.9: Pros and cons of all the methods considered.

63.1 Introduction

Estimating the directions of arrival (DOAs) of propagating plane waves is a requirement in a variety of applications including radar, mobile communications, sonar, and seismology. Due to its simplicity and high-resolution capability, *ESPRIT (Estimation of Signal Parameters via Rotational Invariance Techniques)* [18] has become one of the most popular signal subspace-based DOA or spatial frequency estimation schemes. ESPRIT is explicitly premised on a point source model for the sources and is restricted to use with array geometries that exhibit so-called invariances [18]. However, this requirement is not very restrictive as many of the common array geometries used in practice exhibit these invariances, or their output may be transformed to effect these invariances.

ESPRIT may be viewed as a complement to the MUSIC algorithm, the forerunner of all signal subspace-based DOA methods, in that it is based on properties of the signal eigenvectors whereas MUSIC is based on properties of the noise eigenvectors. This chapter concentrates solely on the use of ESPRIT to estimate the DOAs of plane waves incident upon an antenna array. It should be noted, though, that ESPRIT may be used in the dual problem of estimating the frequencies of sinusoids embedded in a time series [18]. In this application, ESPRIT is more generally applicable than MUSIC as it can handle damped sinusoids and provides estimates of the damping factors as well

as the constituent frequencies. The standard ESPRIT algorithm for one-dimensional (1-D) arrays is reviewed in Section 63.2. There are three primary steps in any ESPRIT-type algorithm:

- 1. Signal Subspace Estimation** computation of a basis for the estimated signal subspace,
- 2. Solution of the Invariance Equation** solution of an (in general) overdetermined system of equations, the so-called invariance equation, derived from the basis matrix estimated in Step 1, and
- 3. Spatial Frequency Estimation** computation of the eigenvalues of the solution of the invariance equation formed in Step 2.

Many antenna arrays used in practice have geometries that possess some form of symmetry. For example, a linear array of equi-spaced identical antennas is symmetric about the center of the linear aperture it occupies. In Section 63.3.1, an efficient implementation of ESPRIT is presented that exploits the symmetry present in so-called centro-symmetric arrays to formulate the three steps of ESPRIT in terms of real-valued computations, despite the fact that the input to the algorithm needs to be the complex analytic signal output from each antenna. This reduces the computational complexity significantly. A reduced dimension beamspace version of ESPRIT is developed in Section 63.3.2. Advantages to working in beamspace include reduced computational complexity [3], decreased sensitivity to array imperfections [1], and lower SNR resolution thresholds [11].

With a 1-D array, one can only estimate the angle of each incident plane wave relative to the array axis. For source localization purposes, this only places the source on a cone whose axis of symmetry is the array axis. The use of a 2-D or planar array enables one to passively estimate the 2-D arrival angles of each emitting source. The remainder of the chapter presents ESPRIT-based techniques for use in conjunction with circular and rectangular arrays that provide estimates of the azimuth and elevation angle of each incident signal. As in the 1-D case, the symmetries present in these array geometries are exploited to formulate the three primary steps of ESPRIT in terms of real-valued computations.

63.1.1 Notation

Throughout this chapter, column vectors and matrices are denoted by lower case and upper case boldfaced letters, respectively. For any positive integer p , \mathbf{I}_p is the $p \times p$ identity matrix and $\mathbf{\Pi}_p$ the $p \times p$ exchange matrix with ones on its antidiagonal and zeros elsewhere,

$$\mathbf{\Pi}_p = \begin{bmatrix} & & & 1 \\ & & 1 & \\ & . & & \\ 1 & & & \end{bmatrix} \in \mathbb{R}^{p \times p}. \quad (63.1)$$

Pre-multiplication of a matrix by $\mathbf{\Pi}_p$ will reverse the order of its rows, while post-multiplication of a matrix by $\mathbf{\Pi}_p$ reverses the order of its columns. Furthermore, the superscripts $(\cdot)^H$ and $(\cdot)^T$ denote complex conjugate transposition and transposition without complex conjugation, respectively. Complex conjugation by itself is denoted by an overbar $\overline{(\cdot)}$, such that $X^H = \overline{X}^T$. A diagonal matrix $\mathbf{\Phi}$ with the diagonal elements $\phi_1, \phi_2, \dots, \phi_d$ may be written as

$$\mathbf{\Phi} = \text{diag} \{\phi_i\}_{i=1}^d = \begin{bmatrix} \phi_1 & & & \\ & \phi_2 & & \\ & & . & \\ & & & \phi_d \end{bmatrix} \in \mathbb{C}^{d \times d}.$$

Moreover, matrices $\mathbf{Q} \in \mathbb{C}^{p \times q}$ satisfying

$$\mathbf{\Pi}_p \overline{\mathbf{Q}} = \mathbf{Q} \quad (63.2)$$

will be called left $\mathbf{\Pi}$ -real [10]. Often left $\mathbf{\Pi}$ -real matrices are also called conjugate centro-symmetric [24].

63.2 The Standard ESPRIT Algorithm

The algorithm ESPRIT [18] must be used in conjunction with an M -element sensor array composed of m pairs of pairwise identical, but displaced, sensors (doublets) as depicted in Fig. 63.1. If the subarrays do not overlap, i.e., if they do not share any elements, $M = 2m$, but in general $M \leq 2m$ since overlapping subarrays are allowed, cf. Fig. 63.2. Let Δ denote the distance between the two subarrays. Incident on both subarrays are d narrowband noncoherent¹ planar wavefronts with distinct directions

FIGURE 63.1: Planar array composed of $m = 3$ pairwise identical, but displaced, sensors (doublets).

of arrival (DOAs) θ_i , $1 \leq i \leq d$, relative to the displacement between the two subarrays.² Their complex pre-envelope at an arbitrary reference point may be expressed as $s_i(t) = \alpha_i(t)e^{j(2\pi f_c t + \beta_i(t))}$, where f_c denotes the common carrier frequency of the d wavefronts. Without loss of generality, we assume that the reference point is the array centroid. The signals are called *narrowband* if their amplitudes $\alpha_i(t)$ and phases $\beta_i(t)$ vary slowly with respect to the propagation time across the array τ , i.e., if

$$\alpha_i(t - \tau) \approx \alpha_i(t) \quad \text{and} \quad \beta_i(t - \tau) \approx \beta_i(t). \quad (63.3)$$

In other words, the narrowband assumption allows the time-delay of the signals across the array τ to be modeled as a simple phase shift of the carrier frequency, such that

$$s_i(t - \tau) \approx \alpha_i(t)e^{j(2\pi f_c(t - \tau) + \beta_i(t))} = e^{-j2\pi f_c \tau} s_i(t).$$

Figure 63.1 shows that the propagation delay of a plane wave signal between the two identical sensors of a doublet equals $\tau_i = \frac{\Delta \sin \theta_i}{c}$, where c denotes the signal propagation velocity. Due to the narrowband assumption (63.3), this propagation delay τ_i corresponds to the multiplication of the complex envelope signal by the complex exponential $e^{j\mu_i}$, referred to as the phase factor, such that

$$s_i(t - \tau_i) = e^{-j\frac{2\pi f_c}{c} \Delta \sin \theta_i} s_i(t) = e^{j\mu_i} s_i(t), \quad (63.4)$$

where the *spatial frequencies* μ_i are given by $\mu_i = -\frac{2\pi}{\lambda} \Delta \sin \theta_i$. Here, $\lambda = \frac{c}{f_c}$ denotes the common wavelength of the signals. We also assume that there is a one-to-one correspondence between the

¹ This restriction can be modified later as Unitary ESPRIT can estimate the directions of arrival of two coherent wavefronts due to an inherent forward-backward averaging effect. Two wavefronts are called *coherent* if their cross-correlation coefficient has magnitude one. The directions of arrival of *more than two* coherent wavefronts can be estimated by using spatial smoothing as a preprocessing step.

² $\theta_k = 0$ corresponds to the direction perpendicular to Δ .

spatial frequencies $-\pi < \mu_i < \pi$ and the range of possible DOAs. Thus, the maximum range is achieved for $\Delta \leq \lambda/2$. In this case, the DOAs are restricted to the interval $-90^\circ < \theta_i < 90^\circ$ to avoid ambiguities.

In the sequel, the d impinging signals $s_i(t)$, $1 \leq i \leq d$, are combined to a column vector $s(t)$. Then the noise-corrupted measurements taken at the M sensors at time t obey the linear model

$$\mathbf{x}(t) = \begin{bmatrix} \mathbf{a}(\mu_1) & \mathbf{a}(\mu_2) & \cdots & \mathbf{a}(\mu_d) \end{bmatrix} \begin{bmatrix} s_1(t) \\ s_2(t) \\ \vdots \\ s_d(t) \end{bmatrix} + \mathbf{n}(t) = \mathbf{A}s(t) + \mathbf{n}(t) \in \mathbb{C}^M, \quad (63.5)$$

where the columns of the array steering matrix $\mathbf{A} \in \mathbb{C}^{M \times d}$, the array response or array steering vectors $\mathbf{a}(\mu_i)$, are functions of the unknown spatial frequencies μ_i , $1 \leq i \leq d$. For example, for a uniform linear array (ULA) of M identical omnidirectional antennas,

$$\mathbf{a}(\mu_i) = e^{-j\left(\frac{M-1}{2}\right)\mu_i} \begin{bmatrix} 1 & e^{j\mu_i} & e^{j2\mu_i} & \cdots & e^{j(M-1)\mu_i} \end{bmatrix}^T, \quad 1 \leq i \leq d.$$

Moreover, the additive noise vector $\mathbf{n}(t)$ is taken from a zero-mean, spatially uncorrelated random process with variance σ_N^2 , which is also uncorrelated with the signals. Since every row of \mathbf{A} corresponds to an element of the sensor array, a particular subarray configuration can be described by two selection matrices, each choosing m elements of $\mathbf{x}(t) \in \mathbb{C}^M$, where m , $d \leq m < M$, is the number of elements in each subarray. Figure 63.2, for example, displays the appropriate subarray choices for three centro-symmetric arrays of $M = 6$ identical sensors.

FIGURE 63.2: Three centro-symmetric line arrays of $M = 6$ identical sensors and the corresponding subarrays required for ESPRIT-type algorithms.

In case of a ULA with maximum overlap, cf. Figure 63.2 (a), \mathbf{J}_1 picks the first $m = M - 1$ rows of \mathbf{A} , while \mathbf{J}_2 selects the last $m = M - 1$ rows of the array steering matrix. In this case, the corresponding selection matrices are given by

$$\mathbf{J}_1 = \begin{bmatrix} 1 & 0 & 0 & \cdots & 0 & 0 \\ 0 & 1 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & 0 \end{bmatrix} \in \mathbb{R}^{m \times M} \quad \text{and} \quad \mathbf{J}_2 = \begin{bmatrix} 0 & 1 & 0 & \cdots & 0 & 0 \\ 0 & 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 0 & 1 \end{bmatrix} \in \mathbb{R}^{m \times M}.$$

Notice that \mathbf{J}_1 and \mathbf{J}_2 are centro-symmetric with respect to one another, i.e., they obey $\mathbf{J}_2 = \mathbf{\Pi}_m \mathbf{J}_1 \mathbf{\Pi}_M$. This property holds for all centro-symmetric arrays and plays a key role in the derivation of Unitary ESPRIT [7]. Since we have two identical, but physically displaced subarrays, Eq. (63.4) indicates that an array steering vector of the *second* subarray $\mathbf{J}_2 \mathbf{a}(\mu_i)$ is just a scaled version of the corresponding array steering vector of the *first* subarray $\mathbf{J}_1 \mathbf{a}(\mu_i)$, namely

$$\mathbf{J}_1 \mathbf{a}(\mu_i) e^{j\mu_i} = \mathbf{J}_2 \mathbf{a}(\mu_i), \quad 1 \leq i \leq d. \quad (63.6)$$

This *shift invariance property* of all d array steering vectors $\mathbf{a}(\mu_i)$ may be expressed in compact form as

$$\mathbf{J}_1 \mathbf{A} \Phi = \mathbf{J}_2 \mathbf{A}, \quad \text{where} \quad \Phi = \text{diag} \{e^{j\mu_i}\}_{i=1}^d \quad (63.7)$$

is the unitary diagonal $d \times d$ matrix of the phase factors. All ESPRIT-type algorithms are based on this invariance property of the array steering matrix \mathbf{A} , where \mathbf{A} is assumed to have full column rank d .

Let \mathbf{X} denote an $M \times N$ complex data matrix composed of N snapshots $\mathbf{x}(t_n)$, $1 \leq n \leq N$,

$$\begin{aligned} \mathbf{X} &= [\mathbf{x}(t_1) \quad \mathbf{x}(t_2) \quad \cdots \quad \mathbf{x}(t_N)] \\ &= \mathbf{A} [\mathbf{s}(t_1) \quad \mathbf{s}(t_2) \quad \cdots \quad \mathbf{s}(t_N)] + [\mathbf{n}(t_1) \quad \mathbf{n}(t_2) \quad \cdots \quad \mathbf{n}(t_N)] \\ &= \mathbf{A} \cdot \mathbf{S} + \mathbf{N} \in \mathbb{C}^{M \times N}. \end{aligned} \quad (63.8)$$

The starting point is a singular value decomposition (SVD) of the noise-corrupted data matrix \mathbf{X} (direct data approach). Assume that $\mathbf{U}_s \in \mathbb{C}^{M \times d}$ contains the d left singular vectors corresponding to the d largest singular values of \mathbf{X} . Alternatively, \mathbf{U}_s can be obtained via an eigendecomposition of the (scaled) sample covariance matrix $\mathbf{X}\mathbf{X}^H$ (covariance approach). Then, $\mathbf{U}_s \in \mathbb{C}^{M \times d}$ contains the d eigenvectors corresponding to the d largest eigenvalues of $\mathbf{X}\mathbf{X}^H$.

Asymptotically, i.e., as the number of snapshots N becomes infinitely large, the range space of \mathbf{U}_s is the d -dimensional range space of the array steering matrix \mathbf{A} referred to as the *signal subspace*. Therefore, there exists a nonsingular $d \times d$ matrix \mathbf{T} such that $\mathbf{A} \approx \mathbf{U}_s \mathbf{T}$. Let us express the shift-invariance property (63.7) in terms of the matrix \mathbf{U}_s that spans the estimated signal subspace,

$$\mathbf{J}_1 \mathbf{U}_s \mathbf{T} \Phi \approx \mathbf{J}_2 \mathbf{U}_s \mathbf{T} \iff \mathbf{J}_1 \mathbf{U}_s \Psi \approx \mathbf{J}_2 \mathbf{U}_s, \quad \text{where} \quad \Psi = \mathbf{T} \Phi \mathbf{T}^{-1}$$

is a nonsingular $d \times d$ matrix. Since Φ in Eq. (63.7) is diagonal, $\mathbf{T} \Phi \mathbf{T}^{-1}$ is in the form of an eigenvalue decomposition. This implies that $e^{j\mu_i}$, $1 \leq i \leq d$, are the eigenvalues of Ψ . These observations form the basis for the subsequent steps of the algorithm. By applying the two selection matrices to the signal subspace matrix, the following (in general) overdetermined set of equations is formed,

$$\mathbf{J}_1 \mathbf{U}_s \Psi \approx \mathbf{J}_2 \mathbf{U}_s \in \mathbb{C}^{m \times d}. \quad (63.9)$$

This set of equations, the so-called invariance equation, is usually solved in the least squares (LS) or total least squares (TLS) sense. Notice, however, that Eq. (63.9) is highly structured if overlapping subarray configurations are used. Structured least squares (SLS) is a new algorithm to solve the invariance equation by preserving its structure [8]. Formally, SLS was derived as a linearized iterative solution of a nonlinear optimization problem. If SLS is initialized with the LS solution of the invariance equation, only one “iteration”, i.e., the solution of one linear system of equations, is required to achieve a significant improvement of the estimation accuracy [8].

Then an eigendecomposition of the resulting solution $\Psi \in \mathbb{C}^{d \times d}$ may be expressed as

$$\Psi = \mathbf{T} \Phi \mathbf{T}^{-1} \quad \text{with} \quad \Phi = \text{diag} \{\phi_i\}_{i=1}^d. \quad (63.10)$$

The eigenvalues ϕ_i , i.e., the diagonal elements of Φ , represent estimates of the phase factors $e^{j\mu_i}$. Notice that the ϕ_i are not guaranteed to be on the unit circle. Notwithstanding, estimates of the spatial frequencies μ_i and the corresponding DOAs θ_i are obtained via the relationships,

$$\mu_i = \arg(\phi_i) \quad \text{and} \quad \theta_i = -\frac{\lambda}{2\pi \Delta} \arcsin(\mu_i), \quad 1 \leq i \leq d. \quad (63.11)$$

To end this section, a brief summary of the standard ESPRIT algorithm is given in Table 63.1.

TABLE 63.1 Summary of the Standard ESPRIT Algorithm

1. *Signal Subspace Estimation:* Compute $U_s \in \mathbb{C}^{M \times d}$ as the d dominant left singular vectors of $X \in \mathbb{C}^{M \times N}$.
2. *Solution of the Invariance Equation:* Solve

$$\underbrace{J_1 U_s}_{\mathbb{C}^{m \times d}} \Psi \approx \underbrace{J_2 U_s}_{\mathbb{C}^{m \times d}}$$

by means of LS, TLS, or SLS.

3. *Spatial Frequency Estimation:* Calculate the eigenvalues of the resulting complex-valued solution

$$\Psi = T \Phi T^{-1} \in \mathbb{C}^{d \times d} \quad \text{with} \quad \Phi = \text{diag} \{ \phi_i \}_{i=1}^d$$

- $\mu_i = \arg(\phi_i)$, $1 \leq i \leq d$

63.3 1-D Unitary ESPRIT

In contrast to the standard ESPRIT algorithm, Unitary ESPRIT is efficiently formulated in terms of real-valued computations throughout [7]. It is applicable to centro-symmetric array configurations that possess the discussed invariance structure, cf. Figs. 63.1 and 63.2. A sensor array is called *centro-symmetric* [23] if its element locations are symmetric with respect to the centroid. If the sensor elements have identical radiation characteristics, the array steering matrix of a centro-symmetric array satisfies

$$\Pi_M \bar{A} = A, \quad (63.12)$$

since the array centroid is chosen as the phase reference.

63.3.1 1-D Unitary ESPRIT in Element Space

Before presenting an efficient element space implementation of Unitary ESPRIT, let us define the sparse unitary matrices

$$Q_{2n} = \frac{1}{\sqrt{2}} \begin{bmatrix} I_n & jI_n \\ \Pi_n & -j\Pi_n \end{bmatrix} \quad \text{and} \quad Q_{2n+1} = \frac{1}{\sqrt{2}} \begin{bmatrix} I_n & \mathbf{0} & jI_n \\ \mathbf{0}^T & \sqrt{2} & \mathbf{0}^T \\ \Pi_n & \mathbf{0} & -j\Pi_n \end{bmatrix}. \quad (63.13)$$

They are left Π -real matrices of even and odd order, respectively.

Since Unitary ESPRIT involves forward-backward averaging, it can efficiently be formulated in terms of real-valued computations throughout, due to a one-to-one mapping between centro-Hermitian and real matrices [10]. The forward-backward averaged sample covariance matrix is centro-Hermitian and can, therefore, be transformed into a real-valued matrix of the same size, cf. [12], [15], and [7]. A real-valued square-root factor of this transformed sample covariance matrix is given by

$$\mathcal{T}(X) = Q_M^H \begin{bmatrix} X & \Pi_M \bar{X} \Pi_N \end{bmatrix} Q_{2N} \in \mathbb{R}^{M \times 2N}, \quad (63.14)$$

where Q_M and Q_{2N} were defined in Eq. (63.13).³ If M is even, an efficient computation of $\mathcal{T}(X)$ from the complex-valued data matrix X only requires $M \times 2N$ real additions and no multiplication [7]. Instead of computing a complex-valued SVD as in the standard ESPRIT case, the signal subspace estimate is obtained via a real-valued SVD of $\mathcal{T}(X)$ (direct data approach). Let $E_s \in \mathbb{R}^{M \times d}$ contain the d left singular vectors corresponding to the d largest singular values of $\mathcal{T}(X)$.⁴ Then the columns

³ The results of this chapter also hold if Q_M and Q_{2N} denote arbitrary left Π -real matrices that are also unitary.

⁴ Alternatively, E_s can be obtained through a real-valued eigendecomposition of $\mathcal{T}(X)\mathcal{T}(X)^H$ (covariance approach).

of

$$\mathbf{U}_s = \mathbf{Q}_M \mathbf{E}_s \quad (63.15)$$

span the estimated signal subspace, and spatial frequency estimates could be obtained from the eigenvalues of the complex-valued matrix $\mathbf{\Psi}$ that solves Eq. (63.9). These complex-valued computations, however, are not required because the transformed array steering matrix

$$\mathbf{D} = \mathbf{Q}_M^H \mathbf{A} = \begin{bmatrix} \mathbf{d}(\mu_1) & \mathbf{d}(\mu_2) & \cdots & \mathbf{d}(\mu_d) \end{bmatrix} \in \mathbb{R}^{M \times d} \quad (63.16)$$

satisfies the following shift invariance property

$$\mathbf{K}_1 \mathbf{D} \mathbf{\Omega} = \mathbf{K}_2 \mathbf{D}, \quad \text{where} \quad \mathbf{\Omega} = \text{diag} \left\{ \tan \left(\frac{\mu_i}{2} \right) \right\}_{i=1}^d \quad (63.17)$$

and the transformed selection matrices \mathbf{K}_1 and \mathbf{K}_2 are given by

$$\mathbf{K}_1 = 2 \cdot \text{Re}\{\mathbf{Q}_m^H \mathbf{J}_2 \mathbf{Q}_M\} \quad \text{and} \quad \mathbf{K}_2 = 2 \cdot \text{Im}\{\mathbf{Q}_m^H \mathbf{J}_2 \mathbf{Q}_M\}. \quad (63.18)$$

Here, $\text{Re}\{\cdot\}$ and $\text{Im}\{\cdot\}$ denote the real and the imaginary part, respectively. Notice that Eq. (63.17) is similar to Eq. (63.7) except for the fact that all matrices in Eq. (63.17) are real-valued.

Let us take a closer look at the transformed selection matrices defined in Eq. (63.18). If \mathbf{J}_2 is sparse, \mathbf{K}_1 and \mathbf{K}_2 are also sparse. This is illustrated by the following example. For the ULA with $M = 6$ sensors and maximum overlap sketched in Fig. 63.2 (a), \mathbf{J}_2 is given by

$$\mathbf{J}_2 = \begin{bmatrix} 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \in \mathbb{R}^{5 \times 6}.$$

According to Eq. (63.18), straightforward calculations yield the transformed selection matrices

$$\mathbf{K}_1 = \begin{bmatrix} 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & \sqrt{2} & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 \end{bmatrix} \quad \text{and} \quad \mathbf{K}_2 = \begin{bmatrix} 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & 0 & 0 & 0 & -1 & 1 \\ 0 & 0 & 0 & 0 & 0 & -\sqrt{2} \\ 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 1 & -1 & 0 & 0 & 0 \end{bmatrix}.$$

In this case, applying \mathbf{K}_1 or \mathbf{K}_2 to \mathbf{E}_s only requires $(m-1)d$ real additions and d real multiplications.

Asymptotically, the real-valued matrices \mathbf{E}_s and \mathbf{D} span the same d -dimensional subspace, i.e., there is a nonsingular matrix $\mathbf{T} \in \mathbb{R}^{d \times d}$ such that $\mathbf{D} \approx \mathbf{E}_s \mathbf{T}$. Substituting this into Eq. (63.17) yields the real-valued invariance equation

$$\mathbf{K}_1 \mathbf{E}_s \mathbf{\Upsilon} \approx \mathbf{K}_2 \mathbf{E}_s \in \mathbb{R}^{m \times d}, \quad \text{where} \quad \mathbf{\Upsilon} = \mathbf{T} \mathbf{\Omega} \mathbf{T}^{-1}. \quad (63.19)$$

Thus, the eigenvalues of the solution $\mathbf{\Upsilon} \in \mathbb{R}^{d \times d}$ to the matrix equation above are

$$\omega_i = \tan \left(\frac{\mu_i}{2} \right) = \frac{1}{j} \frac{e^{j\mu_i} - 1}{e^{j\mu_i} + 1}, \quad 1 \leq i \leq d. \quad (63.20)$$

This reveals a spatial frequency warping identical to the temporal frequency warping incurred in designing a digital filter from an analog filter via the bilinear transformation. Consider $\Delta = \frac{\lambda}{2}$ so that $\mu_i = -\frac{2\pi}{\lambda} \Delta \sin \theta_i = -\pi \sin \theta_i$. In this case, there is a one-to-one mapping between

$-1 < \sin \theta_i < 1$, corresponding to the range of possible values for the DOAs $-90^\circ < \theta_i < 90^\circ$, and $-\infty < \omega_i < \infty$.

Note that the fact that the eigenvalues of a real matrix have to either be real-valued or occur in complex conjugate pairs gives rise to an ad-hoc *reliability test*. That is, if the final step of the algorithm yields a complex conjugate pair of eigenvalues, then either the SNR is too low, not enough snapshots have been averaged, or two corresponding signal arrivals have not been resolved. In the latter case, taking the tangent inverse of the real part of the eigenvalues can sometimes provide a rough estimate of the direction of arrival of the two closely spaced signals. In general, though, if the algorithm yields one or more complex-conjugate pairs of eigenvalues in the final stage, the estimates should be viewed as unreliable.

The element space implementation of 1-D Unitary ESPRIT is summarized in Table 63.2.

TABLE 63.2 Summary of 1-D Unitary ESPRIT in Element Space

1. *Signal Subspace Estimation:* Compute $E_s \in \mathbb{R}^{M \times d}$ as the d dominant left singular vectors of $\mathcal{T}(X) \in \mathbb{R}^{M \times 2N}$.

2. *Solution of the Invariance Equation:* Then solve

$$\underbrace{K_1 E_s}_{\mathbb{R}^{m \times d}} \Upsilon \approx \underbrace{K_2 E_s}_{\mathbb{R}^{m \times d}}$$

by means of LS, TLS, or SLS.

3. *Spatial Frequency Estimation:* Calculate the eigenvalues of the resulting real-valued solution

$$\Upsilon = T \Omega T^{-1} \in \mathbb{R}^{d \times d} \quad \text{with} \quad \Omega = \text{diag} \{ \omega_i \}_{i=1}^d$$

$$\bullet \quad \mu_i = 2 \arctan(\omega_i), \quad 1 \leq i \leq d$$

63.3.2 1-D Unitary ESPRIT in DFT Beamspace

Reduced dimension processing in beamspace, yielding reduced computational complexity, is an option when one has *a priori* information on the general angular locations of the incident signals, as in a radar application, for example. In the case of a uniform linear array (ULA), transformation from element space to DFT beamspace may be effected by pre-multiplying the data by those rows of the DFT matrix that form beams encompassing the sector of interest. (Each row of the DFT matrix forms a beam pointed to a different angle.) If there is no *a priori* information, one may examine the DFT spectrum and apply Unitary ESPRIT in DFT beamspace to a small set of DFT values around each spectral peak above a particular threshold. In a more general setting, Unitary ESPRIT in DFT beamspace can simply be applied via parallel processing to each of a number of sets of successive DFT values corresponding to overlapping sectors.

Note, though, that in the development to follow, we will initially employ all M DFT beams for the sake of notational simplicity. Without loss of generality, we consider an omnidirectional ULA. Let $W_M^H \in \mathbb{C}^{M \times M}$ be the scaled M -point DFT matrix with its M rows given by

$$w_k^H = e^{j\left(\frac{M-1}{2}\right)k\frac{2\pi}{M}} \begin{bmatrix} 1 & e^{-jk\frac{2\pi}{M}} & e^{-j2k\frac{2\pi}{M}} & \dots & e^{-j(M-1)k\frac{2\pi}{M}} \end{bmatrix}, \quad 0 \leq k \leq (M-1). \quad (63.21)$$

Notice that W_M is left Π -real or column conjugate symmetric, i.e., $\Pi_M \bar{W}_M = W_M$. Thus, as pointed out for D in Eq. (63.16), the transformed steering matrix of the ULA

$$B = W_M^H A = \begin{bmatrix} b(\mu_1) & b(\mu_2) & \dots & b(\mu_d) \end{bmatrix} \in \mathbb{R}^{M \times d} \quad (63.22)$$

is real-valued. It has been shown in [24] that \mathbf{B} satisfies a shift invariance property which is similar to Eq. (63.17), namely

$$\mathbf{\Gamma}_1 \mathbf{B} \mathbf{\Omega} = \mathbf{\Gamma}_2 \mathbf{B}, \quad \text{where} \quad \mathbf{\Omega} = \text{diag} \left\{ \tan \left(\frac{\mu_i}{2} \right) \right\}_{i=1}^d. \quad (63.23)$$

Here, the selection matrices $\mathbf{\Gamma}_1$ and $\mathbf{\Gamma}_2$ of size $M \times M$ are defined as

$$\mathbf{\Gamma}_1 = \begin{bmatrix} 1 & \cos\left(\frac{\pi}{M}\right) & 0 & 0 & \cdots & 0 & 0 \\ 0 & \cos\left(\frac{\pi}{M}\right) & \cos\left(\frac{2\pi}{M}\right) & 0 & \cdots & 0 & 0 \\ 0 & 0 & \cos\left(\frac{2\pi}{M}\right) & \cos\left(\frac{3\pi}{M}\right) & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & \cos\left((M-2)\frac{\pi}{M}\right) & \cos\left((M-1)\frac{\pi}{M}\right) \\ (-1)^M & 0 & 0 & 0 & \cdots & 0 & \cos\left((M-1)\frac{\pi}{M}\right) \end{bmatrix} \quad (63.24)$$

$$\mathbf{\Gamma}_2 = \begin{bmatrix} 0 & \sin\left(\frac{\pi}{M}\right) & 0 & 0 & \cdots & 0 & 0 \\ 0 & \sin\left(\frac{\pi}{M}\right) & \sin\left(\frac{2\pi}{M}\right) & 0 & \cdots & 0 & 0 \\ 0 & 0 & \sin\left(\frac{2\pi}{M}\right) & \sin\left(\frac{3\pi}{M}\right) & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \cdots & \sin\left((M-2)\frac{\pi}{M}\right) & \sin\left((M-1)\frac{\pi}{M}\right) \\ 0 & 0 & 0 & 0 & \cdots & 0 & \sin\left((M-1)\frac{\pi}{M}\right) \end{bmatrix}. \quad (63.25)$$

As an alternative to Eq. (63.14), another real-valued square-root factor of the transformed sample covariance matrix is given by

$$\begin{bmatrix} \text{Re}\{\mathbf{Y}\} & \text{Im}\{\mathbf{Y}\} \end{bmatrix} \in \mathbb{R}^{M \times 2N}, \quad \text{where} \quad \mathbf{Y} = \mathbf{W}_M^H \mathbf{X} \in \mathbb{C}^{M \times N}. \quad (63.26)$$

The matrix \mathbf{Y} can efficiently be computed via an FFT, which exploits the Vandermonde form of the rows of the DFT matrix, followed by an appropriate scaling, cf. Eq. (63.21). Let the columns of $\mathbf{E}_s \in \mathbb{R}^{M \times d}$ contain the d left singular vectors corresponding to the d largest singular values of Eq. (63.26). Asymptotically, the real-valued matrices \mathbf{E}_s and \mathbf{B} span the same d -dimensional subspace, i.e., there is a nonsingular matrix $\mathbf{T} \in \mathbb{R}^{d \times d}$, such that $\mathbf{B} \approx \mathbf{E}_s \mathbf{T}$. Substituting this into Eq. (63.23), yields the real-valued invariance equation

$$\mathbf{\Gamma}_1 \mathbf{E}_s \mathbf{\Upsilon} \approx \mathbf{\Gamma}_2 \mathbf{E}_s \in \mathbb{R}^{M \times d}, \quad \text{where} \quad \mathbf{\Upsilon} = \mathbf{T} \mathbf{\Omega} \mathbf{T}^{-1}. \quad (63.27)$$

Thus, the eigenvalues of the solution $\mathbf{\Upsilon} \in \mathbb{R}^{d \times d}$ to the matrix equation above are also given by Eq. (63.20).

It is a crucial observation that one row of the matrix equation (63.23) relates *two successive components* of the transformed array steering vectors $\mathbf{b}(\mu_i)$, cf. (63.24) and (63.25). This insight enables us to apply only $B \ll M$ successive rows of \mathbf{W}_M^H (instead of all M rows) to the data matrix \mathbf{X} in Eq. (63.26). To stress the reduced number of rows, we call the resulting beamforming matrix $\mathbf{W}_B^H \in \mathbb{C}^{B \times M}$. The number of its rows, B , depends on the width of the sector of interest and may be substantially less than the number of sensors M . Thereby, the SVD of Eq. (63.26) and, therefore, also $\mathbf{E}_s \in \mathbb{R}^{B \times d}$ and the invariance equation (63.27) will have a reduced dimensionality. Employing the appropriate subblocks of $\mathbf{\Gamma}_1$ and $\mathbf{\Gamma}_2$ as selection matrices, the algorithm is the same as the one described previously except for its reduced dimensionality. In the sequel, the resulting selection matrices of size $(B-1) \times B$ will be called $\mathbf{\Gamma}_1^{(B)}$ and $\mathbf{\Gamma}_2^{(B)}$. The whole algorithm that operates in a B -dimensional DFT beamspace is summarized in Table 63.3.

Consider, for example, a ULA of $M = 8$ sensors. The structure of the corresponding selection matrices $\mathbf{\Gamma}_1$ and $\mathbf{\Gamma}_2$ is sketched in Fig. 63.3. Here, the symbol \times denotes entries of both selection matrices that might be nonzero, cf. (63.24) and (63.25). If one employed rows 4, 5, and 6 of \mathbf{W}_8^H to form $B = 3$ beams in estimating the DOAs of two closely spaced signal arrivals, as in the low-angle

TABLE 63.3 Summary of 1-D Unitary ESPRIT in DFT Beamspace

0. *Transformation to Beamspace:* $Y = W_B^H X \in \mathbb{C}^{B \times N}$

1. *Signal Subspace Estimation:* Compute $E_s \in \mathbb{R}^{B \times d}$ as the d dominant left singular vectors of $\begin{bmatrix} \text{Re}\{Y\} & \text{Im}\{Y\} \end{bmatrix} \in \mathbb{R}^{B \times 2N}$.

2. *Solution of the Invariance Equation:* Solve

$$\underbrace{\Gamma_1^{(B)} E_s}_{\mathbb{R}^{(B-1) \times d}} \Upsilon \approx \underbrace{\Gamma_2^{(B)} E_s}_{\mathbb{R}^{(B-1) \times d}}$$

by means of LS, TLS, or SLS.

3. *Spatial Frequency Estimation:* Calculate the eigenvalues of the resulting real-valued solution

$$\Upsilon = T \Omega T^{-1} \in \mathbb{R}^{d \times d} \quad \text{with} \quad \Omega = \text{diag} \{\omega_i\}_{i=1}^d$$

$$\bullet \quad \mu_i = 2 \arctan(\omega_i), \quad 1 \leq i \leq d$$

FIGURE 63.3: Structure of the selection matrices Γ_1 and Γ_2 for a ULA of $M = 8$ sensors. The symbol \times denotes entries of both selection matrices that might be nonzero. The shaded areas illustrate how to choose the appropriate subblocks of the selection matrices for reduced dimension processing, i.e., how to form $\Gamma_1^{(B)}$ and $\Gamma_2^{(B)}$, if only $B = 3$ successive rows of W_8^H are applied to the data matrix X . Here, the following two examples are used: (a) rows 4, 5, and 6. (b) rows 8, 1, and 2.

radar tracking scheme described by Zoltowski and Lee [26], the corresponding 2×3 subblock of the selection matrices Γ_1 and Γ_2 is shaded in Fig. 63.3 (a).⁵ Notice that the first and the last (M th) row of W_M^H steer beams that are also physically adjacent to one another (the wrap-around property of the DFT). If, for example, one employed rows 8, 1, and 2 of W_8^H to form $B = 3$ beams in estimating the DOAs of two closely spaced signal arrivals, the corresponding subblocks of the selection matrices Γ_1 and Γ_2 are shaded in Fig. 63.3 (b).⁶

⁵ Here, the first row of $\Gamma_1^{(3)}$ and $\Gamma_2^{(3)}$ combines beams 4 and 5, while the second row of $\Gamma_1^{(3)}$ and $\Gamma_2^{(3)}$ combines beams 5 and 6.

⁶ Here, the first row of $\Gamma_1^{(3)}$ and $\Gamma_2^{(3)}$ combines beams 1 and 2, while the second row of $\Gamma_1^{(3)}$ and $\Gamma_2^{(3)}$ combines beams 1 and 8.

63.4 UCA-ESPRIT for Circular Ring Arrays

FIGURE 63.4: Definitions of azimuth ($-180^\circ < \phi_i \leq 180^\circ$) and elevation ($0^\circ \leq \theta_i \leq 90^\circ$). The direction cosines u_i and v_i are the rectangular coordinates of the projection of the corresponding point on the unit ball onto the equatorial plane.

UCA-ESPRIT [15, 16, 17] is a 2-D angle estimation algorithm developed for use with uniform circular arrays (UCAs). The algorithm provides automatically paired azimuth and elevation angle estimates of far-field signals incident on the UCA via a closed-form procedure. The rotational symmetry of the UCA makes it desirable for a variety of applications where one needs to discriminate in both azimuth and elevation, as opposed to just conical angle of arrival which is all the ULA can discriminate on. For example, UCAs are commonly employed as part of an anti-jam spatial filter for GPS receivers. Some experimental UCA based systems are described in [4]. The development of a closed-form 2-D angle estimation technique for a UCA provides further motivation for the use of a UCA in a given application.

Consider an M element UCA in which the array elements are uniformly distributed over the circumference of a circle of radius R . We will assume that the array is located in the x - y plane, with its center at the origin of the coordinate system. The elevation angles θ_i and azimuth angles ϕ_i of the d impinging sources are defined in Fig. 63.4, as are the direction cosines u_i and v_i , $1 \leq i \leq d$. UCA-ESPRIT is premised on phase mode excitation-based beamforming. The maximum phase mode (integer valued) excitable by a given UCA is

$$K \approx \frac{2\pi R}{\lambda},$$

where λ is the common (carrier) wavelength of the incident signals. Phase mode excitation-based beamforming requires $M > 2K$ array elements ($M = 2K + 3$ is usually adequate). UCA-ESPRIT can resolve a maximum of $d_{\max} = K - 1$ sources. As an example, if the array radius is $r = \lambda$, $K = 6$ (the largest integer smaller than 2π) and at least $M = 15$ array elements are needed. UCA-ESPRIT can resolve five sources in conjunction with this UCA.

UCA-ESPRIT operates in a $K' = 2K + 1$ dimensional beamspace. It employs a $K' \times M$ beamforming matrix to transform from element space to beamspace. After this transformation, the algorithm has the same three basic steps of any ESPRIT-type algorithm: (1) the computation of a basis for the signal subspace, (2) the solution to an (in general) overdetermined system of equations derived from

the matrix of vectors spanning the signal subspace, and (3) the computation of the eigenvalues of the solution to the system of equations formed in Step (2). As illustrated in Fig. 63.6, the i th eigenvalue obtained in the final step is ideally of the form $\xi_i = \sin \theta_i e^{j\phi_i}$, where ϕ_i and θ_i are the azimuth and elevation angles of the i th source. Note that

$$\xi_i = \sin \theta_i e^{j\phi_i} = u_i + jv_i, \quad 1 \leq i \leq d,$$

where u_i and v_i are the direction cosines of the i th source relative to the x - and y -axis, respectively, as indicated in Fig. 63.4.

The formulation of UCA-ESPRIT is based on the special structure of the resulting K' -dimensional beamspace manifold. The following vector and matrix definitions are needed to summarize the algorithm in Table 63.4.

$$\mathbf{v}_k^H = \frac{1}{M} \begin{bmatrix} 1 & e^{jk\frac{2\pi}{M}} & e^{j2k\frac{2\pi}{M}} & \dots & e^{j(M-1)k\frac{2\pi}{M}} \end{bmatrix} \quad (63.28)$$

$$\mathbf{V} = \sqrt{M} \begin{bmatrix} \mathbf{v}_{-K} & \dots & \mathbf{v}_{-1} & \mathbf{v}_0 & \mathbf{v}_1 & \dots & \mathbf{v}_K \end{bmatrix} \in \mathbb{C}^{M \times K'}$$

$$\mathbf{C}_v = \text{diag} \left\{ j^k \right\}_{k=-K}^K \in \mathbb{C}^{K' \times K'}$$

$$\mathbf{F}_r^H = \mathbf{Q}_{K'}^T \mathbf{C}_v \mathbf{V}^H \in \mathbb{C}^{K' \times M} \quad (63.29)$$

$$\mathbf{C}_o = \text{diag} \left\{ \text{sign}(k)^{-k} \right\}_{k=-K}^K \in \mathbb{R}^{K' \times K'}$$

$$\mathbf{D} = \text{diag} \left\{ (-1)^{|k|} \right\}_{k=-(K-2)}^K \in \mathbb{R}^{(K'-2) \times (K'-2)}$$

$$\mathbf{\Gamma} = \frac{\lambda}{\pi r} \cdot \text{diag} \{ k \}_{k=-(K-1)}^{(K-1)} \in \mathbb{R}^{(K'-2) \times (K'-2)}$$

Note that the columns of the matrix \mathbf{V} consist of the DFT weight vectors \mathbf{v}_k defined in Eq. (63.28). The beamforming matrix \mathbf{F}_r^H in Eq. (63.29) synthesizes a real-valued beamspace manifold and facilitates signal subspace estimation via a real-valued SVD or eigendecomposition. Recall that the sparse left Π -real matrix $\mathbf{Q}_{K'} \in \mathbb{C}^{K' \times K'}$ has been defined in Eq. (63.13). The complete UCA-ESPRIT algorithm is summarized in Table 63.4.

63.4.1 Results of Computer Simulations

Simulations were conducted with a UCA of radius $R = \lambda$, with $K = 6$ and $M = 19$ (performance close to that reported below can be expected even if $M = 15$ elements are employed). The simulation employed two sources with arrival angles given by $(\theta_1, \phi_1) = (72.73^\circ, 90^\circ)$ and $(\theta_2, \phi_2) = (50.44^\circ, 78^\circ)$. The sources were highly correlated, with the correlation coefficient referred to the center of the array being $0.9e^{j\frac{\pi}{4}}$. The signal-to-noise ratio (SNR) was 10 dB (per array element) for each source. The number of snapshots was $N = 64$, and arrival angle estimates were obtained for 200 independent trials. Figure 63.5 depicts the results of the simulation. Here, the UCA-ESPRIT eigenvalues ξ_i are denoted by the symbol \times .⁷ The results from all 200 trials are superimposed in the figure. The eigenvalues are seen to be clustered around the expected locations (the dashed circles indicate the true elevation angles).

⁷ The horizontal axis represents $\text{Re}\{\xi_i\}$, and the vertical axis represents $\text{Im}\{\xi_i\}$.

TABLE 63.4 Summary of UCA-ESPRIT

0. Transformation to Beamspace:	$Y = F_r^H X \in \mathbb{C}^{K' \times N}$
1. Signal Subspace Estimation:	Compute $E_s \in \mathbb{R}^{K' \times d}$ as the d dominant left singular vectors of $\begin{bmatrix} \text{Re}\{Y\} & \text{Im}\{Y\} \end{bmatrix} \in \mathbb{R}^{K' \times 2N}.$
2. Solution of the Invariance Equation:	<ul style="list-style-type: none"> • Compute $E_u = C_o \overline{Q}_{K'} E_s$. Form the matrix E_{-1} that consists of all but the last two rows of E_u. Similarly form the matrix E_0 that consists of all but the first and last rows of E_u. • Compute $\underline{\Psi} \in \mathbb{C}^{2d \times d}$, the least squares solution to the system $\begin{bmatrix} E_{-1} & D \Pi_{(K'-2)} \overline{E}_{-1} \end{bmatrix} \underline{\Psi} = \Gamma E_0 \in \mathbb{C}^{(K'-2) \times d}.$ <p>Recall that the overbar denotes complex conjugation. Form Ψ by extracting the upper $d \times d$ block from $\underline{\Psi}$. Note that Ψ can be computed efficiently by solving a <i>real-valued</i> system of $2d$ equations (see [17]).</p>
3. Spatial Frequency Estimation:	Compute the eigenvalues ξ_i , $1 \leq i \leq d$, of $\Psi \in \mathbb{C}^{d \times d}$. The estimates of the elevation and azimuth angles of the i th source are $\theta_i = \arcsin(\xi_i) \quad \text{and} \quad \phi_i = \arg(\xi_i),$ <p>respectively. If direction cosine estimates are desired, we have $u_i = \text{Re}\{\xi_i\} \quad \text{and} \quad v_i = \text{Im}\{\xi_i\}.$</p> <p>Again, ξ_i can be efficiently computed via a <i>real-valued</i> EVD (see [17]).</p>

63.5 FCA-ESPRIT for Filled Circular Arrays

The use of a circular ring array and the attendant use of UCA-ESPRIT is ideal for applications where the array aperture is not very large as on the top of a mobile communications unit. For much larger array apertures as in phased array surveillance radars, too much of the aperture is devoid of elements so that a lot of the signal energy impinging on the aperture is not intercepted. As an example, each of the four panels comprising either the SPY-1A or SPY-1B radars of the AEGIS series is composed of 4400 identical elements regularly spaced on a flat panel over a circular aperture [19]. The sampling lattice is hexagonal. Recent prototype arrays for satellite-based communications have also employed the filled circular array geometry [2].

This section presents an algorithm similar to UCA-ESPRIT that provides the same closed-form 2-D angle estimation capability for a *Filled Circular Array* (FCA). Similar to UCA-ESPRIT, the far field pattern arising from the sampled excitation is approximated by the far field pattern arising from the continuous excitation from which the sampled excitation is derived through sampling. (Note, Steinberg [20] shows that the array pattern for a ULA of N elements with interelement spacing d is nearly identical to the far field pattern for a continuous linear aperture of length $(N + 1)d$, except near the fringes of the visible region.) That is, it is assumed that the interelement spacings have been chosen so that aliasing effects are negligible as in the generation of phase modes with a single ring array. It can be shown that this is the case for any sampling lattice as long as the inter-sensor spacings is roughly half a wavelength or less on the average and that the sources of interest are at least 20° in elevation above the plane of the array, i.e., we require that the elevation angle of the i th source satisfies $0 \leq \theta_i \leq 70^\circ$. In practice, many phased arrays only provide reliable coverage for $0 \leq \theta_i \leq 60^\circ$ (plus or minus 60° away from boresite) due to a reduced aperture effect and the fact that the gain of each individual antenna has a significant roll-off at elevation angles near the horizon, i.e., the plane of the array. FCA-ESPRIT has been successfully applied to rectangular, hexagonal, polar raster, and random sampling lattices.

The key to the development of UCA-ESPRIT was phase-mode (DFT) excitation and exploitation of a recurrence relationship that Bessel functions satisfy. In the case of a filled circular array, the same

FIGURE 63.5: Plot of the UCA-ESPRIT eigenvalues $\xi_1 = \sin \theta_1 e^{j\phi_1}$ and $\xi_2 = \sin \theta_2 e^{j\phi_2}$ for 200 trials.

type of processing is facilitated by the use of a phase-mode dependent aperture taper derived from an integral relationship that Bessel functions satisfy.

Consider an M element FCA where the array elements are distributed over a circular aperture of radius R . We assume that the array is centered at the origin of the coordinate system and contained in the x - y plane. The i th element is located at a radial distance r_i from the origin and at an angle γ_i relative to the x -axis measured counter-clockwise in the x - y plane. In contrast to a UCA, $0 \leq r_i \leq R$, i.e., the elements lie within, rather than on, a circle of radius R . The beamforming weight vectors employed in FCA-ESPRIT are

$$\mathbf{w}_m = \frac{1}{M} \begin{bmatrix} A_1 \left(\frac{r_1}{R}\right)^{|m|} e^{-jm\gamma_1} \\ \vdots \\ A_i \left(\frac{r_i}{R}\right)^{|m|} e^{-jm\gamma_i} \\ \vdots \\ A_M \left(\frac{r_M}{R}\right)^{|m|} e^{-jm\gamma_M} \end{bmatrix}, \quad (63.30)$$

where m ranges from $-K$ to K with $K \approx \frac{2\pi R}{\lambda}$. Here A_i is proportional to the area surrounding the i th array element. A_i is a constant (and can be omitted) for hexagonal and rectangular lattices and proportional to the radius ($A_i = r_i$) for a polar raster. The transformation from element space to beamspace is effected through pre-multiplication by the beamforming matrix

$$\mathbf{W} = \sqrt{M} \begin{bmatrix} \mathbf{w}_{-K} & \cdots & \mathbf{w}_{-1} & \mathbf{w}_0 & \mathbf{w}_1 & \cdots & \mathbf{w}_K \end{bmatrix} \in \mathbb{C}^{M \times K'} \quad (K' = 2K + 1). \quad (63.31)$$

The following matrix definitions are needed to summarize FCA-ESPRIT.

$$\begin{aligned} \mathbf{B} &= \mathbf{W}\mathbf{C} \in \mathbb{C}^{M \times K'} \\ \mathbf{C} &= \text{diag} \left\{ \text{sign}(k) \cdot j^k \right\}_{k=-K}^K \in \mathbb{C}^{K' \times K'} \end{aligned} \quad (63.32)$$

FIGURE 63.6: Illustrating the form of signal roots (eigenvalues) obtained with UCA-ESPRIT or FCA-ESPRIT.

$$\begin{aligned}
 \mathbf{B}_r &= \mathbf{B} \mathbf{F} \bar{\mathbf{Q}}_{K'} \in \mathbb{C}^{M \times K'} \\
 \mathbf{F} &= \text{diag}\left([(-1)^{-M-1}, \dots, (-1)^{-2}, 1, 1, \dots, 1]\right) \in \mathbb{R}^{K' \times K'} \\
 \mathbf{\Gamma} &= \frac{\lambda}{\pi R} \text{diag}(\overbrace{[-M, \dots, -3, -2]}^{M-1}, 0, \overbrace{[2, \dots, M]}^{M-1}) \in \mathbb{R}^{(K'-2) \times (K'-2)} \\
 \mathbf{C}_1 &= \text{diag}(\overbrace{[1, \dots, 1]}^{M-2}, -1, -1, \overbrace{[1, \dots, 1]}^{M-1}) \in \mathbb{R}^{(K'-2) \times (K'-2)}
 \end{aligned}$$

The whole algorithm is summarized in Table 63.5. The beamforming matrix \mathbf{B}_r^H synthesizes a real-valued manifold that facilitates signal subspace estimation via a real-valued SVD or eigenvalue decomposition in the first step. As in UCA-ESPRIT, the eigenvalues of $\mathbf{\Psi}$ computed in the final step are asymptotically of the form $\sin(\theta_i)e^{j\phi_i}$, where θ_i and ϕ_i are the elevation and azimuth angles of the i th source, respectively.

63.5.1 Computer Simulation

As an example, a simulation involving a *random filled array* is presented. The element locations are depicted in Fig. 63.7. The outer radius is $R = 5\lambda$ and the average distance between elements is $\lambda/4$. Two plane waves of equal power were incident upon the array. The Signal to Noise Ratio (SNR) per antenna per signal was 0 dB. One signal arrived at 10° elevation and 40° azimuth, while the other arrived at 30° elevation and 60° azimuth. Figure 63.8 shows the results of 32 independent trials of FCA-ESPRIT overlaid; each execution of the algorithm (with a different realization of the noise) produced two eigenvalues. The eigenvalues are observed to be clustered around the expected locations (the dashed circles indicate the true elevation angles).

63.6 2-D Unitary ESPRIT

For uniform circular arrays and filled circular arrays, UCA-ESPRIT and FCA-ESPRIT provide closed-form, automatically paired 2-D angle estimates as long as the direction cosine pair of each signal arrival

TABLE 63.5 Summary of FCA-ESPRIT

0. *Transformation to Beamspace:* $Y = B_r^H X$

1. *Signal Subspace Estimation:* Compute $E_s \in \mathbb{R}^{K' \times d}$ as the d dominant left singular vector of
 $\begin{bmatrix} \text{Re}\{Y\} & \text{Im}\{Y\} \end{bmatrix} \in \mathbb{R}^{K' \times 2N}$.

2. *Solution of the Invariance Equation:*

- Compute $E_u = F Q_{K'} E_s$. Form the matrices E_{-1} , E_0 , and E_1 that consist of all but the last two, first and last, and first two rows, respectively.
- Compute $\underline{\Psi} \in \mathbb{C}^{2d \times d}$, the least squares solution to the system

$$\begin{bmatrix} E_{-1} & C_1 E_1 \end{bmatrix} \underline{\Psi} = \Gamma E_0 \in \mathbb{C}^{(K'-2) \times d}.$$

Form Ψ by extracting the upper $d \times d$ block from $\underline{\Psi}$.

3. *Spatial Frequency Estimation:* Compute the eigenvalues ξ_i , $1 \leq i \leq d$, of $\Psi \in \mathbb{C}^{d \times d}$. The estimates of the elevation and azimuth angles of the i th source are

$$\theta_i = \arcsin(|\xi_i|) \quad \text{and} \quad \phi_i = \arg(\xi_i),$$

respectively.

FIGURE 63.7: Random filled array.

is unique. In this section, we develop 2-D Unitary ESPRIT, a closed-form 2-D angle estimation algorithm that achieves automatic pairing in a similar fashion. It is applicable to 2-D centro-symmetric array configurations with a dual invariance structure such as uniform rectangular arrays (URAs). In the derivations of UCA-ESPRIT and FCA-ESPRIT it was necessary to approximate the sampled aperture pattern by the continuous aperture pattern. Such an approximation is not required in the development of 2-D Unitary ESPRIT.

Apart from the 2-D extension presented here, Unitary ESPRIT has also been extended to the R -dimensional case to solve the R -dimensional harmonic retrieval problem, where $R \geq 3$. R -D Unitary ESPRIT is a closed-form algorithm to estimate several undamped R -dimensional modes (or frequencies) along with their correct pairing. In [6], automatic pairing of the R -dimensional frequency estimates is achieved through a new simultaneous Schur decomposition of R real-valued, non-symmetric matrices that reveals their “average eigenstructure”. Like its 1-D and 2-D counterparts, R -D Unitary ESPRIT inherently includes forward-backward averaging and is efficiently formulated in terms of real-valued computations throughout. In the array processing context, a three-dimensional extension of Unitary ESPRIT can be used to estimate the 2-D arrival angles and carrier frequencies of several impinging wavefronts simultaneously.

FIGURE 63.8: Plot of the FCA-ESPRIT eigenvalues from 32 independent trials.

63.6.1 2-D Array Geometry

Consider a 2-D centro-symmetric sensor array of M elements lying in the x - y plane (Fig. 63.4). Assume that the array also exhibits a *dual* invariance, i.e., two identical subarrays of m_x elements are displaced by Δ_x along the x -axis, and another pair of identical subarrays, consisting of m_y elements each, is displaced by Δ_y along the y -axis. Notice that the four subarrays can overlap and m_x is not required to equal m_y . Such array configurations include uniform rectangular arrays (URAs), uniform rectangular frame arrays (URFAs), i.e., URAs without some of their center elements, and cross arrays consisting of two orthogonal linear arrays with a common phase center as shown in Fig. 63.9.⁸

FIGURE 63.9: Centro-symmetric array configurations with a dual invariance structure: (a) URA with $M = 12$, $m_x = 9$, $m_y = 8$. (b) URFA with $M = 12$, $m_x = m_y = 6$. (c) Cross array with $M = 10$, $m_x = 3$, $m_y = 5$. (d) $M = 12$, $m_x = m_y = 7$.

Incident on the array are d narrowband planar wavefronts with wavelength λ , azimuth ϕ_i , and elevation θ_i , $1 \leq i \leq d$. Let

$$u_i = \cos \phi_i \sin \theta_i \quad \text{and} \quad v_i = \sin \phi_i \sin \theta_i, \quad 1 \leq i \leq d,$$

denote the direction cosines of the i th source relative to the x - and y -axes, respectively. These definitions are illustrated in Fig. 63.4. The fact that $\xi_i = u_i + jv_i = \sin \theta_i e^{j\phi_i}$ yields a simple formula

⁸ In the examples of Fig. 63.9, all values of m_x and m_y correspond to selection matrices with maximum overlap in both directions. For a URA of $M = M_x \cdot M_y$ elements, cf. Fig. 63.9 (a), this assumption implies $m_x = (M_x - 1) M_y$ and $m_y = M_x (M_y - 1)$.

FIGURE 63.10: Subarray selection for a URA of $M = 4 \cdot 4 = 16$ sensor elements (maximum overlap in both directions: $m_x = m_y = 12$).

to determine azimuth ϕ_i and elevation θ_i from the corresponding direction cosines u_i and v_i , namely

$$\phi_i = \arg(\xi_i) \quad \text{and} \quad \theta_i = \arcsin(|\xi_i|), \quad \text{with} \quad \xi_i = u_i + jv_i, \quad 1 \leq i \leq d. \quad (63.33)$$

Similar to the 1-D case, the data matrix \mathbf{X} is an $M \times N$ matrix composed of N snapshots $\mathbf{x}(t_n)$, $1 \leq n \leq N$, of data as columns. Referring to Fig. 63.10 for a URA of $M = 4 \times 4 = 16$ sensors as an illustrative example, the antenna element outputs are stacked columnwise. Specifically, the first element of $\mathbf{x}(t_n)$ is the output of the antenna in the upper left corner. Then sequentially progress downwards along the positive x -axis such that the fourth element of $\mathbf{x}(t_n)$ is the output of the antenna in the bottom left corner. The fifth element of $\mathbf{x}(t_n)$ is the output of the antenna at the top of the second column; the eighth element of $\mathbf{x}(t_n)$ is the output of the antenna at the bottom of the second column, etc. This forms a 16×1 vector at each sampling instant t_n .

Similar to the 1-D case, the array measurements may be expressed as $\mathbf{x}(t) = \mathbf{A}s(t) + \mathbf{n}(t) \in \mathbb{C}^M$. Due to the centro-symmetry of the array, the steering matrix $\mathbf{A} \in \mathbb{C}^{M \times d}$ satisfies Eq. (63.12). The goal is to construct two pairs of selection matrices that are centro-symmetric with respect to each other, i.e.,

$$\mathbf{J}_{\mu 2} = \mathbf{\Pi}_{m_x} \mathbf{J}_{\mu 1} \mathbf{\Pi}_M \quad \text{and} \quad \mathbf{J}_{\nu 2} = \mathbf{\Pi}_{m_y} \mathbf{J}_{\nu 1} \mathbf{\Pi}_M, \quad (63.34)$$

and cause the array steering matrix \mathbf{A} to satisfy the following two invariance properties,

$$\mathbf{J}_{\mu 1} \mathbf{A} \mathbf{\Phi}_{\mu} = \mathbf{J}_{\mu 2} \mathbf{A} \quad \text{and} \quad \mathbf{J}_{\nu 1} \mathbf{A} \mathbf{\Phi}_{\nu} = \mathbf{J}_{\nu 2} \mathbf{A}, \quad (63.35)$$

where the diagonal matrices

$$\mathbf{\Phi}_{\mu} = \text{diag}\{e^{j\mu_i}\}_{i=1}^d \quad \text{and} \quad \mathbf{\Phi}_{\nu} = \text{diag}\{e^{j\nu_i}\}_{i=1}^d \quad (63.36)$$

are unitary and contain the desired 2-D angle information. Here $\mu_i = \frac{2\pi}{\lambda} \Delta_x u_i$ and $\nu_i = \frac{2\pi}{\lambda} \Delta_y v_i$ are the spatial frequencies in x - and y -direction, respectively.

Figure 63.10 visualizes a possible choice of the selection matrices for a URA of $M = 4 \times 4 = 16$ sensor elements. Given the stacking procedure described above and the 1-D selection matrices for a ULA of 4 elements

$$\mathbf{J}_1^{(4)} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad \text{and} \quad \mathbf{J}_2^{(4)} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 \end{bmatrix},$$

$$J_{v2} = J_2^{(M_y)} \otimes I_{M_x} = \begin{bmatrix} 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \in \mathbb{R}^{12 \times 16},$$

where $M_x = M_y = 4$. Notice, however, that it is not required to compute all four selection matrices explicitly, since they are related via Eq. (63.34). In fact, to be able to compute the four transformed selection matrices for 2-D Unitary ESPRIT, it is sufficient to specify $J_{\mu 2}$ and J_{v2} , cf. (63.38) and (63.39).

63.6.2 2-D Unitary ESPRIT in Element Space

Similar to Eq. (63.16) in the 1-D case, let us define the transformed 2-D array steering matrix as $D = Q_M^H A$. Based on the two invariance properties of the 2-D array steering matrix A in Eq. (63.35), it is a straightforward 2-D extension of the derivation of 1-D Unitary ESPRIT to show that the transformed array steering matrix D satisfies

$$K_{\mu 1} D \cdot \Omega_{\mu} = K_{\mu 2} D \quad \text{and} \quad K_{v1} D \cdot \Omega_v = K_{v2} D, \quad (63.37)$$

where the two pairs of transformed selection matrices are defined as

$$K_{\mu 1} = 2 \cdot \text{Re}\{Q_{m_x}^H J_{\mu 2} Q_M\} \quad K_{\mu 2} = 2 \cdot \text{Im}\{Q_{m_x}^H J_{\mu 2} Q_M\} \quad (63.38)$$

$$K_{v1} = 2 \cdot \text{Re}\{Q_{m_y}^H J_{v2} Q_M\} \quad K_{v2} = 2 \cdot \text{Im}\{Q_{m_y}^H J_{v2} Q_M\} \quad (63.39)$$

and the real-valued diagonal matrices

$$\Omega_{\mu} = \text{diag} \left\{ \tan \left(\frac{\mu_i}{2} \right) \right\}_{i=1}^d \quad \text{and} \quad \Omega_v = \text{diag} \left\{ \tan \left(\frac{v_i}{2} \right) \right\}_{i=1}^d \quad (63.40)$$

contain the desired (spatial) frequency information.

Given the noise-corrupted data matrix X , a real-valued matrix E_s , spanning the dominant subspace of $\mathcal{T}(X)$, is obtained as described in Section 63.3.1 for the 1-D case. Asymptotically or without additive noise, E_s and D span the same d -dimensional subspace, i.e., there is a nonsingular matrix T of size $d \times d$ such that $D \approx E_s T$. Substituting this relationship into Eq. (63.37) yields two *real-valued* invariance equations

$$K_{\mu 1} E_s \Upsilon_{\mu} \approx K_{\mu 2} E_s \in \mathbb{R}^{m_x \times d} \quad \text{and} \quad K_{v1} E_s \Upsilon_v \approx K_{v2} E_s \in \mathbb{R}^{m_y \times d}, \quad (63.41)$$

where $\Upsilon_{\mu} = T \Omega_{\mu} T^{-1} \in \mathbb{R}^{d \times d}$ and $\Upsilon_v = T \Omega_v T^{-1} \in \mathbb{R}^{d \times d}$. Thus, Υ_{μ} and Υ_v are related with the diagonal matrices Ω_{μ} and Ω_v via eigenvalue preserving similarity transformations. Moreover, the real-valued matrices Υ_{μ} and Υ_v share the *same set of eigenvectors*. As in the 1-D case, the two real-valued invariance equations (63.41) can be solved independently via LS, TLS, or SLS [9]. As an alternative, they may be solved jointly via 2-D SLS, which is a 2-D extension of structured least squares (SLS) [8].

63.6.3 Automatic Pairing of the 2-D Frequency Estimates

Asymptotically or without additive noise, the real-valued eigenvalues of the solutions $\Upsilon_\mu \in \mathbb{R}^{d \times d}$ and $\Upsilon_\nu \in \mathbb{R}^{d \times d}$ to the invariance equations above are given by $\tan(\mu_i/2)$ and $\tan(\nu_i/2)$, respectively. If these eigenvalues were calculated independently, it would be quite difficult to pair the resulting two distinct sets of frequency estimates. Notice that one can choose a real-valued eigenvector matrix T such that all matrices that appear in the spectral decompositions of $\Upsilon_\mu = T \Omega_\mu T^{-1}$ and $\Upsilon_\nu = T \Omega_\nu T^{-1}$ are real-valued. Moreover, the subspace spanned by the columns of $T \in \mathbb{R}^{d \times d}$ is unique. These observations are critical to achieve automatic pairing of the spatial frequencies μ_i and ν_i , $1 \leq i \leq d$.

With additive noise and a finite number of snapshots N , however, the real-valued matrices Υ_μ and Υ_ν do not exactly share the same set of eigenvectors. To determine an approximation of the set of common eigenvectors from one of these matrices is, obviously, not the best solution, since this strategy would rely on an arbitrary choice and would also discard information contained in the other matrix. Moreover, Υ_μ and Υ_ν might have some degenerate (multiple) eigenvalues, while both of them have well determined common eigenvectors T (for $N \rightarrow \infty$ or $\sigma_N^2 \rightarrow 0$). 2-D Unitary ESPRIT circumvents these difficulties and achieves automatic pairing of the spatial frequency estimates μ_i and ν_i by computing the eigenvalues of the “complexified” matrix $\Upsilon_\mu + j\Upsilon_\nu$ since this complex-valued matrix may be spectrally decomposed as

$$\Upsilon_\mu + j\Upsilon_\nu = T (\Omega_\mu + j\Omega_\nu) T^{-1}. \quad (63.42)$$

Here, automatically paired estimates of Ω_μ and Ω_ν in Eq. (63.40) are given by the real and imaginary parts of the complex eigenvalues of $\Upsilon_\mu + j\Upsilon_\nu$. The maximum number of sources 2-D Unitary ESPRIT can handle is the minimum of m_x and m_y , assuming that at least $d/2$ snapshots are available. If only a single snapshot is available (or more than two sources are highly correlated), one can extract $d/2$ or more identical subarrays out of the overall array to get the effect of multiple snapshots (spatial smoothing), thereby decreasing the maximum number of sources that can be handled. A brief summary of the described element space implementation of 2-D Unitary ESPRIT is given in Table 63.6.

TABLE 63.6 Summary of 2-D Unitary ESPRIT in Element Space

1. *Signal Subspace Estimation:* Compute $E_s \in \mathbb{R}^{M \times d}$ as the d dominant left singular vectors of $\mathcal{T}(X) \in \mathbb{R}^{M \times 2N}$.

2. *Solution of the Invariance Equations:* Solve

$$\underbrace{K_{\mu 1} E_s}_{\mathbb{R}^{m_x \times d}} \Upsilon_\mu \approx \underbrace{K_{\mu 2} E_s}_{\mathbb{R}^{m_x \times d}} \quad \text{and} \quad \underbrace{K_{\nu 1} E_s}_{\mathbb{R}^{m_y \times d}} \Upsilon_\nu \approx \underbrace{K_{\nu 2} E_s}_{\mathbb{R}^{m_y \times d}}$$

by means of LS, TLS, SLS, or 2-D SLS.

3. *Spatial Frequency Estimation:* Calculate the eigenvalues of the complex-valued $d \times d$ matrix

$$\Upsilon_\mu + j\Upsilon_\nu = T \Lambda T^{-1} \quad \text{with} \quad \Lambda = \text{diag} \{ \lambda_i \}_{i=1}^d$$

- $\mu_i = 2 \arctan(\text{Re} \{ \lambda_i \})$, $1 \leq i \leq d$
- $\nu_i = 2 \arctan(\text{Im} \{ \lambda_i \})$, $1 \leq i \leq d$

It is instructive to examine a very simple numerical example. Consider a uniform rectangular array (URA) of $M = 2 \times 2 = 4$ sensor elements, i.e., $M_x = M_y = 2$. Effecting maximum overlap, we have $m_x = m_y = 2$. For the sake of simplicity, assume that the true covariance matrix of the

noise-corrupted measurements

$$\mathbf{R}_{xx} = \mathbb{E}\{\mathbf{x}(t)\mathbf{x}^H(t)\} = \mathbf{A}\mathbf{R}_{ss}\mathbf{A}^H + \sigma_N^2\mathbf{I}_4 = \begin{bmatrix} 3 & 0 & 1-j & -1+j \\ 0 & 3 & 1-j & 1-j \\ 1+j & 1+j & 3 & 0 \\ -1-j & 1+j & 0 & 3 \end{bmatrix}$$

is known. Here, $\mathbf{R}_{ss} = \mathbb{E}\{\mathbf{s}(t)\mathbf{s}^H(t)\} \in \mathbb{C}^{d \times d}$ denotes the unknown signal covariance matrix. Furthermore, the measurement vector $\mathbf{x}(t)$ is defined as

$$\mathbf{x}(t) = \begin{bmatrix} x_{11}(t) & x_{12}(t) & x_{21}(t) & x_{22}(t) \end{bmatrix}^T. \quad (63.43)$$

In this example, we have to use a covariance approach instead of the direct data approach summarized in Table 63.6, since the array measurements $\mathbf{x}(t)$ themselves are not known. To this end, we will compute the eigendecomposition of the real part of the transformed covariance matrix as, for instance, discussed in [25]. According to Eq. (63.13), the left Π -real transformation matrices \mathbf{Q}_M and $\mathbf{Q}_{m_x} = \mathbf{Q}_{m_y}$ take the form

$$\mathbf{Q}_4 = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 0 & j & 0 \\ 0 & 1 & 0 & j \\ 0 & 1 & 0 & -j \\ 1 & 0 & -j & 0 \end{bmatrix} \quad \text{and} \quad \mathbf{Q}_2 = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & j \\ 1 & -j \end{bmatrix},$$

respectively. Therefore, we have

$$\mathbf{R}_Q = \text{Re} \left\{ \mathbf{Q}_4^H \mathbf{R}_{xx} \mathbf{Q}_4 \right\} = \mathbf{Q}_4^H \mathbf{R}_{xx} \mathbf{Q}_4 = \begin{bmatrix} 2 & 1 & 1 & -1 \\ 1 & 4 & -1 & -1 \\ 1 & -1 & 4 & -1 \\ -1 & -1 & -1 & 2 \end{bmatrix}. \quad (63.44)$$

The eigenvalues of \mathbf{R}_Q are given by $\varrho_1 = 5$, $\varrho_2 = 5$, $\varrho_3 = 1$, and $\varrho_4 = 1$. Clearly, ϱ_1 and ϱ_2 are the dominant eigenvalues, and the variance of the additive noise is identified as $\sigma_N^2 = \varrho_3 = \varrho_4 = 1$. Therefore, there are $d = 2$ impinging wavefronts. The columns of

$$\mathbf{E}_s = \begin{bmatrix} 1 & 0 \\ 1 & 1 \\ 1 & -1 \\ -1 & 0 \end{bmatrix}$$

contain eigenvectors of \mathbf{R}_Q corresponding to the $d = 2$ largest eigenvalues ϱ_1 and ϱ_2 . The four selection matrices

$$\begin{aligned} \mathbf{J}_{\mu 1} &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \end{bmatrix}, \quad \mathbf{J}_{\mu 2} = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \\ \mathbf{J}_{\nu 1} &= \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \end{bmatrix}, \quad \mathbf{J}_{\nu 2} = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \end{aligned}$$

are constructed in accordance with Eq. (63.43), cf. Fig. 63.10, yielding

$$\begin{aligned} \mathbf{K}_{\mu 1} &= \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & 1 \end{bmatrix}, & \mathbf{K}_{\mu 2} &= \begin{bmatrix} 0 & 0 & -1 & 1 \\ 1 & -1 & 0 & 0 \end{bmatrix}, \\ \mathbf{K}_{\nu 1} &= \begin{bmatrix} 1 & 1 & 0 & 0 \\ 0 & 0 & 1 & -1 \end{bmatrix}, & \mathbf{K}_{\nu 2} &= \begin{bmatrix} 0 & 0 & -1 & -1 \\ 1 & -1 & 0 & 0 \end{bmatrix}, \end{aligned}$$

according to Eq. (63.38) and Eq. (63.39). With these definitions, the invariance equations (63.41) turn out to be

$$\begin{bmatrix} 2 & 1 \\ 0 & -1 \end{bmatrix} \Upsilon_\mu \approx \begin{bmatrix} -2 & 1 \\ 0 & -1 \end{bmatrix} \quad \text{and} \quad \begin{bmatrix} 2 & 1 \\ 2 & -1 \end{bmatrix} \Upsilon_\nu \approx \begin{bmatrix} 0 & 1 \\ 0 & -1 \end{bmatrix}.$$

Solving these matrix equations, we get

$$\Upsilon_\mu = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad \Upsilon_\nu = \begin{bmatrix} 0 & 0 \\ 0 & 1 \end{bmatrix}.$$

Finally, the eigenvalues of the “complexified” 2×2 matrix $\Upsilon_\mu + j\Upsilon_\nu$ are observed to be $\lambda_1 = -1$ and $\lambda_2 = 1 + j$, corresponding to the spatial frequencies

$$\mu_1 = -\frac{\pi}{2}, \quad \nu_1 = 0 \quad \text{and} \quad \mu_2 = \frac{\pi}{2}, \quad \nu_2 = \frac{\pi}{2}.$$

If we assume that $\Delta_x = \Delta_y = \lambda/2$, the direction cosines are given by $u_i = \mu_i/\pi$ and $v_i = \nu_i/\pi$, $i = 1, 2$. According to Eq. (63.33), the corresponding azimuth and elevation angles can be calculated as

$$\phi_1 = 180^\circ, \quad \theta_1 = 30^\circ, \quad \text{and} \quad \phi_2 = 45^\circ, \quad \theta_2 = 45^\circ.$$

63.6.4 2-D Unitary ESPRIT in DFT Beamspace

Here, we will restrict the presentation of 2-D Unitary ESPRIT in DFT beamspace to uniform rectangular arrays (URAs) of $M = M_x \cdot M_y$ identical sensors, cf. Fig. 63.10.⁹ Without loss of generality, assume that the M sensors are omnidirectional and that the centroid of the URA is chosen as the phase reference.

Let us form B_x out of M_x beams in x -direction and B_y out of M_y beams in y -direction, yielding a total of $B = B_x \cdot B_y$ beams. Then the corresponding scaled DFT-matrices $\mathbf{W}_{B_x}^H \in \mathbb{C}^{B_x \times M_x}$ and $\mathbf{W}_{B_y}^H \in \mathbb{C}^{B_y \times M_y}$ are formed as discussed in Section 63.3.2. Now, viewing the array output at a given snapshot as an $M_x \times M_y$ matrix, premultiply this matrix by $\mathbf{W}_{B_x}^H$ and postmultiply it by $\overline{\mathbf{W}}_{B_y}$.¹⁰ Then apply the $\text{vec}\{\cdot\}$ -operator, and place the resulting $B \times 1$ vector ($B = B_x \cdot B_y$) as a column of a matrix $\mathbf{Y} \in \mathbb{C}^{B \times N}$. The $\text{vec}\{\cdot\}$ -operator maps a $B_x \times B_y$ matrix to a $B \times 1$ vector by stacking the columns of the matrix. Note that if \mathbf{X} denotes the $M \times N$ complex-valued element space data matrix, it is easy to show that the relationship between \mathbf{Y} and \mathbf{X} may be expressed as $\mathbf{Y} = (\mathbf{W}_{B_y}^H \otimes \mathbf{W}_{B_x}^H) \mathbf{X}$ [24]. Here, the symbol \otimes denotes the Kronecker matrix product [5].

Let the columns of $\mathbf{E}_s \in \mathbb{R}^{B \times d}$ contain the d left singular vectors of

$$\begin{bmatrix} \text{Re}\{\mathbf{Y}\} & \text{Im}\{\mathbf{Y}\} \end{bmatrix} \in \mathbb{R}^{B \times 2N} \quad (63.45)$$

corresponding to its d largest singular values. To set up two invariance equations similar to Eq. (63.41), but with a reduced dimensionality, let us define the selection matrices

$$\Gamma_{\mu 1} = \mathbf{I}_{B_y} \otimes \Gamma_1^{(B_x)} \quad \text{and} \quad \Gamma_{\mu 2} = \mathbf{I}_{B_y} \otimes \Gamma_2^{(B_x)} \quad (63.46)$$

⁹ In [24], we have also described how to use 2-D Unitary ESPRIT in DFT beamspace for cross arrays as depicted in Fig. 63.9 (c).

¹⁰ This can be achieved via a 2-D FFT with appropriate scaling.

of size $b_x \times B$ for the x -direction ($b_x = (B_x - 1) \cdot B_y$) and

$$\mathbf{\Gamma}_{v1} = \mathbf{\Gamma}_1^{(B_y)} \otimes \mathbf{I}_{B_x} \quad \text{and} \quad \mathbf{\Gamma}_{v2} = \mathbf{\Gamma}_2^{(B_y)} \otimes \mathbf{I}_{B_x} \quad (63.47)$$

of size $b_y \times B$ for the y -direction ($b_y = B_x \cdot (B_y - 1)$). Then $\mathbf{\Upsilon}_\mu \in \mathbb{R}^{d \times d}$ and $\mathbf{\Upsilon}_v \in \mathbb{R}^{d \times d}$ can be calculated as the LS, TLS, SLS, or 2-D SLS solution of

$$\mathbf{\Gamma}_{\mu 1} \mathbf{E}_s \mathbf{\Upsilon}_\mu \approx \mathbf{\Gamma}_{\mu 2} \mathbf{E}_s \in \mathbb{R}^{b_x \times d} \quad \text{and} \quad \mathbf{\Gamma}_{v 1} \mathbf{E}_s \mathbf{\Upsilon}_v \approx \mathbf{\Gamma}_{v 2} \mathbf{E}_s \in \mathbb{R}^{b_y \times d}, \quad (63.48)$$

respectively. Finally, the desired *automatically paired* spatial frequency estimates μ_i and v_i , $1 \leq i \leq d$, are obtained from the real and imaginary part of the eigenvalues of the “complexified” matrix $\mathbf{\Upsilon}_\mu + j\mathbf{\Upsilon}_v$ as discussed in Section 63.6.2. Here, the maximum number of sources we can handle is given by the minimum of b_x and b_y , assuming that at least $d/2$ snapshots are available. A summary of 2-D Unitary ESPRIT in DFT beamspace is presented in Table 63.7.

TABLE 63.7 Summary of 2-D Unitary ESPRIT in DFT Beamspace

<p>0. <i>Transformation to Beamspace:</i> Compute a 2-D DFT (with appropriate scaling) of the $M_x \times M_y$ matrix of array outputs at each snapshot, apply the $\text{vec}\{\cdot\}$-operator, and place the result as a column of $\mathbf{Y} \implies \mathbf{Y} = \begin{pmatrix} \mathbf{w}_{B_y}^H & \mathbf{w}_{B_x}^H \end{pmatrix} \mathbf{X} \in \mathbb{C}^{B \times N}$ ($B = B_x \cdot B_y$).</p>	
<p>1. <i>Signal Subspace Estimation:</i> Compute $\mathbf{E}_s \in \mathbb{R}^{B \times d}$ as the d dominant left singular vectors of $\begin{bmatrix} \text{Re}\{\mathbf{Y}\} & \text{Im}\{\mathbf{Y}\} \end{bmatrix} \in \mathbb{R}^{B \times 2N}$.</p>	
<p>2. <i>Solution of the Invariance Equations:</i> Solve</p> $\underbrace{\mathbf{\Gamma}_{\mu 1} \mathbf{E}_s \mathbf{\Upsilon}_\mu}_{\substack{\mathbb{R}^{b_x \times d} \\ b_x = (B_x - 1) \cdot B_y}} \approx \underbrace{\mathbf{\Gamma}_{\mu 2} \mathbf{E}_s}_{\mathbb{R}^{b_x \times d}} \quad \text{and} \quad \underbrace{\mathbf{\Gamma}_{v 1} \mathbf{E}_s \mathbf{\Upsilon}_v}_{\substack{\mathbb{R}^{b_y \times d} \\ b_y = B_x \cdot (B_y - 1)}} \approx \underbrace{\mathbf{\Gamma}_{v 2} \mathbf{E}_s}_{\mathbb{R}^{b_y \times d}}$ <p>by means of LS, TLS, SLS, or 2-D SLS.</p>	
<p>3. <i>Spatial Frequency Estimation:</i> Calculate the eigenvalues of the complex-valued $d \times d$ matrix</p> $\mathbf{\Upsilon}_\mu + j\mathbf{\Upsilon}_v = \mathbf{T} \mathbf{\Lambda} \mathbf{T}^{-1} \quad \text{with} \quad \mathbf{\Lambda} = \text{diag}\{\lambda_i\}_{i=1}^d$ <ul style="list-style-type: none"> • $\mu_i = 2 \arctan(\text{Re}\{\lambda_i\})$, $1 \leq i \leq d$ • $v_i = 2 \arctan(\text{Im}\{\lambda_i\})$, $1 \leq i \leq d$ 	

63.6.5 Simulation Results

Simulations were conducted employing a URA of 8×8 elements, i.e., $M_x = M_y = 8$, with $\Delta_x = \Delta_y = \lambda/2$. The source scenario consisted of $d = 3$ equi-powered, uncorrelated sources located at $(u_1, v_1) = (0, 0)$, $(u_2, v_2) = (1/8, 0)$, and $(u_3, v_3) = (0, 1/8)$, where u_i and v_i are the direction cosines of the i th source relative to the x - and y -axes, respectively. Notice that sources 1 and 2 have the same v -coordinates, while sources 2 and 3 have the same u -coordinates. A given trial run at a given SNR level (per source per element) involved $N = 64$ snapshots. The noise was *i.i.d.* from element to element and from snapshot to snapshot. The RMS error defined as

$$\text{RMSE}_i = \sqrt{\text{E}\{(\hat{u}_i - u_i)^2\} + \text{E}\{(\hat{v}_i - v_i)^2\}}, \quad i = 1, 2, 3, \quad (63.49)$$

was employed as the performance metric. Let $(\hat{u}_{ik}, \hat{v}_{ik})$ denote the coordinate estimates of the i th source obtained at the k th run. Sample performance statistics were computed from $K = 1000$

FIGURE 63.11: RMS error of source 1 at $(u_1, v_1) = (0, 0)$ in the u - v plane as a function of the SNR (8×8 sensors, $N = 64$, 1000 trial runs).

FIGURE 63.12: RMS error of source 2 at $(u_2, v_2) = (1/8, 0)$ in the u - v plane as a function of the SNR (8×8 sensors, $N = 64$, 1000 trial runs).

FIGURE 63.13: RMS error of source 3 at $(u_3, v_3) = (0, 1/8)$ in the u - v plane as a function of the SNR (8×8 sensors, $N = 64$, 1000 trial runs).

independent trials as

$$\widehat{\text{RMSE}}_i = \sqrt{\frac{1}{K} \sum_{k=1}^T \{(\hat{u}_{ik} - u_i)^2 + (\hat{v}_{ik} - v_i)^2\}}, \quad i = 1, 2, 3. \quad (63.50)$$

2-D Unitary ESPRIT in DFT beamspace was implemented with a set of $B = 9$ beams centered at $(u, v) = (0, 0)$, using $B_x = 3$ out of $M_x = 8$ in x -direction (rows 8, 1, and 2 of \mathbf{W}_8^H) and also $B_y = 3$ out of $M_y = 8$ in y -direction (again, rows 8, 1, and 2 of \mathbf{W}_8^H). Thus, the corresponding subblocks of the selection matrices $\mathbf{\Gamma}_1 \in \mathbb{R}^{8 \times 8}$ and $\mathbf{\Gamma}_2 \in \mathbb{R}^{8 \times 8}$, used to form $\mathbf{\Gamma}_1^{(B_x)}$ and $\mathbf{\Gamma}_2^{(B_x)}$ in Eq. (63.46) and also used to form $\mathbf{\Gamma}_1^{(B_y)}$ and $\mathbf{\Gamma}_2^{(B_y)}$ in Eq. (63.47), are shaded in Fig. 63.3 (b). The bias of 2-D Unitary ESPRIT in element space and DFT beamspace was found to be negligible, facilitating comparison with the Cramér-Rao (CR) lower bound [15]. The resulting performance curves are plotted in Figs. 63.11, 63.12, and 63.13. We have also included theoretical performance predictions of both implementations based on an asymptotic performance analysis [13, 14]. Observe that the empirical RMSEs closely follow the theoretical predictions, except for deviations at low SNRs. The performance of the DFT beamspace implementation is comparable to that of the element space implementation. However, the former requires significantly less computations than the latter, since it operates in a $B = B_x \cdot B_y = 9$ dimensional beamspace as opposed to an $M = M_x \cdot M_y = 64$ dimensional element space.

For SNRs lower than -9 dB, the DFT beamspace version outperformed the element space version of 2-D Unitary ESPRIT. This is due to fact that the DFT beamspace version exploits *a priori* information on the source locations by forming beams pointed in the general directions of the sources.

[Appendix A: Introduction to IV Methods](#)

The main goal herein is to describe and analyze, in a unifying manner, the *spatial* and *temporal* IV-SSF approaches recently proposed for array signal processing in colored noise fields. (The acronym IV-SSF stands for “Instrumental Variable - Signal Subspace Fitting”). Despite the generality of the approach taken herein, our analysis technique is simpler than those used in previous more specialized publications. We derive a general, optimally-weighted (optimal, for short), IV-SSF direction estimator and show that this estimator encompasses the UNCLE estimator of Wong and Wu, which is a spatial IV-SSF method, and the temporal IV-SSF estimator of Viberg, Stoica and Ottersten. The latter two estimators have seemingly different forms (among others, the first of them makes use of four weights, whereas the second one uses three weights “only”), and hence their asymptotic equivalence shown in this paper comes as a surprising unifying result. We hope that the present paper, along with the original works aforementioned, will stimulate the interest in the IV-SSF approach to array signal processing, which is sufficiently flexible to handle colored noise fields, coherent signals and indeed also situations where only some of the sensors in the array are calibrated.

¹This work was supported in part by the Swedish Research Council for Engineering Sciences (TFR).

64.1 Introduction

Most parametric methods for Direction-Of-Arrival (DOA) estimation require knowledge of the spatial (sensor-to-sensor) color of the background noise. If this information is unavailable, a serious degradation of the quality of the estimates can result, particularly at low Signal-to-Noise Ratio (SNR) [1, 2, 3]. A number of methods have been proposed over the recent years to alleviate the sensitivity to the noise color. If a parametric model of the covariance matrix of the noise is available, the parameters of the noise model can be estimated along with those of the interesting signals [4, 5, 6, 7]. Such an approach is expected to perform well in situations where the noise can be accurately modeled with relatively few parameters. An alternative approach, which does not require a precise model of the noise, is based on the principle of Instrumental Variables (IV). See [8, 9] for thorough treatments of IV methods (IVM) in the context of identification of linear time-invariant dynamical systems. A brief introduction is given in the appendix of this chapter. Computationally simple IVMs for array signal processing appeared in [10, 11]. These methods perform poorly in difficult scenarios involving closely spaced DOAs and correlated signals.

More recently, the combined Instrumental Variable Signal Subspace Fitting (IV-SSF) technique has been proposed as a promising alternative to array signal processing in spatially colored noise fields [12, 13, 14, 15]. The IV-SSF approach has a number of appealing advantages over other DOA estimation methods. These advantages include:

- IV-SSF can handle noises with arbitrary spatial correlation, under minor restrictions on the signals or the array. In addition, estimation of a noise model is avoided, which leads to statistical robustness and computational simplicity.
- The IV-SSF approach is applicable to both non-coherent and coherent signal scenarios.
- The spatial IV-SSF technique can make use of the information contained in the output of a completely uncalibrated subarray under certain weak conditions, which other methods cannot.

Depending on the type of “instrumental variables” used, two classes of IV methods have appeared in the literature:

1. *Spatial IVM*, for which the instrumental variables are derived from the output of a (possibly uncalibrated) subarray the noise of which is uncorrelated with the noise in the main calibrated subarray under consideration (see [12, 13]).
2. *Temporal IVM*, which obtains instrumental variables from the delayed versions of the array output, under the assumption that the temporal-correlation length of the noise field is shorter than that of the signals (see [11, 14]).

The previous literature on IV-SSF has treated and analyzed the above two classes of spatial and temporal methods separately, ignoring their common basis. In this contribution, we reveal the common roots of these two classes of DOA estimation methods and study them under the same umbrella. Additionally, we establish the statistical properties of a general (either spatial or temporal) weighted IV-SSF method and present the optimal weights that minimize the variance of the DOA estimation errors. In particular, we point out that the optimal four-weight spatial IV-SSF of [12, 13] (called UNCLE there, and arrived at by using canonical correlation decomposition ideas) and the optimal three-weight temporal IV-SSF of [14] are asymptotically equivalent when used under the same conditions. This asymptotic equivalence property, which is a main result of the present section, is believed to be important as it shows the close ties that exist between two seemingly different DOA estimators.

This section is organized as follows. In Section 64.2 the data model and technical assumptions are introduced. Next, in Section 64.3 the IV-SSF method is presented in a fairly general setting. In

Section 64.4, the statistical performance of the method is presented along with the optimal choices of certain user-specified quantities. The data requirements and the optimal IV-SSF (UNCLE) algorithm are summarized in Section 64.5. The anxious reader may wish to jump directly to this point to investigate the usefulness of the algorithm in a specific application. In Section 64.6, some numerical examples and computer simulations are presented to illustrate the performance. The conclusions are given in Section 64.7. In the appendix we give a brief introduction to IV methods. The reader who is not familiar with IV might be helped by reading the appendix before the rest of the paper. Background material on the subspace-based approach to DOA estimation can be found in Chapter 62 of this Handbook.

64.2 Problem Formulation

Consider a scenario in which n narrowband plane waves, generated by point sources, impinge on an array comprising m calibrated sensors. Assume, for simplicity, that the n sources and the array are situated in the same plane. Let $\mathbf{a}(\theta)$ denote the complex array response to a unit-amplitude signal with DOA parameter equal to θ . Under these assumptions, the output of the array, $\mathbf{y}(t) \in \mathbb{C}^{m \times 1}$, can be described by the following well-known equation [16, 17]:

$$\mathbf{y}(t) = \mathbf{A}\mathbf{x}(t) + \mathbf{e}(t) \quad (64.1)$$

where $\mathbf{x}(t) \in \mathbb{C}^{n \times 1}$ denotes the signal vector, $\mathbf{e}(t) \in \mathbb{C}^{m \times 1}$ is a noise term, and

$$\mathbf{A} = [\mathbf{a}(\theta_1) \cdots \mathbf{a}(\theta_n)] \quad (64.2)$$

Hereafter, θ_k denotes the k th DOA parameter.

The following assumptions on the quantities in the array equation, (64.1), are considered to hold throughout this section:

A1. The signal vector $\mathbf{x}(t)$ is a normally distributed random variable with zero mean and a possibly singular covariance. The signals may be temporally correlated; in fact the temporal IV-SSF approach relies on the assumption that the signals exhibit some form of temporal correlation (see below for details).

A2. The noise $\mathbf{e}(t)$ is a random vector that is temporally white, uncorrelated with the signals and circularly symmetric normally distributed with zero mean and unknown covariance matrix² $\mathbf{Q} > \mathbf{O}$,

$$\mathbb{E}[\mathbf{e}(t)\mathbf{e}^*(s)] = \mathbf{Q} \delta_{t,s}; \quad \mathbb{E}[\mathbf{e}(t)\mathbf{e}^T(s)] = \mathbf{O} \quad (64.3)$$

A3. The manifold vectors $\{\mathbf{a}(\theta)\}$, corresponding to any set of m different values of θ , are linearly independent.

Note that assumption A1 above allows for coherent signals, and that in A2 the noise field is allowed to be arbitrarily spatially correlated with an unknown covariance matrix. Assumption A3 is a well-known condition that, under a weak restriction on m , guarantees DOA parameter identifiability in the case \mathbf{Q} is known (to within a multiplicative constant) [18]. When \mathbf{Q} is completely unknown, DOA identifiability can only be achieved if further assumptions are made on the scenario under consideration. The following assumption is typical of the IV-SSF approach:

²Henceforth, the superscript “*” denotes the conjugate transpose; whereas the transpose is designated by a superscript “ T ”. The notation $\mathbf{A} \geq \mathbf{B}$, for two Hermitian matrices \mathbf{A} and \mathbf{B} , is used to mean that $(\mathbf{A} - \mathbf{B})$ is a nonnegative definite matrix. Also, \mathbf{O} denotes a zero matrix of suitable dimension.

A4. There exists a vector $\mathbf{z}(t) \in \mathcal{C}^{\bar{m} \times 1}$, which is normally distributed and satisfies

$$\mathbf{E}[\mathbf{z}(t)\mathbf{e}^*(s)] = \mathbf{O} \quad \text{for } t \leq s \quad (64.4)$$

$$\mathbf{E}[\mathbf{z}(t)\mathbf{e}^T(s)] = \mathbf{O} \quad \text{for all } t, s \quad (64.5)$$

Furthermore, denote

$$\mathbf{\Gamma} = \mathbf{E}[\mathbf{z}(t)\mathbf{x}^*(t)] \quad (\bar{m} \times n) \quad (64.6)$$

$$\bar{n} = \text{rank}(\mathbf{\Gamma}) \leq \bar{m}. \quad (64.7)$$

It is assumed that no row of $\mathbf{\Gamma}$ is identically zero and that the inequality

$$\bar{n} > 2n - m \quad (64.8)$$

holds (note that a rank-one $\mathbf{\Gamma}$ matrix can satisfy the condition (64.8) if m is large enough, and hence the condition in question is rather weak). Owing to its (partial) uncorrelatedness with $\{\mathbf{e}(t)\}$, the vector $\{\mathbf{z}(t)\}$ can be used to eliminate the noise from the array output equation (64.1), and for this reason $\{\mathbf{z}(t)\}$ is called an IV vector. Below, we briefly describe three possible ways to derive an IV vector from the available data measured with an array of sensors (for more details on this aspect, the reader should consult [12, 13, 14]).

EXAMPLE 64.1: Spatial IV

Assume that the n signals, which impinge on the main (sub)array under consideration, are also received by another (sub)array that is sufficiently distanced from the main one so that the noise vectors in the two subarrays are uncorrelated with one another. Then $\mathbf{z}(t)$ can be made from the outputs of the sensors in the second subarray (note that those sensors need not be calibrated) [12, 13, 15].

EXAMPLE 64.2: Temporal IV

When a second subarray, as described above, is not available but the signals are temporally correlated, one can obtain an IV vector by delaying the output vector: $\mathbf{z}(t) = [\mathbf{y}^T(t-1) \ \mathbf{y}^T(t-2) \ \cdots]^T$. Clearly, such a vector $\mathbf{z}(t)$ satisfies (64.4) and (64.5), and it also satisfies (64.8) under weak conditions on the signal temporal correlation. This construction of an IV vector can be readily extended to cases where $\mathbf{e}(t)$ is temporally correlated, provided that the signal temporal correlation length is longer than that corresponding to the noise [11, 14].

In a sense, the above examples are both special cases of the following more general situation:

EXAMPLE 64.3: Reference Signal

In many systems a reference or pilot signal [19, 20] $\mathbf{z}(t)$ (scalar or vector) is available. If the reference signal is sufficiently correlated with all signals of interest (in the sense of (64.8)) and uncorrelated with the noise, it can be used as an IV. Note that all signals that are not correlated with the reference will be treated as noise. Reference signals are commonly available in communication applications, for example a PN-code in spread spectrum communication [20] or a training signal used for synchronization and/or equalizer training [21]. A closely related possibility is utilization of cyclo-stationarity (or self-coherence), a property that is exhibited by many man-made signals. The reference signal(s) can then consist, for example, of sinusoids of different frequencies [22, 23]. In these techniques, the data is usually pre-processed by computing the auto-covariance function (or a higher-order statistic) before correlating with the reference signal.

The problem considered in this section concerns the estimation of the DOA vector

$$\boldsymbol{\theta} = [\theta_1, \dots, \theta_n]^T \quad (64.9)$$

given N snapshots of the array output and of the IV vector, $\{\mathbf{y}(t), \mathbf{z}(t)\}_{t=1}^N$. The number of signals, n , and the rank of the covariance matrix $\boldsymbol{\Gamma}$, \bar{n} , are assumed to be given (for the estimation of these integer-valued parameters by means of IV/SSF-based methods, we refer to [24, 25]).

64.3 The IV-SSF Approach

Let

$$\hat{\mathbf{R}} = \hat{\mathbf{W}}_L \left[\frac{1}{N} \sum_{t=1}^N \mathbf{z}(t) \mathbf{y}^*(t) \right] \hat{\mathbf{W}}_R \quad (\bar{m} \times m) \quad (64.10)$$

where $\hat{\mathbf{W}}_L$ and $\hat{\mathbf{W}}_R$ are two nonsingular Hermitian weighting matrices which are possibly data-dependent (as indicated by the fact that they are roofed). Under the assumptions made, as $N \rightarrow \infty$, $\hat{\mathbf{R}}$ converges to the matrix:

$$\mathbf{R} = \mathbf{W}_L \mathbf{E}[\mathbf{z}(t) \mathbf{y}^*(t)] \mathbf{W}_R = \mathbf{W}_L \boldsymbol{\Gamma} \mathbf{A}^* \mathbf{W}_R \quad (64.11)$$

where \mathbf{W}_L and \mathbf{W}_R are the limiting weighting matrices (assumed to be bounded and nonsingular). Owing to assumptions A2 and A3,

$$\text{rank}(\mathbf{R}) = \bar{n} \quad (64.12)$$

Hence, the Singular Value Decomposition (SVD) [26] of \mathbf{R} can be written as

$$\mathbf{R} = [\mathbf{U} \quad ?] \begin{bmatrix} \boldsymbol{\Lambda} & \mathbf{O} \\ \mathbf{O} & \mathbf{O} \end{bmatrix} \begin{bmatrix} \mathbf{S}^* \\ ? \end{bmatrix} = \mathbf{U} \boldsymbol{\Lambda} \mathbf{S}^* \quad (64.13)$$

where $\mathbf{U}^* \mathbf{U} = \mathbf{S}^* \mathbf{S} = \mathbf{I}$, $\boldsymbol{\Lambda} \in \mathcal{R}^{\bar{n} \times \bar{n}}$ is diagonal and nonsingular, and where the question marks stand for blocks that are of no importance for the present discussion.

The following key equality is obtained by comparing the two expressions for \mathbf{R} in Eqs. (64.11) and (64.13) above:

$$\mathbf{S} = \mathbf{W}_R \mathbf{A} \mathbf{C} \quad (64.14)$$

where $\mathbf{C} \triangleq \boldsymbol{\Gamma}^* \mathbf{W}_L \mathbf{U} \boldsymbol{\Lambda}^{-1} \in \mathcal{C}^{n \times \bar{n}}$ has full column rank. For a given \mathbf{S} , the true DOA vector can be obtained as the unique solution to Eq. (64.14) under the parameter identifiability condition (64.8) (see, e.g., [18]). In the more realistic case when \mathbf{S} is unknown, one can make use of Eq. (64.14) to estimate the DOA vector in the following steps.

The IV step — Compute the pre- and post-weighted sample covariance matrix $\hat{\mathbf{R}}$ in Eq. (64.10), along with its SVD:

$$\hat{\mathbf{R}} = [\hat{\mathbf{U}} \quad ?] \begin{bmatrix} \hat{\boldsymbol{\Lambda}} & \mathbf{O} \\ \mathbf{O} & ? \end{bmatrix} \begin{bmatrix} \hat{\mathbf{S}}^* \\ ? \end{bmatrix} \quad (64.15)$$

where $\hat{\boldsymbol{\Lambda}}$ contains the \bar{n} largest singular values. Note that $\hat{\mathbf{U}}$, $\hat{\boldsymbol{\Lambda}}$, and $\hat{\mathbf{S}}$ are consistent estimates of \mathbf{U} , $\boldsymbol{\Lambda}$, and \mathbf{S} in the SVD of \mathbf{R} .

The SSF step — Compute the DOA estimate as the minimizing argument of the following signal subspace fitting criterion:

$$\min_{\theta} \{ \min_{\mathbf{C}} [\text{vec}(\hat{\mathbf{S}} - \hat{\mathbf{W}}_R \mathbf{A} \mathbf{C})]^* \hat{\mathbf{V}} [\text{vec}(\hat{\mathbf{S}} - \hat{\mathbf{W}}_R \mathbf{A} \mathbf{C})] \} \quad (64.16)$$

where $\hat{\mathbf{V}}$ is a positive definite weighting matrix, and “vec” is the vectorization operator³. Alternatively, one can estimate the DOA instead by minimizing the following criterion:

$$\min_{\theta} \{ [\text{vec}(\mathbf{B}^* \hat{\mathbf{W}}_R^{-1} \hat{\mathbf{S}})]^* \hat{\mathbf{W}} [\text{vec}(\mathbf{B}^* \hat{\mathbf{W}}_R^{-1} \hat{\mathbf{S}})] \} \quad (64.17)$$

where $\hat{\mathbf{W}}$ is a positive definite weight, and $\mathbf{B} \in \mathbb{C}^{m \times (m-n)}$ is a matrix whose columns form a basis of the null-space of \mathbf{A}^* (hence, $\mathbf{B}^* \mathbf{A} = 0$ and $\text{rank}(\mathbf{B}) = m - n$). The alternative fitting criterion above is obtained from the simple observation that Eq. (64.14) along with the definition of \mathbf{B} imply that

$$\mathbf{B}^* \mathbf{W}_R^{-1} \mathbf{S} = 0 \quad (64.18)$$

It can be shown [27] that *the classes of DOA estimates derived from Eqs. (64.16) and (64.17), respectively, are asymptotically equivalent*. More exactly, for any $\hat{\mathbf{V}}$ in Eq. (64.16) one can choose $\hat{\mathbf{W}}$ in Eq. (64.17) so that the DOA estimates obtained by minimizing Eq. (64.16) and, respectively, Eq. (64.17) have the same asymptotic distribution and vice-versa.

In view of the previous result, in an asymptotical analysis it suffices to consider only one of the two criteria above. In the following, we focus on Eq. (64.17). Compared with Eq. (64.16), the criterion (64.17) has the advantage that it depends on the DOA only. On the other hand, for a general array there is no known closed-form parameterization of \mathbf{B} in terms of θ . However, as shown in the following, this is no drawback because the optimally weighted criterion (which is the one to be used in applications) is an explicit function of θ .

64.4 The Optimal IV-SSF Method

In what follows, we deal with the essential problem of choosing the weights $\hat{\mathbf{W}}$, $\hat{\mathbf{W}}_R$, and $\hat{\mathbf{W}}_L$ in the IV-SSF criterion (64.17) so as to maximize the DOA estimation accuracy. First, we optimize the accuracy with respect to $\hat{\mathbf{W}}$, and then with respect to $\hat{\mathbf{W}}_R$ and $\hat{\mathbf{W}}_L$.

Optimal Selection of $\hat{\mathbf{W}}$

Define

$$\mathbf{g}(\theta) = \text{vec}(\mathbf{B}^* \hat{\mathbf{W}}_R^{-1} \hat{\mathbf{S}}) \quad (64.19)$$

and observe that the criterion function in Eq. (64.17) can be written as,

$$\mathbf{g}^*(\theta) \hat{\mathbf{W}} \mathbf{g}(\theta) \quad (64.20)$$

In [27] it is shown that $\mathbf{g}(\theta)$ (evaluated at the true DOA vector) has, asymptotically in N , a circularly symmetric normal distribution with zero mean and the following covariance:

$$\mathbf{G}(\theta) = \frac{1}{N} [(\mathbf{W}_L \mathbf{U} \mathbf{\Lambda}^{-1})^* \mathbf{R}_z (\mathbf{W}_L \mathbf{U} \mathbf{\Lambda}^{-1})]^T \otimes [\mathbf{B}^* \mathbf{R}_y \mathbf{B}] \quad (64.21)$$

³If \mathbf{x}_k is the k th column of a matrix \mathbf{X} , then $\text{vec}(\mathbf{X}) = [\mathbf{x}_1^T \ \mathbf{x}_2^T \ \dots]^T$.

where \otimes denotes the Kronecker matrix product [28]; and where, for a stationary signal $s(t)$, we use the notation

$$\mathbf{R}_s = \text{E}[s(t)s^*(t)] . \quad (64.22)$$

Then, it follows from the ABC (Asymptotically Best Consistent) theory of parameter estimation⁴ that the minimum variance estimate, in the class of estimates under discussion, is given by the minimizing argument of the criterion in Eq. (64.20) with $\hat{\mathbf{W}} = \hat{\mathbf{G}}^{-1}(\boldsymbol{\theta})$, that is

$$f(\boldsymbol{\theta}) = \mathbf{g}^*(\boldsymbol{\theta})\hat{\mathbf{G}}^{-1}(\boldsymbol{\theta})\mathbf{g}(\boldsymbol{\theta}) \quad (64.23)$$

where

$$\hat{\mathbf{G}}(\boldsymbol{\theta}) = \frac{1}{N}[(\hat{\mathbf{W}}_L \hat{\mathbf{U}} \hat{\mathbf{A}}^{-1})^* \hat{\mathbf{R}}_z (\hat{\mathbf{W}}_L \hat{\mathbf{U}} \hat{\mathbf{A}}^{-1})^T \otimes [\mathbf{B}^* \hat{\mathbf{R}}_y \mathbf{B}] \quad (64.24)$$

and where $\hat{\mathbf{R}}_z$ and $\hat{\mathbf{R}}_y$ are the usual sample estimates of \mathbf{R}_z and \mathbf{R}_y . Furthermore, it is easily shown that the minimum variance estimate, obtained by minimizing Eq. (64.23), is asymptotically normally distributed with mean equal to the true parameter vector and the following covariance matrix:

$$\mathbf{H} = \frac{1}{2} \{\text{Re} [\mathbf{J}^* \mathbf{G}^{-1}(\boldsymbol{\theta}) \mathbf{J}]\}^{-1} \quad (64.25)$$

where

$$\mathbf{J} = \lim_{N \rightarrow \infty} \frac{\partial \mathbf{g}(\boldsymbol{\theta})}{\partial \boldsymbol{\theta}} . \quad (64.26)$$

The following more explicit formula for \mathbf{H} is derived in [27]:

$$\mathbf{H} = \frac{1}{2N} \left(\text{Re} \left\{ \left[\mathbf{D}^* \mathbf{R}_y^{-1/2} \boldsymbol{\Pi}_{R_y^{-1/2} \mathbf{A}}^\perp \mathbf{R}_y^{-1/2} \mathbf{D} \right] \odot \boldsymbol{\Omega}^T \right\} \right)^{-1} \quad (64.27)$$

where \odot denotes the Hadamard-Schur matrix product (elementwise multiplication) and

$$\boldsymbol{\Omega} = \boldsymbol{\Gamma}^* \mathbf{W}_L \mathbf{U} (\mathbf{U}^* \mathbf{W}_L \mathbf{R}_z \mathbf{W}_L \mathbf{U})^{-1} \mathbf{U}^* \mathbf{W}_L \boldsymbol{\Gamma} . \quad (64.28)$$

Furthermore, the notation $\mathbf{Y}^{-1/2}$ is used for a Hermitian (for notational convenience) square root of the inverse of a positive definite matrix \mathbf{Y} , the matrix \mathbf{D} is made from the direction vector derivatives,

$$\mathbf{D} = [d_1 \quad \cdots \quad d_n]; \quad d_k = \frac{\partial \mathbf{a}(\boldsymbol{\theta}_k)}{\partial \boldsymbol{\theta}_k}$$

and, for a full column-rank matrix \mathbf{X} , $\boldsymbol{\Pi}_X^\perp$ defines the orthogonal projection onto the nullspace of \mathbf{X}^* as

$$\boldsymbol{\Pi}_X^\perp = \mathbf{I} - \boldsymbol{\Pi}_X; \quad \boldsymbol{\Pi}_X = \mathbf{X}(\mathbf{X}^* \mathbf{X})^{-1} \mathbf{X}^* . \quad (64.29)$$

To summarize, for fixed $\hat{\mathbf{W}}_R$ and $\hat{\mathbf{W}}_L$, the statistically optimal selection of $\hat{\mathbf{W}}$ leads to DOA estimates with an asymptotic normal distribution with mean equal to the true DOA vector and covariance matrix given by Eq. (64.27).

⁴For details on the ABC theory, which is an extension of the classical BLUE (Best Linear Unbiased Estimation) / Markov theory of linear regression to a class of nonlinear regressions with asymptotically vanishing residuals, the reader is referred to [9, 29].

Optimal Selection of \hat{W}_R and \hat{W}_L

The optimal weights \hat{W}_R and \hat{W}_L are, by definition, those that minimize the limiting covariance matrix \mathbf{H} of the DOA estimation errors. In the expression (64.27) of \mathbf{H} , only $\mathbf{\Omega}$ depends on \mathbf{W}_R and \mathbf{W}_L (the dependence on \mathbf{W}_R is implicit, via \mathbf{U}). Since the matrix $\mathbf{\Gamma}$ has rank \bar{n} , it can be factorized as follows:

$$\mathbf{\Gamma} = \mathbf{\Gamma}_1 \mathbf{\Gamma}_2^* \quad (64.30)$$

where both $\mathbf{\Gamma}_1 \in \mathcal{C}^{\bar{m} \times \bar{n}}$ and $\mathbf{\Gamma}_2 \in \mathcal{C}^{n \times \bar{n}}$ have full column rank. Insertion of Eq. (64.30) into the equality $\mathbf{W}_L \mathbf{\Gamma} \mathbf{A}^* \mathbf{W}_R = \mathbf{U} \mathbf{\Lambda} \mathbf{S}^*$ yields the following equation, after a simple manipulation,

$$\mathbf{W}_L \mathbf{\Gamma}_1 \mathbf{T} = \mathbf{U} \quad (64.31)$$

where $\mathbf{T} = \mathbf{\Gamma}_2^* \mathbf{A}^* \mathbf{W}_R \mathbf{\Lambda}^{-1} \in \mathcal{C}^{\bar{n} \times \bar{n}}$ is a nonsingular transformation matrix. By using Eq. (64.31) in Eq. (64.28), we obtain:

$$\mathbf{\Omega} = \mathbf{\Gamma}_2 (\mathbf{\Gamma}_1^* \mathbf{W}_L^2 \mathbf{\Gamma}_1) (\mathbf{\Gamma}_1^* \mathbf{W}_L^2 \mathbf{R}_z \mathbf{W}_L^2 \mathbf{\Gamma}_1)^{-1} (\mathbf{\Gamma}_1^* \mathbf{W}_L^2 \mathbf{\Gamma}_1) \mathbf{\Gamma}_2^* \quad (64.32)$$

Observe that $\mathbf{\Omega}$ does not actually depend on \mathbf{W}_R . Hence, \hat{W}_R can be arbitrarily selected, as any nonsingular Hermitian matrix, without affecting the asymptotics of the DOA parameter estimates! Concerning the choice of \hat{W}_L , it is easily verified that

$$\mathbf{\Omega} \leq \mathbf{\Omega} \mid_{\mathbf{W}_L = \mathbf{R}_z^{-1/2}} = \mathbf{\Gamma}_2 (\mathbf{\Gamma}_1^* \mathbf{R}_z^{-1} \mathbf{\Gamma}_1) \mathbf{\Gamma}_2^* = \mathbf{\Gamma}^* \mathbf{R}_z^{-1} \mathbf{\Gamma} \quad (64.33)$$

Indeed,

$$\begin{aligned} \mathbf{\Gamma}^* \mathbf{R}_z^{-1} \mathbf{\Gamma} - \mathbf{\Omega} &= \mathbf{\Gamma}_2 [\mathbf{\Gamma}_1^* \mathbf{R}_z^{-1} \mathbf{\Gamma}_1 - (\mathbf{\Gamma}_1^* \mathbf{W}_L^2 \mathbf{\Gamma}_1) (\mathbf{\Gamma}_1^* \mathbf{W}_L^2 \mathbf{R}_z \mathbf{W}_L^2 \mathbf{\Gamma}_1)^{-1} \times \\ &\times (\mathbf{\Gamma}_1^* \mathbf{W}_L^2 \mathbf{\Gamma}_1)] \mathbf{\Gamma}_2^* = \mathbf{\Gamma}^* \mathbf{R}_z^{-1/2} \mathbf{\Pi}_{\mathbf{R}_z^{-1/2} \mathbf{W}_L^2 \mathbf{\Gamma}_1}^\perp \mathbf{R}_z^{-1/2} \mathbf{\Gamma} \end{aligned} \quad (64.34)$$

which is obviously a nonnegative definite matrix. Hence, $\mathbf{W}_L = \mathbf{R}_z^{-1/2}$ maximizes $\mathbf{\Omega}$. Then, it follows from the expression of the matrix \mathbf{H} and the properties of the Hadamard-Schur product that this same choice of \mathbf{W}_L minimizes \mathbf{H} . The conclusion is that *the optimal weight \hat{W}_L , which yields the best limiting accuracy, is*

$$\hat{W}_L = \hat{R}_z^{-1/2} \quad (64.35)$$

The (minimum) covariance matrix \mathbf{H} , corresponding to the above choice, is given by

$$\mathbf{H}_o = \frac{1}{2N} \{ \text{Re} [(\mathbf{D}^* \mathbf{R}_y^{-1/2} \mathbf{\Pi}_{\mathbf{R}_y^{-1/2} \mathbf{A}}^\perp \mathbf{R}_y^{-1/2} \mathbf{D}) \odot (\mathbf{\Gamma}^* \mathbf{R}_z^{-1} \mathbf{\Gamma})^T] \}^{-1} \quad (64.36)$$

Remark It is worth noting that \mathbf{H}_o monotonically decreases as \bar{m} (the dimension of $\mathbf{z}(t)$) increases. The proof of this claim is similar to the proof of the corresponding result in [9], Complement C8.5. Hence, as could be intuitively expected, one should use all available instruments (spatial and/or temporal) to obtain maximal theoretical accuracy. However, practice has shown that too large a dimension of the IV vector may in fact decrease the empirically observed accuracy. This phenomenon can be explained by the fact that increasing \bar{m} means that a longer data set is necessary for the asymptotic results to be valid.

Optimal IV-SSF Criteria

Fortunately, the criterion, (64.23) and (64.24) can be expressed in a functional form that depends on the indeterminate θ in an explicit way (recall that, for most cases, the dependence of \mathbf{B} in Eq. (64.23) on θ is not available in explicit form). By using the following readily verified equality [28],

$$\text{tr}(\mathbf{A} \mathbf{X}^* \mathbf{B} \mathbf{Y}) = [\text{vec}(\mathbf{X})]^* [\mathbf{A}^T \otimes \mathbf{B}] [\text{vec}(\mathbf{Y})] \quad (64.37)$$

which holds for any conformable matrices A , X , B , and Y , one can write Eq. (64.23) as:⁵

$$f(\theta) = \text{tr} \{ [(\hat{W}_L \hat{U} \hat{\Lambda}^{-1})^* \hat{R}_z (\hat{W}_L \hat{U} \hat{\Lambda}^{-1})]^{-1} \hat{S}^* \hat{W}_R^{-1} B (B^* \hat{R}_y B)^{-1} B^* \hat{W}_R^{-1} \hat{S} \} \quad (64.38)$$

However, observe that

$$B (B^* \hat{R}_y B)^{-1} B^* = \hat{R}_y^{-1/2} \Pi_{\hat{R}_y^{1/2} B} \hat{R}_y^{-1/2} = \hat{R}_y^{-1/2} \Pi_{\hat{R}_y^{-1/2} A}^\perp \hat{R}_y^{-1/2} \quad (64.39)$$

Inserting Eq. (64.39) into Eq. (64.38) yields:

$$f(\theta) = \text{tr} [\hat{\Lambda} (\hat{U}^* \hat{W}_L \hat{R}_z \hat{W}_L \hat{U})^{-1} \hat{\Lambda} \hat{S}^* \hat{W}_R^{-1} \hat{R}_y^{-1/2} \Pi_{\hat{R}_y^{-1/2} A}^\perp \hat{R}_y^{-1/2} \hat{W}_R^{-1} \hat{S}] \quad (64.40)$$

which is an explicit function of θ . Insertion of the optimal choice of W_L into Eq. (64.40) leads to a further simplification of the criterion as seen below.

Owing to the arbitrariness in the choice of \hat{W}_R , there exists an infinite class of optimal IV-SSF criteria. In what follows, we consider two members of this class.

Let

$$\hat{W}_R = \hat{R}_y^{-1/2} \quad (64.41)$$

Insertion of Eq. (64.41), along with Eq. (64.35), into Eq. (64.40) yields the following criterion function:

$$f_{WW}(\theta) = \text{tr} \left(\Pi_{\hat{R}_y^{-1/2} A}^\perp \tilde{S} \tilde{\Lambda}^2 \tilde{S}^* \right) \quad (64.42)$$

where \tilde{S} and $\tilde{\Lambda}$ are made from the principal singular right vectors and singular values of the matrix

$$\tilde{R} = \hat{R}_z^{-1/2} \hat{R}_{zy} \hat{R}_y^{-1/2} \quad (64.43)$$

(with \hat{R}_{zy} defined in an obvious way). The function (64.42) is the UNCLE (spatial IV-SSF) criterion of Wong and Wu [12, 13].

Next, choose \hat{W}_R as

$$\hat{W}_R = I \quad (64.44)$$

The corresponding criterion function is

$$f_{VSO}(\theta) = \text{tr} \left(\Pi_{\hat{R}_y^{-1/2} A}^\perp \hat{R}_y^{-1/2} \bar{S} \bar{\Lambda}^2 \bar{S}^* \hat{R}_y^{-1/2} \right) \quad (64.45)$$

where \bar{S} and $\bar{\Lambda}$ are made from the principal singular pairs of

$$\bar{R} = \hat{R}_z^{-1/2} \hat{R}_{zy} \quad (64.46)$$

The function (64.45) above is recognized as the optimal (temporal) IV-SSF criterion of Viberg et al. [14].

An important consequence of the previous discussion is that the DOA estimation methods of [12, 13] and [14], respectively, which were derived in seemingly unrelated contexts and by means of somewhat different approaches, are in fact asymptotically equivalent when used under the same conditions. These two methods have very similar computational burdens, which can be seen by comparing Eqs. (64.42) and (64.43) with Eqs. (64.45) and (64.46). Also, their finite-sample properties appear to be rather similar, as demonstrated in the simulation examples. Numerical algorithms for the minimization of the type of criterion function associated with the optimal IV-SSF methods are discussed in [17]. Some suggestions are also given in the summary below.

⁵To within a multiplicative constant.

64.5 Algorithm Summary

The estimation method presented in this section is useful for direction finding in the presence of noise of unknown spatial color. The underlying assumptions and the algorithm can be summarized as follows:

Assumptions — A batch of N samples of the array output $\mathbf{y}(t)$, that can accurately be described by the model (64.1) and (64.2) is available. The array is calibrated in the sense that $\mathbf{a}(\theta)$ is a known function of its argument θ . In addition, N samples of the IV-vector $\mathbf{z}(t)$, fulfilling Eqs. (64.4) through (64.8), are given. In words, the IV vector is uncorrelated with the noise but well correlated with the signal. In practice, $\mathbf{z}(t)$ may be taken from a second subarray, a delayed version of $\mathbf{y}(t)$, or a reference (pilot) signal. In the former case, the second subarray need not be calibrated.

Algorithm — In the following we summarize the UNCLE version (64.42) of the algorithm. First, compute $\tilde{\mathbf{R}}$ from the sample statistics of $\mathbf{y}(t)$ and $\mathbf{z}(t)$, according to

$$\tilde{\mathbf{R}} = \hat{\mathbf{R}}_z^{-1/2} \hat{\mathbf{R}}_{zy} \hat{\mathbf{R}}_y^{-1/2}.$$

From a numerical point of view, this is best done using QR factorization. Next, partition the singular value decomposition of $\tilde{\mathbf{R}}$ according to

$$\tilde{\mathbf{R}} = \begin{bmatrix} \tilde{\mathbf{U}} & ? \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{\Lambda}} & \mathbf{O} \\ \mathbf{O} & ? \end{bmatrix} \begin{bmatrix} \tilde{\mathbf{S}}^* \\ ? \end{bmatrix},$$

where $\tilde{\mathbf{S}}$ contains the \bar{n} principal right singular vectors and the diagonal matrix $\tilde{\mathbf{\Lambda}}$ the corresponding singular values. If \bar{n} is unknown, it can be estimated as the number of significant singular values. Finally, compute the DOA estimates as the minimizing arguments of the criterion function

$$f_{WW}(\theta) = \text{tr} \left(\mathbf{\Pi}_{\hat{\mathbf{R}}_y^{-1/2} \mathbf{A}}^\perp \tilde{\mathbf{S}} \tilde{\mathbf{\Lambda}}^2 \tilde{\mathbf{S}}^* \right)$$

using $n = \bar{n}$. If the minimum value of the criterion is “large”, it is an indication that more than \bar{n} sources are present. In the general case, a numerical search must be performed to find the minimum. The **leastsq** implementation in MatlabTM, which uses the Levenberg-Marquardt or Gauss-Newton techniques [30], is a possible choice. To initialize the search, one can use the alternating projection procedure [31]. In short, a grid search over $f_{WW}(\theta)$ is first performed assuming $n = 1$, i.e., using $f_{WW}(\theta_1)$. The resulting DOA estimate $\hat{\theta}_1$ is then “projected out” from the data, and a grid search for the second DOA is performed using the modified criterion $f_2(\theta_2)$. The procedure is repeated until initial estimates are available for all DOAs. The k th modified criterion can be expressed as

$$f_k(\theta_k) = - \frac{\mathbf{a}^*(\theta_k) \mathbf{\Pi}_{\hat{\mathbf{R}}_y^{-1/2} \hat{\mathbf{A}}_{k-1}}^\perp \tilde{\mathbf{S}} \tilde{\mathbf{\Lambda}}^2 \tilde{\mathbf{S}}^* \mathbf{\Pi}_{\hat{\mathbf{R}}_y^{-1/2} \hat{\mathbf{A}}_{k-1}}^\perp \mathbf{a}(\theta_k)}{\mathbf{a}^*(\theta_k) \mathbf{\Pi}_{\hat{\mathbf{R}}_y^{-1/2} \hat{\mathbf{A}}_{k-1}}^\perp \mathbf{a}(\theta_k)}$$

where

$$\begin{aligned} \hat{\mathbf{A}}_k &= \mathbf{A}(\hat{\theta}_k) \\ \hat{\theta}_k &= [\hat{\theta}_1, \dots, \hat{\theta}_k]^T. \end{aligned}$$

The initial estimate of θ_k is taken as the minimizing argument of $f_k(\theta_k)$. Once all DOAs have been initialized one can, in principle, continue the alternating projection minimization in the same way. However, the procedure usually converges rather slowly and therefore it is recommended instead to switch to a Newton-type search as indicated above. Empirical investigations in [17, 32] using similar subspace fitting criteria, have indicated that this indeed leads to the global minimum with high probability.

64.6 Numerical Examples

This section reports the results of a comparative performance study based on Monte-Carlo simulations. The scenarios are identical to those presented in [33] (spatial IV-SSF) and [14] (temporal IV-SSF). The plots presented below contain theoretical standard deviations of the DOA estimates along with empirically observed RMS (root mean square) errors. The former are obtained from Eq. (64.36), whereas the latter are based on 512 independent noise and signal realizations. The minimizers of Eq. (64.42) (UNCLE) and Eq. (64.45) (IV-SSF) are computed using a modified Gauss-Newton search initialized at the true DOAs (since here we are interested only in the quality of the global optimum). DOA estimates that are more than 5° off the true value are declared failures, and not included in the empirical RMS calculation. If the number of failures exceeds 30%, no RMS value is calculated.

In all scenarios, two planar wavefronts arrive from DOAs 0° and 5° relative to the array broadside. Unless otherwise stated, the emitter signals are zero-mean Gaussian with signal covariance matrix $\mathbf{P} = \mathbf{I}$. Only the estimation statistics for $\theta_1 = 0^\circ$ are shown in the plots below, the ones for θ_2 being similar.

The array output (both subarrays in the spatial IV scenario) is corrupted by additive zero-mean temporally white Gaussian noise. The noise covariance matrix has k/l th element

$$\mathbf{Q}_{kl} = \sigma^2 0.9^{|k-l|} e^{j\frac{\pi}{2}(k-l)}. \quad (64.47)$$

The noise level σ^2 is adjusted to give a desired SNR, defined as $\mathbf{P}_{11}/\sigma^2 = \mathbf{P}_{22}/\sigma^2$. This noise is reminiscent of a strong signal cluster at the location $\theta = 30^\circ$.

EXAMPLE 64.4: Spatial IVM

In the first example, a ULA of 16 elements and half-wavelength separation is employed. The first $m = 8$ contiguous sensors form a calibrated subarray, whereas the outputs of the last $\bar{m} = 8$ sensors are used as instrumental variables, and these sensors could therefore be uncalibrated. Letting $\tilde{\mathbf{y}}(t)$ denote the 16-element array output, we thus take

$$\mathbf{y}(t) = \tilde{\mathbf{y}}_{1:8}(t) \quad \mathbf{z}(t) = \tilde{\mathbf{y}}_{9:16}(t).$$

Both subarray outputs are perturbed by independent additive noise vectors, both having 8×8 covariance matrices given by Eq. (64.47). In this example, the emitter signals are assumed to be temporally white.

In Fig. 64.1, the theoretical and empirical RMS errors are displayed vs. the number of samples. The SNR is fixed at 6 dB.

Figure 64.2 shows the theoretical and empirical RMS errors vs. the SNR. The number of snapshots is here fixed to $N = 100$.

To demonstrate the applicability to situations involving highly correlated signals, Fig. 64.2 is repeated but using the signal covariance

$$\mathbf{P} = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}$$

The resulting RMS errors are plotted with their theoretical values in Fig. 64.3. By comparing Figs. 64.2 and 64.3, we see that the methods are not insensitive to the signal correlation. However, the observed RMS errors agree well with the theoretically predicted values, and in spatial scenarios this is the best possible RMS performance (the empirical RMS error appears to be lower than the CRB for low SNR; however this is at the price of a notable bias).

FIGURE 64.1: RMS error of DOA estimate vs. number of snapshots. Spatial IVM. The solid line is the theoretical standard deviation.

FIGURE 64.2: RMS error of DOA estimate vs SNR. Spatial IVM. The solid line is the theoretical standard deviation.

FIGURE 64.3: RMS error of DOA estimate vs. SNR. Spatial IVM. Coherent signals. The solid line is the theoretical standard deviation.

FIGURE 64.4: RMS error of DOA estimate vs. number of snapshots. Temporal IVM. The solid line is the theoretical standard deviation.

In conclusion, no significant performance difference is observed between the two IV-SSF versions. The observed RMS errors of both methods follow the theoretical curves quite closely, even in fairly difficult scenarios involving closely spaced DOAs and highly correlated signals.

EXAMPLE 64.5: Temporal IVM

In this example, the temporal IV approach is investigated. The array is a 6-element ULA of half wavelength interelement spacing. The real and imaginary parts of both signals are generated as uncorrelated first-order complex AR processes with identical spectra. The poles of the driving AR-processes are 0.6. In this case, $y(t)$ is the array output, whereas the instrumental variable vector is chosen as $z(t) = y(t - 1)$.

In Fig. 64.4, we show the theoretical and empirical RMS errors vs. the number of snapshots. The SNR is fixed at 10 dB. Figure 64.5 displays the theoretical and empirical RMS errors vs. the SNR. The number of snapshots is here fixed at $N = 100$.

FIGURE 64.5: RMS error of DOA estimate vs. SNR. Temporal IVM. The solid line is the theoretical standard deviation.

The figures indicate a slight performance difference among the methods in temporal scenarios, namely when the number of samples is small but the SNR is relatively high. However, no definite conclusions can be drawn regarding this somewhat unexpected phenomenon from our limited simulation study.

64.7 Concluding Remarks

The main points made by the present contribution can be summarized as follows:

1. The spatial and temporal IV-SSF approaches can be treated in a unified manner under general conditions. In fact, a general IV-SSF approach using both spatial and temporal instruments is also possible.
2. The optimization of the DOA parameter estimation accuracy, for fixed weights $\hat{\mathbf{W}}_L$ and $\hat{\mathbf{W}}_R$, can be most conveniently carried out using the ABC theory. The resulting derivations are more concise than those based on other analysis techniques.
3. The column (or post-)weight $\hat{\mathbf{W}}_R$ has no effect on the asymptotics.
4. An important corollary of the above-mentioned result is that the optimal IV-SSF methods of [12, 13] and, respectively, [14] are asymptotically equivalent when used on the same data.

In closing this section, we reiterate the fact that the IV-SSF approaches can deal with coherent signals, handle noise fields with general (unknown) spatial correlations, and, in their spatial versions, can make use of outputs from completely uncalibrated sensors. They are also comparatively simple from a computational standpoint, since no noise modelling is required. Additionally, the optimal IV-SSF methods provide highly accurate DOA estimates. More exactly, in spatial IV scenarios these DOA estimation methods can be shown to be asymptotically statistically efficient under weak conditions [33]. In temporal scenarios, they are no longer exactly statistically efficient, yet their accuracy is quite close to the best possible one [14]. All these features and properties should make the optimal IV-SSF approach appealing for practical array signal processing applications. The IV-SSF approach can also be applied, with some modifications, to system identification problems [34] and is hence expected to play a role in that type of application as well.

Appendix A: Introduction to IV Methods

In this appendix we give a brief introduction to instrumental variable methods in their original context, which is time series analysis. Let $y(t)$ be a real-valued scalar time series, modeled by the auto-regressive moving average (ARMA) equation

$$y(t) + a_1 y(t-1) + \cdots + a_p y(t-p) = e(t) + b_1 e(t-1) + \cdots + b_q e(t-q) . \quad (64.48)$$

Here, $e(t)$ is assumed to be a stationary white noise. Suppose we are given measurements of $y(t)$ for $t = 1, \dots, N$ and wish to estimate the AR parameters a_1, \dots, a_p . The roots of the AR polynomial $z^p + a_1 z^{p-1} + \cdots + a_p$ are the system poles, and their estimation is of importance, for instance, for stability monitoring. Also, the first step of any “linear” method for ARMA modeling involves finding the AR parameters as the first step. The optimal way to approach the problem requires a non-linear search over the entire parameter set $\{a_k\}_{k=1}^p, \{b_k\}_{k=1}^q$; using a maximum likelihood or a prediction error criterion [9, 35]. However, in many cases this is computationally prohibitive, and in addition the “noise model” (the MA parameters) is sometimes of less interest per se. In contrast, the IV approach produces estimates of the AR part from a solution of a (possibly overdetermined) linear system of equations as follows: Rewrite Eq. (64.48) as

$$y(t) = \boldsymbol{\varphi}^T(t) \boldsymbol{\theta} + v(t) , \quad (64.49)$$

where

$$\boldsymbol{\varphi}(t) = [-y(t-1), \dots, -y(t-p)]^T \quad (64.50)$$

$$\boldsymbol{\theta} = [a_1, \dots, a_p]^T \quad (64.51)$$

$$v(t) = e(t) + b_1 e(t-1) + \cdots + b_q e(t-q) . \quad (64.52)$$

Note that Eq. (64.49) is a linear regression in the unknown parameter $\boldsymbol{\theta}$. A standard least-squares (LS) estimate is obtained by minimizing the LS criterion

$$V_{LS}(\boldsymbol{\theta}) = \mathbb{E} \left[(y(t) - \boldsymbol{\varphi}^T(t) \boldsymbol{\theta})^2 \right] . \quad (64.53)$$

Equating the derivative of Eq. (64.53) (w.r.t. $\boldsymbol{\theta}$) to zero gives the so-called normal equations

$$\mathbb{E} \left[\boldsymbol{\varphi}(t) \boldsymbol{\varphi}^T(t) \right] \hat{\boldsymbol{\theta}} = \mathbb{E} \left[\boldsymbol{\varphi}(t) y(t) \right] . \quad (64.54)$$

resulting in

$$\hat{\boldsymbol{\theta}} = \mathbf{R}_{\varphi\varphi}^{-1} \mathbf{R}_{\varphi y} = \left(\mathbb{E} \left[\boldsymbol{\varphi}(t) \boldsymbol{\varphi}^T(t) \right] \right)^{-1} \mathbb{E} \left[\boldsymbol{\varphi}(t) y(t) \right] . \quad (64.55)$$

Inserting Eq. (64.49) into Eq. (64.55) shows that

$$\hat{\boldsymbol{\theta}} = \boldsymbol{\theta} + \mathbf{R}_{\varphi\varphi}^{-1} \mathbf{R}_{\varphi v} . \quad (64.56)$$

In case $q = 0$ (i.e., $y(t)$ is an AR process), we have $v(t) = e(t)$. Because $\boldsymbol{\varphi}(t)$ and $e(t)$ are uncorrelated, Eq. (64.56) shows that the LS method produces a consistent estimate of $\boldsymbol{\theta}$. However, when $q > 0$, $\boldsymbol{\varphi}(t)$ and $v(t)$ are in general correlated, implying that the LS method gives biased estimates.

From the above we conclude that the problem with the LS estimate in the ARMA case is that the regression vector $\boldsymbol{\varphi}(t)$ is correlated with the “equation error noise” $v(t)$. An instrumental variable

vector $\zeta(t)$ is one that is uncorrelated with $v(t)$, while still “sufficiently correlated” with $\varphi(t)$. The most natural choice in the ARMA case (provided the model orders are known) is

$$\zeta(t) = \varphi(t - q) \quad (64.57)$$

which clearly fulfills both requirements. Now, multiply both sides of the linear regression model (64.49) by $\zeta(t)$ and take expectation, resulting in the “IV normal equations”

$$\mathbb{E}[\zeta(t)y(t)] = \mathbb{E}[\zeta(t)\varphi^T(t)]\theta. \quad (64.58)$$

The IV estimate is obtained simply by solving the linear system of equations (64.58), but with the unknown cross-covariance matrices $R_{\zeta\varphi}$ and $R_{\zeta y}$ replaced by their corresponding estimates using time averaging. Since the latter are consistent, so are the IV estimates of θ . The method is also referred to as the *extended Yule-Walker* approach in the literature. Its finite sample properties may often be improved upon by increasing the dimension of the IV vector, which means that Eq. (64.58) must be solved in an LS sense, and also by appropriately pre-filtering the IV-vector. This is quite similar to the optimal weighting proposed herein.

In order to make the connection to the IV-SSF method more clear, a slightly modified version of Eq. (64.58) is presented. Let us rewrite Eq. (64.58) as follows

$$R_{\zeta\phi} \begin{bmatrix} 1 \\ \theta \end{bmatrix} = \mathbf{0}, \quad (64.59)$$

where

$$R_{\zeta\phi} = \mathbb{E} \left\{ \zeta(t) [y(t), -\varphi^T(t)] \right\}. \quad (64.60)$$

The relation (64.59) shows that $R_{\zeta\phi}$ is singular, and that θ can be computed from a suitably normalized vector in its one-dimensional nullspace. However, when $R_{\zeta\phi}$ is estimated using a finite number of data, it will with probability one have full rank. The best (in a least squares sense) low-rank approximation of $R_{\zeta\phi}$ is obtained by truncating its singular value decomposition. A natural estimate of θ can therefore be obtained from the right singular vector of $\hat{R}_{\zeta\phi}$ that corresponds to the minimum singular value. The proposed modification is essentially an IV-SSF version of the extended Yule-Walker method, although the SSF step is trivial because the parameter vector of interest can be computed directly from the estimated subspace.

Turning to the array processing problem, the counterpart of Eq. (64.49) is the (Hermitian transposed) data model (64.1)

$$\mathbf{y}^*(t) = \mathbf{x}^*(t)\mathbf{A}^* + \mathbf{e}^*(t).$$

Note that this is a non-linear regression model, owing to the non-linear dependence of \mathbf{A} on θ . Also observe that $\mathbf{y}(t)$ is a complex vector as opposed to the real scalar $y(t)$ in Eq. (64.49). Similar to Eq. (64.58), the IV normal equations are given by

$$\mathbb{E}[\mathbf{z}(t)\mathbf{y}^*(t)] = \mathbb{E}[\mathbf{z}(t)\mathbf{x}^*(t)]\mathbf{A}^* \quad (64.61)$$

under the assumption that the IV-vector $\mathbf{z}(t)$ is uncorrelated with the noise $\mathbf{e}(t)$. Unlike the standard IV problem, the “regressor” $\mathbf{x}(t)$ [corresponding to $\varphi(t)$ in Eq. (64.49)] cannot be measured. Thus, it is not possible to get a direct estimate of the “regression variable” \mathbf{A} . However, its range space, or at least a subset thereof, can be computed from the principal right singular vectors. In the finite sample case, the performance can be improved by using row and column weighting, which leads to the weighted IV normal equations (64.11). The exact relation involving the principal right singular vectors is Eq. (64.14), and two SSF formulations for revealing θ from the computed signal subspace are given in Eqs. (64.16) and (64.17).

65.1 Introduction

This article (see also [1, 2]) considers new methods for multiple electromagnetic source localization using sensors whose output is a *vector* corresponding to the complete electric and magnetic fields at the sensor. These sensors, which will be called *vector sensors*, can consist for example of two orthogonal triads of scalar sensors that measure the electric and magnetic field components. Our approach is in contrast to other articles in this chapter that employ sensor arrays in which the output of each sensor is a scalar corresponding, for example, to a scalar function of the electric field. The main advantage of the vector sensors is that they make use of all available electromagnetic information and hence should outperform the scalar sensor arrays in accuracy of direction of arrival (DOA) estimation. Vector sensors should also allow the use of smaller array apertures while improving performance.

¹This work was supported by the U.S. Air Force Office of Scientific Research under Grant no. F49620-97-1-0481, the Office of Naval Research under Grant no. N00014-96-1-1078, the National Science Foundation under Grant no. MIP-9615590, and the HTI Fellowship.

(Note that we use the term “vector sensor” for a device that measures a complete physical vector quantity.)

Section 65.2 derives the measurement model. The electromagnetic sources considered can originate from two types of transmissions: (1) Single signal transmission (SST), in which a single signal message is transmitted, and (2) dual signal transmission (DST), in which two separate signal messages are transmitted simultaneously (from the same source), see for example [3, 4]. The interest in DST is due to the fact that it makes full use of the two spatial degrees of freedom present in a transverse electromagnetic plane wave. This is particularly important in the wake of increasing demand for economical spectrum usage by existing and emerging modern communication technologies.

Section 65.3 analyzes the minimum attainable variance of unbiased DOA estimators for a general vector sensor array model and multi-electromagnetic sources that are assumed to be stochastic and stationary. A compact expression for the corresponding Cramér-Rao bound (CRB) on the DOA estimation error that extends previous results for the scalar sensor array case in [5] (see also [6]) is presented.

A significant property of the vector sensors is that they enable DOA (azimuth and elevation) estimation of an electromagnetic source with a *single* vector sensor and a single snapshot. This result is explicitly shown by using the CRB expression for this problem in Section 65.4. A bound on the associated normalized mean-square angular error (MSAE, to be defined later) which is invariant to the reference coordinate system is used for an in-depth performance study. Compact expressions for this MSAE bound provide physical insight into the SST and DST source localization problems with a single vector sensor.

The CRB matrix for an SST source in the sensor coordinate frame exhibits some nonintrinsic singularities (i.e., singularities that are not inherent in the physical model while being dependent on the choice of the reference coordinate system) and has complicated entry expressions. Therefore, we introduce a new vector angular error defined in terms of the incoming wave frame. A bound on the normalized asymptotic covariance of the vector angular error (CVAE) is derived. The relationship between the CVAE and MSAE and their bounds is presented. The CVAE matrix bound for the SST source case is shown to be diagonal, easy to interpret, and to have only intrinsic singularities.

We propose a simple algorithm for estimating the source DOA with a single vector sensor, motivated by the Poynting vector. The algorithm is applicable to various types of sources (e.g., wide-band and non-Gaussian); it does not require a minimization of a cost function and can be applied in real time. Statistical performance analysis evaluates the variance of the estimator under mild assumptions and compares it with the MSAE lower bound.

Section 65.5 extends these results to the multi-source multi-vector sensor case, with special attention to the two-source single-vector sensor case. Section 65.6 summarizes the main results and gives some ideas of possible extensions.

The main difference between the topics of this article and other articles on source direction estimation is in our use of vector sensors with *complete* electric and magnetic data. Most papers have dealt with scalar sensors. Other papers that considered estimation of the polarization state and source direction are [7]–[12]. Reference [7] discussed the use of subspace methods to solve this problem using diversely polarized electric sensors. References [8]–[10] devised algorithms for arrays with two dimensional electric measurements. Reference [11] provided performance analysis for arrays with two types of electric sensor polarizations (diversely polarized). An earlier reference, [12], proposed an estimation method using a three-dimensional vector sensor and implemented it with magnetic sensors. All these references used only part of the electromagnetic information at the sensors, thereby reducing the observability of DOAs. In most of them, time delays between distributed sensors played an essential role in the estimation process.

For a plane wave (typically associated with a single source in the far-field) the magnitude of the electric and magnetic fields can be found from each other. Hence, it may be felt that one (complete) field is deducible from the other. However, this is not true when the source direction is unknown.

Additionally, the electric and magnetic fields are orthogonal to each other and to the source DOA vector, hence measuring both fields increases significantly the accuracy of the source DOA estimation. This is true in particular for an incoming wave which is nearly linearly polarized, as will be explicitly shown by the CRB (see Table 65.1).

The use of the complete electromagnetic vector data enables source parameter estimation with a single sensor (even with a single snapshot) where time delays are not used at all. In fact, this is shown to be possible for at least two sources. As a result, the derived CRB expressions for this problem are applicable to wide-band sources. The source DOA parameters considered include azimuth and elevation. This section also considers direction estimation to DST sources, as well as the CRB on wave ellipticity and orientation angles (to be defined later) for SST sources using vector sensors, which were first presented in [1, 2]. This is true also for the MSAE and CVAE quality measures and the associated bounds. Their application is not limited to electromagnetic vector sensor processing.

We comment that electromagnetic vector sensors as measuring devices are commercially available and actively researched. EMC Baden Ltd. in Baden, Switzerland, is a company that manufactures them for signals in the 75 Hz to 30 MHz frequency range, and Flam and Russell, Inc. in Horsham, Pennsylvania, makes them for the 2 to 30 MHz frequency band. Lincoln Labs at MIT has performed some preliminary localization tests with vector sensors [13]. Some examples of recent research on sensor development are [14] and [15].

Following the recent impressive progress in the performance of DSP processors, there is a trend to fuse as much data as possible using smart sensors. Vector sensors, which belong to this category of sensors, are expected to find larger use and provide important contribution in improving the performance of DSP in the near future.

65.2 The Measurement Model

This section presents the measurement model for the estimation problems that are considered in the latter parts of the article.

65.2.1 Single-Source Single-Vector Sensor Model

Basic Assumptions

Throughout the article it will be assumed that the wave is traveling in a nonconductive, homogeneous, and isotropic medium. Additionally, the following will be assumed:

- A1:** Plane wave at the sensor: This is equivalent to a far-field assumption (or maximum wavelength much smaller than the source to sensor distance), a point source assumption (i.e., the source size is much smaller than the source to sensor distance) and a point-like sensor (i.e., the sensor's dimensions are small compared to the minimum wave-length).
- A2:** Band-limited spectrum: The signal has a spectrum including only frequencies ω satisfying $\omega_{\min} \leq |\omega| \leq \omega_{\max}$ where $0 < \omega_{\min} < \omega_{\max} < \infty$. This assumption is satisfied in practice. The lower and upper limits on ω are also needed, respectively, for the far-field and point-like sensor assumptions.

Let $\mathcal{E}(t)$ and $\mathcal{H}(t)$ be the vector phasor representations (or complex envelopes, see e.g., [16, 17] and [1, Appendix A]) of the electric and magnetic fields at the sensor. Also, let \mathbf{u} be the unit vector at the sensor pointing towards the source, i.e.,

$$\mathbf{u} = \begin{bmatrix} \cos \theta_1 \cos \theta_2 \\ \sin \theta_1 \cos \theta_2 \\ \sin \theta_2 \end{bmatrix} \quad (65.1)$$

where θ_1 and θ_2 denote, respectively, the azimuth and elevation angles of \mathbf{u} , see Fig. 65.1. Thus, $\theta_1 \in [0, 2\pi)$ and $|\theta_2| \leq \pi/2$.

FIGURE 65.1: The orthonormal vector triad $(\mathbf{u}, \mathbf{v}_1, \mathbf{v}_2)$.

In [1, Appendix A] it is shown that for plane waves Maxwell's equations can be reduced to an equivalent set of two equations without any loss of information. Under the additional assumption of a band-limited signal, these two equations can be written in terms of phasors. The results are summarized in the following theorem.

THEOREM 65.1 *Under assumption A1, Maxwell's equations can be reduced to an equivalent set of two equations. With the additional band-limited spectrum assumption A2, they can be written as:*

$$\mathbf{u} \times \mathcal{E}(t) = -\eta \mathcal{H}(t) \quad (65.2a)$$

$$\mathbf{u} \cdot \mathcal{E}(t) = 0 \quad (65.2b)$$

where η is the intrinsic impedance of the medium and “ \times ” and “ \cdot ” are the cross and inner products of \mathbb{R}^3 applied to vectors in \mathbb{C}^3 . (That is, if $\mathbf{v}, \mathbf{w} \in \mathbb{C}^3$ then $\mathbf{v} \cdot \mathbf{w} = \sum_i v_i w_i$. This is different than the usual inner product of \mathbb{C}^3).

PROOF 65.1 See [1, Appendix A]. (Note that $\mathbf{u} = -\boldsymbol{\kappa}$ where $\boldsymbol{\kappa}$ is the unit vector in the direction of the wave propagation).

Thus, under the plane and band-limited wave assumptions, the vector phasor equations (65.2) provide all the information contained in the original Maxwell equations. This result will be used in the following to construct measurement models in which the Maxwell equations are incorporated entirely.

The Measurement Model

Suppose that a vector sensor measures all six components of the electric and magnetic fields. (It is assumed that the sensor does not influence the electric and magnetic fields). The measurement model is based on the phasor representation of the measured electromagnetic data (with respect to a reference frame) at the sensor. Let $\mathbf{y}_E(t)$ be the measured electric field phasor vector at the sensor at time t and $\mathbf{e}_E(t)$ its noise component. Then the electric part of the measurement will be

$$\mathbf{y}_E(t) = \mathcal{E}(t) + \mathbf{e}_E(t) \quad (65.3)$$

Similarly, from Eq. (65.2a), after appropriate scaling, the magnetic part of the measurement will be taken as

$$\mathbf{y}_H(t) = \mathbf{u} \times \mathcal{E}(t) + \mathbf{e}_H(t) \quad (65.4)$$

In addition to Eq. (65.3) and (65.4), we have the constraint (65.2b).

Define the matrix cross product operator that maps a vector $\mathbf{v} \in \mathbb{R}^{3 \times 1}$ to $(\mathbf{u} \times \mathbf{v}) \in \mathbb{R}^{3 \times 1}$ by

$$(\mathbf{u} \times) \triangleq \begin{bmatrix} 0 & -u_z & u_y \\ u_z & 0 & -u_x \\ -u_y & u_x & 0 \end{bmatrix} \quad (65.5)$$

where u_x, u_y, u_z are the x, y, z components of the vector \mathbf{u} . With this definition, Eqs. (65.3) and (65.4) can be combined to

$$\begin{bmatrix} \mathbf{y}_E(t) \\ \mathbf{y}_H(t) \end{bmatrix} = \begin{bmatrix} I_3 \\ (\mathbf{u} \times) \end{bmatrix} \mathcal{E}(t) + \begin{bmatrix} \mathbf{e}_E(t) \\ \mathbf{e}_H(t) \end{bmatrix} \quad (65.6)$$

where I_3 denotes the 3×3 identity matrix. For notational convenience the dimension subscript of the identity matrix will be omitted whenever its value is clear from the context.

The constraint (65.2b) implies that the electric phasor $\mathcal{E}(t)$ can be written

$$\mathcal{E}(t) = V \boldsymbol{\xi}(t) \quad (65.7)$$

where V is a 3×2 matrix whose columns span the orthogonal complement of \mathbf{u} and $\boldsymbol{\xi}(t) \in \mathbb{C}^{2 \times 1}$. It is easy to check that the matrix

$$V = \begin{bmatrix} -\sin \theta_1 & -\cos \theta_1 \sin \theta_2 \\ \cos \theta_1 & -\sin \theta_1 \sin \theta_2 \\ 0 & \cos \theta_2 \end{bmatrix} \quad (65.8)$$

whose columns are orthonormal, satisfies this requirement. We note that since $\|\mathbf{u}\|^2 = 1$ the columns of V , denoted by \mathbf{v}_1 and \mathbf{v}_2 , can be constructed, for example, from the partial derivatives of \mathbf{u} with respect to θ_1 and θ_2 and post-normalization when needed. Thus,

$$\mathbf{v}_1 = \frac{1}{\cos \theta_2} \frac{\partial \mathbf{u}}{\partial \theta_1} \quad (65.9a)$$

$$\mathbf{v}_2 = \mathbf{u} \times \mathbf{v}_1 = \frac{\partial \mathbf{u}}{\partial \theta_2} \quad (65.9b)$$

and $(\mathbf{u}, \mathbf{v}_1, \mathbf{v}_2)$ is a right orthonormal triad, see Fig. 65.1. (Observe that the two coordinate systems shown in the figure actually have the same origin). The signal $\boldsymbol{\xi}(t)$ fully determines the components of $\mathcal{E}(t)$ in the plane where it lies, namely the plane orthogonal to \mathbf{u} spanned by $\mathbf{v}_1, \mathbf{v}_2$. This implies that there are two degrees of freedom present in the spatial domain (or the wave's plane), or two independent signals can be transmitted simultaneously.

Combining Eq. (65.6) and Eq. (65.7) we now have

$$\begin{bmatrix} \mathbf{y}_E(t) \\ \mathbf{y}_H(t) \end{bmatrix} = \begin{bmatrix} I \\ (\mathbf{u} \times) \end{bmatrix} V \boldsymbol{\xi}(t) + \begin{bmatrix} \mathbf{e}_E(t) \\ \mathbf{e}_H(t) \end{bmatrix} \quad (65.10)$$

This system is equivalent to Eq. (65.6) with Eq. (65.2b).

The measured signals in the sensor reference frame can be further related to the original source signal at the transmitter using the following lemma.

LEMMA 65.1 Every vector $\boldsymbol{\xi} = [\xi_1, \xi_2]^T \in \mathbb{C}^{2 \times 1}$ has the representation

$$\boldsymbol{\xi} = \|\boldsymbol{\xi}\| e^{i\varphi} Q \mathbf{w} \quad (65.11)$$

where

$$Q = \begin{bmatrix} \cos \theta_3 & \sin \theta_3 \\ -\sin \theta_3 & \cos \theta_3 \end{bmatrix} \quad (65.12a)$$

$$\mathbf{w} = \begin{bmatrix} \cos \theta_4 \\ i \sin \theta_4 \end{bmatrix} \quad (65.12b)$$

and where $\varphi \in (-\pi, \pi]$, $\theta_3 \in (-\pi/2, \pi/2]$, $\theta_4 \in [-\pi/4, \pi/4]$. Moreover, $\|\boldsymbol{\xi}\|$, φ , θ_3 , θ_4 in Eq. (65.11) are uniquely determined if and only if $\xi_1^2 + \xi_2^2 \neq 0$.

PROOF 65.2 See [1, Appendix B].

The equality $\xi_1^2 + \xi_2^2 = 0$ holds if and only if $|\theta_4| = \pi/4$, corresponding to circular polarization (defined below). Hence, from Lemma 65.1 the representation (65.11), (65.12) is not unique in this case as should be expected, since the orientation angle θ_3 is ambiguous. It should be noted that the representation (65.11), (65.12) is known and was used (see, e.g., [18]) without a proof. However, Lemma 65.1 of existence and uniqueness appears to be new. The existence and uniqueness properties are important to guarantee identifiability of parameters.

The physical interpretations of the quantities in the representation (65.11), (65.12) are as follows.

$\|\boldsymbol{\xi}\| e^{i\varphi}$: Complex envelope of the source signal (including amplitude and phase).

\mathbf{w} : Normalized overall transfer vector of the source's antenna and medium, i.e., from the source complex envelope signal to the principal axes of the received electric wave.

Q : A rotation matrix that performs the rotation from the principal axes of the incoming electric wave to the $(\mathbf{v}_1, \mathbf{v}_2)$ coordinates.

Let ω_c be the reference frequency of the signal phasor representation, see [1, Appendix A]. In the narrow-band SST case, the incoming electric wave signal $\text{Re}\{e^{i\omega_c t} \|\boldsymbol{\xi}(t)\| e^{i\varphi(t)} Q \mathbf{w}\}$ moves on a quasi-stationary ellipse whose semi-major and semi-minor axes' lengths are proportional, respectively, to $\cos \theta_4$ and $\sin \theta_4$, see Fig. 65.2 and [19]. The ellipse's eccentricity is thus determined by the magnitude of θ_4 . The sign of θ_4 determines the spin sign or direction. More precisely, a positive (negative) θ_4 corresponds to a positive (negative) spin with right-(left) handed rotation with respect to the wave propagation vector $\boldsymbol{\kappa} = -\mathbf{u}$. As shown in Fig. 65.2, θ_3 is the rotation angle between the $(\mathbf{v}_1, \mathbf{v}_2)$ coordinates and the electric ellipse axes $(\tilde{\mathbf{v}}_1, \tilde{\mathbf{v}}_2)$. The angles θ_3 and θ_4 will be referred to, respectively,

FIGURE 65.2: The electric polarization ellipse.

as the orientation and ellipticity angles of the received electric wave ellipse. In addition to the electric ellipse, there is also a similar but perpendicular magnetic ellipse.

It should be noted that if the transfer matrix from the source to the sensor is time invariant, then so are θ_3 and θ_4 .

The signal $\xi(t)$ can carry information coded in various forms. In the following we discuss briefly both existing forms and some motivated by the above representation.

Single Signal Transmission (SST) Model

Suppose that a single modulated signal is transmitted. Then, using Eq. (65.11), this is a special case of Eq. (65.10) with

$$\xi(t) = Q w_s(t) \quad (65.13)$$

where $s(t)$ denotes the complex envelope of the (scalar) transmitted signal. Thus, the measurement model is

$$\begin{bmatrix} y_E(t) \\ y_H(t) \end{bmatrix} = \begin{bmatrix} I \\ (u \times) \end{bmatrix} V Q w_s(t) + \begin{bmatrix} e_E(t) \\ e_H(t) \end{bmatrix} \quad (65.14)$$

Special cases of this transmission are linear polarization with $\theta_4 = 0$ and circular polarization with $|\theta_4| = \pi/4$.

Recall that since there are two spatial degrees of freedom in a transverse electromagnetic plane wave, one could, in principle, transmit two separate signals simultaneously. Thus, the SST method does not make full use of the two spatial degrees of freedom present in a transverse electromagnetic plane wave.

Dual Signal Transmission (DST) Models

Methods of transmission in which two separate signals are transmitted simultaneously from the same source will be called *dual signal transmissions*. Various DST forms exist, and all of them can be modeled by Eq. (65.10) with $\xi(t)$ being a linear transformation of the two-dimensional source signal vector.

One DST form uses two linearly polarized signals that are spatially and temporally orthogonal with an amplitude or phase modulation (see e.g., [3, 4]). This is a special case of Eq. (65.10), where

the signal $\xi(t)$ is written in the form

$$\xi(t) = Q \begin{bmatrix} s_1(t) \\ i s_2(t) \end{bmatrix} \quad (65.15)$$

where $s_1(t)$ and $s_2(t)$ represent the complex envelopes of the transmitted signals. To guarantee unique decoding of the two signals (when θ_3 is unknown) using Lemma 65.1, they have to satisfy $s_1(t) \neq 0$, $s_2(t)/s_1(t) \in (-1, 1)$. (Practically this can be achieved by using a proper electronic antenna adapter that yields a desirable overall transfer matrix.)

Another DST form uses two circularly polarized signals with opposite spins. In this case

$$\xi(t) = Q[\mathbf{w}\tilde{s}_1(t) + \bar{\mathbf{w}}\tilde{s}_2(t)] \quad (65.16a)$$

$$\mathbf{w} = (1/\sqrt{2})[1, i]^T \quad (65.16b)$$

where $\bar{\mathbf{w}}$ denotes the complex conjugate of \mathbf{w} . The signals $\tilde{s}_1(t)$, $\tilde{s}_2(t)$ represent the complex envelopes of the transmitted signals. The first term on the r.h.s. of Eqs. (65.16) corresponds to a signal with positive spin and circular polarization ($\theta_4 = \pi/4$), while the second term corresponds to a signal with negative spin and circular polarization ($\theta_4 = -\pi/4$). The uniqueness of Eqs. (65.16) is guaranteed without the conditions needed for the uniqueness of Eq. (65.15).

The above-mentioned DST models can be applied to communication problems. Assuming that \mathbf{u} is given, it is possible to measure the signal $\xi(t)$ and recover the original messages as follows. For Eq. (65.15), an existing method resolves the two messages using mechanical orientation of the receiver's antenna (see, e.g., [4]). Alternatively, this can be done electronically using the representation of Lemma 65.1, without the need to know the orientation angle. For Eqs. (65.16), note that $\xi(t) = \mathbf{w}e^{i\theta_3}\tilde{s}_1(t) + \bar{\mathbf{w}}e^{-i\theta_3}\tilde{s}_2(t)$, which implies the uniqueness of Eqs. (65.16) and indicates that the orientation angle has been converted into a phase angle whose sign depends on the spin sign. The original signals can be directly recovered from $\xi(t)$ up to an additive constant phase without knowledge of the orientation angle. In some cases, it is of interest to estimate the orientation angle. Let W be a matrix whose columns are \mathbf{w} , $\bar{\mathbf{w}}$. For Eqs. (65.16) this can be done using equal calibrating signals and then premultiplying the measurement by W^{-1} and measuring the phase difference between the two components of the result. This can also be used for real time estimation of the angular velocity $d\theta_3/dt$.

In general it can be stated that the advantage of the DST method is that it makes full use of the spatial degrees of freedom of transmission. However, the above DST methods need the knowledge of \mathbf{u} and, in addition, may suffer from possible cross polarizations (see, e.g., [3]), multipath effects, and other unknown distortions from the source to the sensor.

The use of the proposed vector sensor can motivate the design of new improved transmission forms. Here we suggest a new dual signal transmission method that uses on line electronic calibration in order to resolve the above problems. Similar to the previous methods it also makes full use of the spatial degrees of freedom in the system. However, it overcomes the need to know \mathbf{u} and the overall transfer matrix from source to sensor.

Suppose the transmitted signal is $\mathbf{z}(t) \in \mathbb{C}^{2 \times 1}$ (this signal is as it appears before reaching the source's antenna). The measured signal is

$$\begin{bmatrix} \mathbf{y}_E(t) \\ \mathbf{y}_H(t) \end{bmatrix} = C(t)\mathbf{z}(t) + \begin{bmatrix} \mathbf{e}_E(t) \\ \mathbf{e}_H(t) \end{bmatrix} \quad (65.17)$$

where $C(t) \in \mathbb{C}^{6 \times 2}$ is the unknown source to sensor transfer matrix that may be slowly varying due to, for example, the source dynamics. To facilitate the identification of $\mathbf{z}(t)$, the transmitter can send calibrating signals, for instance, transmit $\mathbf{z}_1(t) = [1, 0]^T$ and $\mathbf{z}_2(t) = [0, 1]^T$ separately. Since these

inputs are in phasor form, this means that actually constant carrier waves are transmitted. Obviously, one can then estimate the columns of $C(t)$ by averaging the received signals, which can be used later for finding the original signal $z(t)$ by using, for example, least-squares estimation. Better estimation performance can be achieved by taking into account *a priori* information about the model.

The use of vector sensors is attractive in communication systems as it doubles the channel capacity (compared with scalar sensors) by making full use of the electromagnetic wave properties. This spatial multiplexing has vast potential for performance improvement in cellular communications.

In future research it would be of interest to develop optimal coding methods (modulation forms) for maximum channel capacity while maintaining acceptable distortions of the decoded signals despite unknown varying channel characteristics. It would also be of interest to design communication systems that utilize entire arrays of vector sensors.

Observe that actually any combination of the variables $\|\xi\|$, φ , θ_3 and θ_4 can be modulated to carry information. A binary signal can be transmitted using the spin sign of the polarization ellipse (sign of θ_4). Lemma 65.1 guarantees the identifiability of these signals from $\xi(t)$.

65.2.2 Multi-Source Multi-Vector Sensor Model

Suppose that waves from n distant electromagnetic sources are impinging on an array of m vector sensors and that assumptions A1 and A2 hold for each source. To extend the model (65.10) to this scenario we need the following additional assumptions, which imply that A1, A2 hold uniformly on the array:

- A3:** Plane wave across the array: In addition to A1, for each source the array size d_A has to be much smaller than the source to array distance, so that the vector u is approximately independent of the individual sensor positions.
- A4:** Narrow-band signal assumption: The maximum frequency of $\mathcal{E}(t)$, denoted by ω_m , satisfies $\omega_m d_A / c \ll 1$, where c is the velocity of wave propagation (i.e., the minimum modulating wave-length is much larger than the array size). This implies that $\mathcal{E}(t - \tau) \simeq \mathcal{E}(t)$ for all differential delays τ of the source signals between the sensors.

Note that (under the assumption $\omega_m < \omega_c$) since $\omega_m = \max\{|\omega_{\min} - \omega_c|, |\omega_{\max} - \omega_c|\}$, it follows that A4 is satisfied if $(\omega_{\max} - \omega_{\min})d_A/2c \ll 1$ and ω_c is chosen to be close enough to $(\omega_{\max} + \omega_{\min})/2$.

Let $y_{EH}(t)$ and $e_{EH}(t)$ be the $6m \times 1$ dimensional electromagnetic sensor phasor measurement and noise vectors,

$$y_{EH}(t) \triangleq \left[(y_E^{(1)}(t))^T, (y_H^{(1)}(t))^T, \dots, (y_E^{(m)}(t))^T, (y_H^{(m)}(t))^T \right]^T \quad (65.18a)$$

$$e_{EH}(t) \triangleq \left[(e_E^{(1)}(t))^T, (e_H^{(1)}(t))^T, \dots, (e_E^{(m)}(t))^T, (e_H^{(m)}(t))^T \right]^T \quad (65.18b)$$

where $y_E^{(j)}(t)$ and $y_H^{(j)}(t)$ are, respectively, the measured phasor electric and magnetic vector fields at the j th sensor and similarly for the noise components $e_E^{(j)}(t)$ and $e_H^{(j)}(t)$. Then, under assumptions A3 and A4 and from Eq. (65.10), we find that the array measured phasor signal can be written as

$$y_{EH}(t) = \sum_{k=1}^n e_k \otimes \begin{bmatrix} I_3 \\ (u_k \times) \end{bmatrix} V_k \xi_k(t) + e_{EH}(t) \quad (65.19)$$

where \otimes is the Kronecker product, e_k denotes the k th column of the matrix $E \in \mathbb{C}^{m \times n}$ whose (j, k) entry is

$$E_{jk} = e^{-i\omega_c \tau_{jk}} \quad (65.20)$$

where τ_{jk} is the differential delay of the k th source signal between the j th sensor and the origin of some fixed reference coordinate system (e.g., at one of the sensors). Thus, $\tau_{jk} = -(\mathbf{u}_k \cdot \mathbf{r}_j)/c$, where \mathbf{u}_k is the unit vector in the direction from the array to the k th source and \mathbf{r}_j is the position vector of the j th sensor in the reference frame. The rest of the notation in Eq. (65.19) is similar to the single source case, cf. Eqs. (65.1), (65.8), and (65.10). The vector $\xi_k(t)$ can have either the SST or the DST form described above.

Observe that the signal manifold matrix in Eq. (65.19) can be written as the Khatri-Rao product (see, e.g., [20, 21]) of E and a second matrix whose form depends on the source transmission type (i.e., SST or DST), see also later.

65.3 Cramér-Rao Bound for a Vector Sensor Array

65.3.1 Statistical Model

Consider the problem of finding the parameter vector θ in the following discrete-time vector sensor array model associated with n vector sources and m vector sensors:

$$\mathbf{y}(t) = A(\theta)\mathbf{x}(t) + \mathbf{e}(t) \quad t = 1, 2, \dots \quad (65.21)$$

where $\mathbf{y}(t) \in \mathbb{C}^{\bar{\mu} \times 1}$ are the vectors of observed sensor outputs (or snapshots), $\mathbf{x}(t) \in \mathbb{C}^{\bar{\nu} \times 1}$ are the unknown source signals, and $\mathbf{e}(t) \in \mathbb{C}^{\bar{\mu} \times 1}$ are the additive noise vectors. The transfer matrix $A(\theta) \in \mathbb{C}^{\bar{\mu} \times \bar{\nu}}$ and the parameter vector $\theta \in \mathbb{R}^{\bar{q} \times 1}$ are given by

$$A(\theta) = \begin{bmatrix} A_1(\theta^{(1)}) & \dots & A_n(\theta^{(n)}) \end{bmatrix} \quad (65.22a)$$

$$\theta = \begin{bmatrix} (\theta^{(1)})^T, \dots, (\theta^{(n)})^T \end{bmatrix}^T \quad (65.22b)$$

where $A_k(\theta^{(k)}) \in \mathbb{C}^{\bar{\mu} \times \nu_k}$ and the parameter vector of the k th source $\theta^{(k)} \in \mathbb{R}^{q_k \times 1}$, thus $\bar{\nu} = \sum_{k=1}^n \nu_k$ and $\bar{q} = \sum_{k=1}^n q_k$. The following notation will also be used:

$$\mathbf{y}(t) = \begin{bmatrix} (\mathbf{y}^{(1)}(t))^T, \dots, (\mathbf{y}^{(m)}(t))^T \end{bmatrix}^T \quad (65.23a)$$

$$\mathbf{x}(t) = \begin{bmatrix} (\mathbf{x}^{(1)}(t))^T, \dots, (\mathbf{x}^{(n)}(t))^T \end{bmatrix}^T \quad (65.23b)$$

where $\mathbf{y}^{(j)}(t) \in \mathbb{C}^{\mu_j \times 1}$ is the vector measurement of the j th sensor, implying $\bar{\mu} = \sum_{j=1}^m \mu_j$, and $\mathbf{x}^{(k)}(t) \in \mathbb{C}^{\nu_k \times 1}$ is the vector signal of the k th source. Clearly $\bar{\mu}$ and $\bar{\nu}$ correspond, respectively, to the total number of sensor components and source signal components.

The model (65.21) generalizes the commonly used multi-scalar source multi-scalar sensor one (see, e.g., [7, 22]). It will be shown later that the electromagnetic multi-vector source multi-vector sensor data models are special cases of Eq. (65.21) with appropriate choices of matrices.

For notational simplicity, the explicit dependence on θ and t will be occasionally omitted.

We make the following commonly used assumptions on the model (65.21):

- A5:** The source signal sequence $\{\mathbf{x}(1), \mathbf{x}(2), \dots\}$ is a sample from a temporally uncorrelated stationary (complex) Gaussian process with zero mean and

$$\begin{aligned} E \mathbf{x}(t) \mathbf{x}^*(s) &= P \delta_{t,s} \\ E \mathbf{x}(t) \mathbf{x}^T(s) &= 0 \quad (\text{for all } t \text{ and } s). \end{aligned}$$

where E is the expectation operator, the superscript “*” denotes the conjugate transpose, and $\delta_{t,s}$ is the Kronecker delta.

A6: The noise $\mathbf{e}(t)$ is (complex) Gaussian distributed with zero mean and

$$\begin{aligned} \mathbb{E} \mathbf{e}(t) \mathbf{e}^*(s) &= \sigma^2 I \delta_{t,s} \\ \mathbb{E} \mathbf{e}(t) \mathbf{e}^T(s) &= 0 \quad (\text{for all } t \text{ and } s). \end{aligned}$$

It is also assumed that the signals $\mathbf{x}(t)$ and the noise $\mathbf{e}(s)$ are independent for all t and s .

A7: The matrix A has full rank $\bar{\nu} < \bar{\mu}$ (thus A^*A is p.d.) and a continuous Jacobian $\partial A / \partial \boldsymbol{\theta}$ in some neighborhood of the true $\boldsymbol{\theta}$. The matrix $A P A^* + \sigma^2 I$ is assumed to be positive definite, which implies that the probability density functions of the model are well defined in some neighborhood of the true $\boldsymbol{\theta}$, P , σ^2 . Additionally, the matrix in braces in Eq. (65.24) below is assumed to be nonsingular.

The unknown parameters in the model (65.21) include the vector $\boldsymbol{\theta}$, the signal covariance matrix P , and the noise variance σ^2 . The problem of estimating $\boldsymbol{\theta}$ in (65.21) from N snapshots $\mathbf{y}(1), \dots, \mathbf{y}(N)$ and the statistical performance of estimation methods are the main concerns of this article.

65.3.2 The Cramér-Rao Bound

Consider the estimation of $\boldsymbol{\theta}$ in the model (65.21) under the above assumptions and with $\boldsymbol{\theta}$, P , σ^2 unknown. We have the following theorem.

THEOREM 65.2 *The Cramér-Rao lower bound on the covariance matrix of any (locally) unbiased estimator of the vector $\boldsymbol{\theta}$ in the model (65.21), under assumptions A5 through A7 with $\boldsymbol{\theta}$, P , σ^2 unknown and $\nu_k = \nu$ for all k , is a positive definite matrix given by*

$$\text{CRB}(\boldsymbol{\theta}) = \frac{\sigma^2}{2N} \left\{ \text{Re} \left[\text{btr} \left((\mathbf{1} \boxtimes U) \boxtimes (D^* \Pi_c D)^{bT} \right) \right] \right\}^{-1} \quad (65.24)$$

where

$$U = P \left(A^* A P + \sigma^2 I \right)^{-1} A^* A P \quad (65.25a)$$

$$\Pi_c = I - \Pi \quad (65.25b)$$

$$\Pi = A (A^* A)^{-1} A^* \quad (65.25c)$$

$$D = \begin{bmatrix} D_1^{(1)} \cdots D_{q_1}^{(1)} & \cdots & D_1^{(n)} \cdots D_{q_n}^{(n)} \end{bmatrix} \quad (65.25d)$$

$$D_\ell^{(k)} = \frac{\partial A_k}{\partial \theta_\ell^{(k)}} \quad (65.25e)$$

and where $\mathbf{1}$ denotes a $\bar{q} \times \bar{q}$ matrix with all entries equal to one, and the block trace operator $\text{btr}(\cdot)$, the block Kronecker product \boxtimes , the block Schur-Hadamard product \boxtimes , and the block transpose operator bT are as defined in the Appendix with blocks of dimensions $\nu \times \nu$, except for the matrix $\mathbf{1}$ that has blocks of dimensions $q_i \times q_j$.

Furthermore, the CRB in Eq. (65.24) remains the same independently of whether σ^2 is known or unknown.

PROOF 65.3 See [1, Appendix C].

Theorem 65.2 can be extended to include a larger class of unknown sensor noise covariance matrices (see [1, Appendix D]).

65.4 MSAE, CVAE, and Single-Source Single-Vector Sensor Analysis

This section introduces the MSAE and CVAE quality measures and their bounds for source direction and orientation estimation in three-dimensional space. The bounds are applied to analyze the statistical performance of parameter estimation of an electromagnetic source whose covariance is unknown using a single vector sensor. Note that single vector sensor analysis is valid for *wide-band* sources, as assumptions A3 and A4 are not needed.

65.4.1 The MSAE

We define the mean-square angular error which is a quality measure that is useful for gaining physical insight into DOA (azimuth and elevation) estimation and for performance comparisons. The analysis of this subsection is not limited to electromagnetic measurements or to Gaussian data.

The angular error, say δ , corresponding to a direction error $\Delta \mathbf{u}$ in \mathbf{u} , can be shown to be $\delta = 2 \arcsin(\|\Delta \mathbf{u}\|/2)$. Hence, $\delta^2 = \|\Delta \mathbf{u}\|^2 + O(\|\Delta \mathbf{u}\|^4)$. Since $\Delta \mathbf{u} = \left(\frac{\partial \mathbf{u}}{\partial \theta_1}\right) \Delta \theta_1 + \left(\frac{\partial \mathbf{u}}{\partial \theta_2}\right) \Delta \theta_2 + O((\Delta \theta_1)^2 + (\Delta \theta_2)^2)$ where $\Delta \theta_1, \Delta \theta_2$ are the errors in θ_1 and θ_2 , we have

$$\delta^2 = (\cos \theta_2 \cdot \Delta \theta_1)^2 + (\Delta \theta_2)^2 + O(|\Delta \theta_1|^3 + |\Delta \theta_2|^3) \quad (65.26)$$

We introduce the following definitions.

DEFINITION 65.1 A model will be called *regular* if it satisfies any set of sufficient conditions for the CRB to hold (see, e.g., [23, 24]).

DEFINITION 65.2 The *normalized asymptotic mean-square angular error* of a direction estimator will be defined as

$$\text{MSAE} \triangleq \lim_{N \rightarrow \infty} \left\{ N E(\delta^2) \right\} \quad (65.27)$$

whenever this limit exists.

DEFINITION 65.3 A direction estimator will be called *regular* if its errors satisfy $E[|\Delta \theta_1|^3 + |\Delta \theta_2|^3] = o(1/N)$, the gradient of its bias with respect to θ_1, θ_2 exists and is $o(1)$ as $N \rightarrow \infty$, and its MSAE exists. (If $|\theta_2| = \pi/2$ then θ_1 is undefined and we can use the equivalent condition $E[\|\Delta \mathbf{u}\|^3] = o(1/N)$).

Equation (65.26) shows that under the assumptions that the model and estimator are regular we have

$$E(\delta^2) \geq [\cos^2 \theta_2 \cdot \text{CRB}(\theta_1) + \text{CRB}(\theta_2)] + o(1/N) \quad \text{as } N \rightarrow \infty \quad (65.28)$$

where $\text{CRB}(\theta_1)$ and $\text{CRB}(\theta_2)$ are, respectively, the Cramér-Rao bounds for the azimuth and elevation. Using Eq. (65.28) we have the following theorem.

THEOREM 65.3 For a regular model MSAE of any regular direction estimator is bounded from below by

$$\text{MSAE}_{CR} \triangleq N[\cos^2 \theta_2 \cdot \text{CRB}(\theta_1) + \text{CRB}(\theta_2)] \quad (65.29)$$

Observe that MSAE_{CR} is not a function of N . Additionally, MSAE_{CR} is a tight bound if it is attained by some second order efficient regular estimator (usually the maximum likelihood (ML) estimator, see e.g., [25]). For vector sensor measurements this bound has the desirable property of being invariant to the choice of reference coordinate frame, since the information content in the data is invariant under rotational transformations. This invariance property also holds for the MSAE of an estimator if the estimate is independent of known rotational transformations of the data.

For a regular model, the bound (65.29) can be used for performance analysis of any regular direction (azimuth and elevation) finding algorithm.

It is of interest to note that the bound (65.29) actually holds for finite data, when the estimators of \mathbf{u} are unbiased and constrained to be of unit norm, see [26].

65.4.2 DST Source Analysis

Assume that it is desired to estimate the direction to a DST source whose covariance is unknown using a vector sensor. We will first present a statistical model for this problem as a special case of Eq. (65.21) and then investigate in detail the resulting CRB and MSAE.

The measurement model for the DST case is given in Eq. (65.10). Suppose the noise vector of Eq. (65.10) is (complex) Gaussian with zero mean and the following covariances:

$$\begin{aligned} \mathbb{E} \begin{bmatrix} \mathbf{e}_E(t) \\ \mathbf{e}_H(t) \end{bmatrix} \begin{bmatrix} \mathbf{e}_E^*(s) & \mathbf{e}_H^*(s) \end{bmatrix} &= \begin{bmatrix} \sigma_E^2 I_3 & 0 \\ 0 & \sigma_H^2 I_3 \end{bmatrix} \delta_{t,s} \\ \mathbb{E} \begin{bmatrix} \mathbf{e}_E(t) \\ \mathbf{e}_H(t) \end{bmatrix} \begin{bmatrix} \mathbf{e}_E^T(s) & \mathbf{e}_H^T(s) \end{bmatrix} &= 0 \quad (\text{for all } t \text{ and } s). \end{aligned}$$

Our assumption that the noise components are statistically independent stems from the fact that they are created separately at *different* sensor components (even if the sensor components belong to a vector sensor). Note that under assumption A1 the measurement includes a source plane wave component and sensor self noise.

To relate the model (65.10) to (65.21), define a scaled measurement $\mathbf{y}(t) \triangleq [r \mathbf{y}_E^T(t), \mathbf{y}_H^T(t)]^T$ where $r \triangleq \sigma_H / \sigma_E$ is assumed to be known. (The results of this section actually hold also when r is unknown as is explained in [1]). The resulting scaled noise vector $\mathbf{e}(t) \triangleq [r \mathbf{e}_E^T(t), \mathbf{e}_H^T(t)]^T$ then satisfies assumption A6 with $\sigma = \sigma_H$. Assume further that the signal $\xi(t)$ satisfies assumption A5 with $\mathbf{x}(t) = \xi(t)$. Then, under these assumptions, the scaled version of the DST source (65.10) can be viewed as a special case of Eq. (65.21) with $m = n = 1$ and

$$\begin{aligned} \mathbf{A} &= \begin{bmatrix} rV \\ (\mathbf{u} \times) V \end{bmatrix} & \mathbf{x}(t) &= \xi(t) & \sigma^2 &= \sigma_H^2 \\ \boldsymbol{\theta} &= [\theta_1, \theta_2]^T \end{aligned} \quad (65.30)$$

where the unknown parameters are $\boldsymbol{\theta}$, P , σ^2 . The parameter vector of interest is $\boldsymbol{\theta}$ while P and σ^2 are the so-called nuisance parameters.

The above discussion shows that the CRB expression (65.24) is applicable to the present problem with the special choice of variables in Eq. (65.30), thus $n = 1$ and $\bar{q} = 2$. The computation of the CRB is given in [1]. The result is independent of whether r is known or unknown.

Using the CRB results of [1] we find that MSAE_{CR} for the present DST problem is

$$\text{MSAE}_{CR}^D = \frac{(\sigma_E^2 + \sigma_H^2) \sigma_E^2 \sigma_H^2 \text{tr } U}{2 \left[\sigma_E^2 \sigma_H^2 (\text{tr } U)^2 + (\sigma_E^2 - \sigma_H^2)^2 \det(\text{Re } U) \right]} \quad (65.31)$$

Observe that MSAE_{CR}^D is symmetric with respect to σ_E , σ_H , as should be expected from the Maxwell equations. MSAE_{CR}^D is not a function of θ_1 , θ_2 , θ_3 , as should be expected since for vector sensor

measurements the MSAE bound is by definition invariant to the choice of coordinate system. Note that MSAE_{CR}^D is independent of whether σ_E and σ_H are known or unknown.

65.4.3 SST Source (DST Model) Analysis

Consider the MSAE for a single signal transmission source when the estimation is done under the assumption that the source is of a dual signal transmission type. In this case, the model (65.10) has to be used but with a signal in the form of (65.13). The signal covariance is then

$$P = \sigma_s^2 Q \mathbf{w} (Q \mathbf{w})^* \quad (65.32)$$

where $\sigma_s^2 = E s^2(t)$ and Q and \mathbf{w} are defined in Eq. (65.12). Thus, $\text{rank } P = 1$ and P has a unit norm eigenvector $Q \mathbf{w}$ with an eigenvalue σ_s^2 .

Let

$$\sigma_{\parallel}^2 \triangleq \frac{\sigma_E^2 \cdot \sigma_H^2}{\sigma_E^2 + \sigma_H^2} \quad (65.33)$$

The variance σ_{\parallel}^2 can be viewed as an equivalent noise variance of two measurements with independent noise variances σ_E^2 and σ_H^2 . Define $\varrho = \sigma_s^2 / \sigma_{\parallel}^2$, which is an effective SNR.

Using the analysis of U in [1] and expression (65.31) we find that

$$\begin{aligned} \text{MSAE}_{CR}^S &= \frac{(1 + \varrho)(\sigma_E^2 + \sigma_H^2)^2}{2\varrho^2 [\sigma_E^2 \sigma_H^2 + (\sigma_E^2 - \sigma_H^2)^2 \sin^2 \theta_4 \cos^2 \theta_4]} \\ &= \frac{(1 + \varrho)(1 + r^2)^2}{2\varrho^2 [r^2 + (1 - r^2)^2 \sin^2 \theta_4 \cos^2 \theta_4]} \end{aligned} \quad (65.34)$$

where MSAE_{CR}^S denotes the MSAE_{CR} bound for the SST problem under the DST model. (It will be shown later that the same result also holds under the SST model.) Observe that MSAE_{CR}^S is symmetric with respect to σ_E, σ_H . It is also independent of whether σ_H and σ_E are known or unknown, as can be shown from Theorem 65.2 and [1, Appendix D]. Also, MSAE_{CR}^S is not a function of $\theta_1, \theta_2, \theta_3$, since for vector sensor measurements the MSAE bound is invariant under rotational transformations of the reference coordinate system. On the other hand, MSAE_{CR}^S is influenced by the ellipticity angle θ_4 through the difference in the electric and magnetic noise variances.

Table 65.1 summarizes several special cases of the expression (65.34) for MSAE_{CR}^S . The elliptical polarization column corresponds to an arbitrary polarization angle $\theta_4 \in [-\pi/4, \pi/4]$. The circular and linear polarization columns are obtained, respectively, as special cases of Eq. (65.34) with $|\theta_4| = \pi/4$ and $\theta_4 = 0$. The row of precise (noise-free) electric measurement (with noisy magnetic measurements) is obtained by substituting $\sigma_E^2 = 0$ in (65.34). The row of electric measurement only is obtained by deriving the corresponding CRB and MSAE_{CR}^S . Alternatively, MSAE_{CR}^S can be found for this case by taking the limit of Eq. (65.34) as $\sigma_H^2 \rightarrow \infty$.

Observe from Eq. (65.34) that when $\sigma_H^2 \neq \sigma_E^2$, MSAE_{CR}^S is minimized for circular polarization and maximized for linear polarization. This result is illustrated in Fig. 65.3, which shows the square root of MSAE_{CR}^S as a function of $r = \sigma_H / \sigma_E$ for three types of polarizations ($\theta_4 = 0, \pi/12, \pi/4$). The equivalent signal-to-noise ratio $\text{SNR} = \sigma_s^2 / \sigma_{\parallel}^2$ is kept at one, while the individual electric and magnetic noise variances are varied to give the desired value of r . As r becomes larger or smaller than one, MSAE_{CR}^S increases more significantly for sources with polarization closer to linear.

When the electric (or magnetic) field is measured precisely and the source polarization is circular or elliptical, the MSAE_{CR}^S is zero (i.e., no angular error), while for linearly polarized sources it remains positive. In the latter case, the contribution to MSAE_{CR}^S stems from the magnetic (or electric) noisy measurement. When only the electric (or magnetic) field is measured, MSAE_{CR}^S increases as

TABLE 65.1 MSAE Bounds for a Single Signal Transmission Source

	Elliptical	Circular	Linear
General MSAE_{CR}^S	(65.34)	$\frac{2(1+\varrho)}{\varrho^2}$	$\frac{(1+\varrho)(\sigma_E^2 + \sigma_H^2)}{2\varrho\sigma_s^2}$
Precise electric measurement	0	0	$\frac{\sigma_H^2}{2\sigma_s^2}$
Electric measurement only	$\frac{\sigma_E^2(\sigma_E^2 + \sigma_s^2)}{2\sigma_s^4 \sin^2 \theta_4 \cos^2 \theta_4}$	$\frac{2\sigma_E^2(\sigma_E^2 + \sigma_s^2)}{\sigma_s^4}$	∞

FIGURE 65.3: Effect of change in $r = \sigma_H/\sigma_E$ on MSAE_{CR}^S for three types of polarizations ($\theta_4 = 0, \pi/12, \pi/4$). A single SST source, $\text{SNR} = \sigma_s^2/\sigma_{\parallel}^2 = 1$.

the polarization changes from circular to linear. In the linear polarization case, MSAE_{CR}^S tends to infinity. In this case, it is impossible to uniquely identify the source direction \mathbf{u} from the electric field only, since \mathbf{u} can then be anywhere in the plane orthogonal to the electric field vector.

The immediate conclusion is that as the source becomes closer to being linearly polarized it becomes more important to measure both the electric and magnetic fields to get good direction estimates using a single vector sensor.

These results are illustrated in Fig. 65.4, which shows the square root of MSAE_{CR}^S as a function of σ_H^2 and three polarization types ($\theta_4 = 0, \pi/12, \pi/4$). The standard deviations of the signal and electric noise are $\sigma_s = \sigma_E = 1$. The left side of the figure corresponds to (nearly) precise magnetic measurement, while the right side to (nearly) electric measurement only.

65.4.4 SST Source (SST Model) Analysis

Suppose that it is desired to estimate the direction to an SST source whose variance is unknown using a single vector sensor, and the estimation is done under the correct model of an SST source. In the following, the CRB for this problem will be derived and it will be shown that the resulting MSAE bound remains the same as when the estimation was done under the assumption of a DST source. That is, knowledge of the source type does not improve the accuracy of its direction estimate.

FIGURE 65.4: Effect of change in magnitude of σ_H^2 on MSAE_{CR}^S for three types of polarizations ($\theta_4 = 0, \pi/12, \pi/4$). A single SST source, $\sigma_s = \sigma_E = 1$.

To get a statistical model for the SST measurement model (65.14) as a special case of Eq. (65.21), we will make the same assumptions on the noise and use a similar data scaling as in the above DST source case. That will give again equal noise variances in all the sensor coordinates. Assume also that the signal envelope $s(t)$ satisfies assumption A5 with $x(t) = s(t)$ in Eq. (65.14). Then the resulting statistical model becomes a special case of Eq. (65.21) with

$$\begin{aligned} A &= \begin{bmatrix} rV \\ (\mathbf{u} \times) V \end{bmatrix} Q \mathbf{w} & x(t) = s(t) & \sigma^2 = \sigma_H^2 \\ \boldsymbol{\theta} &= [\theta_1, \theta_2, \theta_3, \theta_4]^T \end{aligned} \quad (65.35)$$

The unknown parameters are $\boldsymbol{\theta}$, P , σ^2 .

The matrix expression of $\text{CRB}(\boldsymbol{\theta})$ was calculated and its entries are presented in [1, Appendix F]. The results show that the ellipticity angle θ_4 is decoupled from the rest of the parameters and that its variance is not a function of these parameters. Additionally, the parameter vector $\boldsymbol{\theta}$ is decoupled from σ_E and σ_H .

The MSAE bound for an SST source under the SST model was calculated using the analysis of [1]. The result coincides with Eq. (65.34). That is, *the MSAE bound for an SST source is the same under both the SST and the DST models.*

The CRB expression in [1, Appendix F] implies that the CRB variance of the orientation angle θ_3 tends to infinity as the elevation angle θ_2 approaches $\pi/2$ or $-\pi/2$. This singularity is explained by the fact that the orientation angle is a function of the azimuth (through $\mathbf{v}_1, \mathbf{v}_2$), and the latter becomes increasingly sensitive to measurement errors as the elevation angle approaches the zenith or nadir. (Note that the azimuth is undefined in the zenith and nadir elevations). However, this singularity is not an intrinsic one, as it depends on the chosen reference system, while the information in the vector measurement does not.

65.4.5 CVAE and SST Source Analysis in the Wave Frame

In order to get performance results intrinsic to the SST estimation problem and thereby solve the singularity problems associated with the above model, we choose an alternative error vector that is invariant under known rotational transformations of the coordinate system. The details of the following analysis appear in [1, Appendix G].

Denote by W the wave frame whose coordinate axes are $(u, \tilde{v}_1, \tilde{v}_2)$ where \tilde{v}_1 and \tilde{v}_2 correspond, respectively, to the major and minor axes of the source's electric wave ellipse (see Fig. 65.2). For any estimator $\hat{\theta}_i$, $i = 1, 2, 3$ there is an associated estimated wave frame \hat{W} . Define the vector angular error $\phi_{W\hat{W}}$ which is the vector angle by which \hat{W} is (right-handed) rotated about W , and by $[\phi_{W\hat{W}}]_W$ the representation of $\phi_{W\hat{W}}$ in the coordinate system W (see [1, Appendix G]). The proposed vector angular error will be $[\phi_{W\hat{W}}]_W$.

Observe that $[\phi_{W\hat{W}}]_W$ depends, by definition, only on the frames W , \hat{W} . Thus, for an estimator that is independent of known rotations of the data, the estimated wave frame \hat{W} , the vector angular error and its covariance are independent of the sensor frame. We introduce the following definitions.

DEFINITION 65.4 The *normalized asymptotic covariance of the vector angular error* in the wave frame is defined as

$$\text{CVAE} \triangleq \lim_{N \rightarrow \infty} \left\{ N E \left([\phi_{W\hat{W}}]_W [\phi_{W\hat{W}}]_W^T \right) \right\} \quad (65.36)$$

whenever this limit exists.

DEFINITION 65.5 A direction and orientation estimator will be called *regular* if its errors satisfy $E \sum_{i=1}^3 |\Delta\theta_i|^3 = o(1/N)$ and the gradient of its bias with respect to $\theta_1, \theta_2, \theta_3$ is $o(1)$ as $N \rightarrow \infty$.

Then we have the following theorems.

THEOREM 65.4 For a regular model the CVAE of any regular direction and orientation estimator, whenever it exists, is bounded from below by

$$\text{CVAE}_{CR} \triangleq N \cdot K \text{CRB}(\theta_1, \theta_2, \theta_3) K^T \quad (65.37)$$

where

$$K = \begin{bmatrix} \sin \theta_2 & 0 & -1 \\ -\cos \theta_2 \sin \theta_3 & -\cos \theta_3 & 0 \\ \cos \theta_2 \cos \theta_3 & -\sin \theta_3 & 0 \end{bmatrix} \quad (65.38)$$

and $\text{CRB}(\theta_1, \theta_2, \theta_3)$ is the Cramér-Rao submatrix bound for the azimuth, elevation, and orientation angles for the particular model used.

PROOF 65.4 See [1, Appendix G].

Observe that the result of Theorem 65.4 is obtained using geometrical considerations only. Hence, it is applicable to general direction and orientation estimation problems and is not limited to the SST problem only. It is dependent only on the ability to define a wave frame. For example, one can apply this theorem to a DST source with a wave frame defined by the orientation angle that diagonalizes

the source signal covariance matrix. A generalization of this theorem to estimating non-unit vector systems is given in [26].

For vector sensor measurements, CVAE_{CR} has the desirable property of being invariant to the choice of reference coordinate frame. This invariance property also holds for the CVAE of an estimator if the estimate is independent of deterministic rotational transformations of the data. Note that CVAE_{CR} is not a function of N .

THEOREM 65.5 *The MSAE and CVAE of any regular estimator are related through*

$$\text{MSAE} = [\text{CVAE}]_{2,2} + [\text{CVAE}]_{3,3} \quad (65.39)$$

Furthermore, a similar equality holds for a regular model where the MSAE and CVAE in Eq. (65.39) are replaced by their lower bounds MSAE_{CR} and CVAE_{CR} .

PROOF 65.5 See [1, Appendix G].

In our case, $\text{CRB}(\theta_1, \theta_2, \theta_3)$ is the 3×3 upper left block entry of the CRB matrix in the sensor frame given in [1, Appendix F]. Substituting this block entry into Eq. (65.37) and denoting the CVAE matrix bound for the SST problem by CVAE_{CR}^S , we have that this matrix is diagonal with nonzero entries given by

$$[\text{CVAE}_{CR}^S]_{1,1} = \frac{(1 + \varrho)}{2\varrho^2 \cos^2 2\theta_4} \quad (65.40a)$$

$$[\text{CVAE}_{CR}^S]_{2,2} = \frac{(1 + \varrho)(\sigma_E^2 + \sigma_H^2)}{2\varrho^2[\sigma_H^2 \sin^2 \theta_4 + \sigma_E^2 \cos^2 \theta_4]} \quad (65.40b)$$

$$[\text{CVAE}_{CR}^S]_{3,3} = \frac{(1 + \varrho)(\sigma_E^2 + \sigma_H^2)}{2\varrho^2[\sigma_E^2 \sin^2 \theta_4 + \sigma_H^2 \cos^2 \theta_4]} \quad (65.40c)$$

Some observations on Eqs. (65.40) are summarized in the following:

- Rotation around \mathbf{u} : Singular only for a circularly polarized signal.
- Rotation around $\tilde{\mathbf{v}}_1$ (electric ellipse's major axis): Singular only for a linearly polarized signal and no magnetic measurement.
- Rotation around $\tilde{\mathbf{v}}_2$ (electric ellipse's minor axis): Singular only for a linearly polarized signal and no electric measurement.
- The rotation variances around $\tilde{\mathbf{v}}_1$ and $\tilde{\mathbf{v}}_2$ are symmetric with respect to the electric and magnetic measurements.
- All the three variances in Eq. (65.40) are bounded from below by $(1 + \varrho)/2\varrho^2$ (independent of the wave parameters).

The singular cases above are found by checking when their variances in CVAE_{CR}^S tend to infinity (see, e.g., [25, Theorem 6.3]). The three singular cases above should be expected as the corresponding rotations are unobservable. These singularities are intrinsic to the SST estimation problem and are independent of the reference coordinate system. The symmetry of the variances of the rotations around the major and minor axes of the ellipse with respect to the magnetic and electric measurements should be expected as their axes have a spatial angle difference of $\pi/2$.

The fact that the resulting singularities in the rotational errors are intrinsic (independent of the reference coordinate system) as well as the diagonality of the CVAE_{CR}^S bound matrix with its simple entry expressions indicate that the wave frame is a natural system in which to do the analysis.

65.4.6 A Cross-Product-Based DOA Estimator

We propose a simple algorithm for estimating the DOA of a single electromagnetic source using the measurements of a single vector sensor. The motivation for this algorithm stems from the average cross-product Poynting vector. Observe that $-\mathbf{u}$ is the unit vector in the direction of the Poynting vector given by [27],

$$\begin{aligned} S(t) &= E(t) \times H(t) = \text{Re} \left\{ e^{i\omega_c t} \mathcal{E}(t) \right\} \times \text{Re} \left\{ e^{i\omega_c t} \mathcal{H}(t) \right\} \\ &= \frac{1}{2} \text{Re} \left\{ \mathcal{E}(t) \times \overline{\mathcal{H}}(t) \right\} + \frac{1}{2} \text{Re} \left\{ e^{i2\omega_c t} \mathcal{E}(t) \times \mathcal{H}(t) \right\} \end{aligned}$$

where $\overline{\mathcal{H}}$ denotes the complex conjugate of \mathcal{H} . The carrier time average of the Poynting vector is defined as $\langle S \rangle_t \triangleq \frac{1}{2} \text{Re} \left\{ \mathcal{E}(t) \times \overline{\mathcal{H}}(t) \right\}$. Note that unlike $\mathcal{E}(t)$ and $\mathcal{H}(t)$ this average is not a function of ω_c . Thus, it has an intrinsic physical meaning.

At this point we can see two possible ways for estimating \mathbf{u} :

1. Phasor time averaging of $\langle S \rangle_t$ yielding a vector denoted by $\langle S \rangle$ with the estimated \mathbf{u} taken as the unit vector in the direction of $-\langle S \rangle$.
2. Estimation of \mathbf{u} by phasor time averaging of the unit vectors in the direction of $\text{Re} \left\{ \mathcal{E}(t) \times \overline{\mathcal{H}}(t) \right\}$.

Clearly, the first way is preferable, since then \mathbf{u} is estimated after the measurement noise is reduced by the averaging process, while the estimated \mathbf{u} in the second way is more sensitive to the measurement noises which may be magnified considerably.

Thus, the proposed algorithm computes

$$\hat{\mathbf{s}} = \frac{1}{N} \sum_{t=1}^N \text{Re} \left\{ \mathbf{y}_E(t) \times \overline{\mathbf{y}}_H(t) \right\} \quad (65.41a)$$

$$\hat{\mathbf{u}} = \hat{\mathbf{s}} / \|\hat{\mathbf{s}}\| \quad (65.41b)$$

This algorithm and some of its variants have been patented [28].

The statistical performance of this estimator $\hat{\mathbf{u}}$ is analyzed in [1, Appendix H] under the previous assumptions on $\xi(t)$, $\mathbf{e}_E(t)$, $\mathbf{e}_H(t)$, except that the Gaussian assumption is omitted. The results are summarized by the following theorem.

THEOREM 65.6 *The estimator $\hat{\mathbf{u}}$ has the following properties (for both DST and SST sources):*

- a) *If $\|\xi(t)\|^2$, $\|\mathbf{e}_E(t)\|$, $\|\mathbf{e}_H(t)\|$ have finite first order moments, then $\hat{\mathbf{u}} \rightarrow \mathbf{u}$ almost surely.*
- b) *If $\|\xi(t)\|^2$, $\|\mathbf{e}_E(t)\|$, $\|\mathbf{e}_H(t)\|$ have finite second order moments, then $\sqrt{N}(\hat{\mathbf{u}} - \mathbf{u})$ is asymptotically normal.*
- c) *If $\|\xi(t)\|^2$, $\|\mathbf{e}_E(t)\|$, $\|\mathbf{e}_H(t)\|$ have finite fourth order moments, then the MSAE is*

$$\text{MSAE} = \frac{1}{2} \varrho^{-1} \left(1 + 4\varrho^{-1} \right) \left(r + r^{-1} \right)^2 \quad (65.42)$$

where $\varrho = \text{tr}(P)/\sigma_{\parallel}^2 = \text{SNR}$.

d) Under the conditions of (c), $N\delta^2$ is asymptotically χ^2 distributed with two degrees of freedom.

PROOF 65.6 See [1, Appendix H].

For the Gaussian SST case, the ratio between the MSAE of this estimator to MSAE_{CR}^s in Eq. (65.34) is

$$\text{eff} \triangleq \frac{\text{MSAE}}{\text{MSAE}_{CR}^s} = \frac{\varrho + 4}{\varrho + 1} \left[1 + (r - r^{-1})^2 \sin^2 \theta_4 \cos^2 \theta_4 \right] \quad (65.43)$$

Hence, this estimator is nearly efficient if the following two conditions are met:

$$\varrho \gg 1 \quad (65.44a)$$

$$r \simeq 1 \quad \text{or} \quad \theta_4 \simeq 0 \quad (65.44b)$$

Figure 65.5 illustrates these results using plots of the efficiency factor (65.43) as a function of the ellipticity angle θ_4 for $\text{SNR} = \varrho = 10$ and three different values of r .

FIGURE 65.5: The efficiency factor (65.43) of the cross-product-based direction estimator as a function of the normalized ellipticity angle for three values of $r = \sigma_H/\sigma_E$. A single source, $\text{SNR} = 10$.

The estimator (65.41) can be improved using a weighted average of cross products between all possible pairs of real and imaginary parts of $y_E(t)$ and $y_H(s)$ taken at arbitrary times t and s . (Note that these cross products have directions nearly parallel to the basic estimator \hat{u} in Eq. (65.41); however, before averaging, these cross products should be premultiplied by $+1$ or -1 in accordance with the direction of the basic estimator \hat{u}). A similar algorithm suitable for real time applications can also be developed in the time domain without preprocessing needed for phasor representation. It can be extended to nonstationary inputs by using a moving average window on the data. It is of

interest to find the optimal weights and the performances of these estimators.

The main advantages of the proposed cross-product-based algorithm (65.41) or one of its variants above are

- It can give a direction estimate instantly, i.e., with one time sample.
- It is simple to implement (does not require minimization of a cost function) and can be applied in real time.
- It is equally applicable to sources of various types, including SST, DST, wide-band, and non-Gaussian.
- Its MSAE is nearly optimal in the Gaussian SST case under Eq. (65.44).
- It does not depend on time delays and therefore does not require data synchronization among different sensor components.

65.5 Multi-Source Multi-Vector Sensor Analysis

Consider the case in which it is desired to estimate the directions to multiple electromagnetic sources whose covariance is unknown using an array of vector sensors. The MSAE_{CR} and CVAE_{CR} bound expressions in Eqs. (65.29) and (65.37) are applicable to each of the sources in the multi-source multi-vector sensor scenario. Suppose that the noise vector $\mathbf{e}_{EH}(t)$ in Eq. (65.19) is complex white Gaussian with zero mean and diagonal covariance matrix (i.e., noises from different sensors are uncorrelated) and with electric and magnetic variances σ_E^2 and σ_H^2 , respectively. Suppose also that $r = \sigma_H/\sigma_E$ is known. Similarly to the single sensor case, multiply the electric measurements in Eq. (65.19) by r to obtain equal noise variances in all the sensor coordinates. The resulting models then become special cases of Eq. (65.21) as follows.

For DST signals, the block columns $A_k \in \mathbb{C}^{6m \times 2}$ and the signals $\mathbf{x}(t) \in \mathbb{C}^{2n \times 1}$ are

$$A_k = \mathbf{e}_k \otimes \begin{bmatrix} r I_3 \\ (\mathbf{u}_k \times) \end{bmatrix} V_k \quad (65.45a)$$

$$\mathbf{x}(t) = [\xi_1^T(t), \dots, \xi_n^T(t)]^T \quad (65.45b)$$

The parameter vector of the k th source includes here its azimuth and elevation.

For the SST case, the columns $A_k \in \mathbb{C}^{6m \times 1}$ and the signals $\mathbf{x}(t) \in \mathbb{C}^{n \times 1}$ are

$$A_k = \mathbf{e}_k \otimes \begin{bmatrix} r I_3 \\ (\mathbf{u}_k \times) \end{bmatrix} V_k Q_k \mathbf{w}_k \quad (65.46a)$$

$$\mathbf{x}(t) = [s_1(t), \dots, s_n(t)]^T \quad (65.46b)$$

The parameter vector of the k th source includes here its azimuth, elevation, orientation, and ellipticity angles.

The matrices A whose (block) columns are given in Eqs. (65.45a) and (65.46a) are the Khatri-Rao products (see, e.g., [20, 21]) of the two matrices whose (block) columns are the arguments of the Kronecker products in these equations.

Mixed single and dual signal transmissions are also special cases of Eq. (65.21) with appropriate combinations of the above expressions.

65.5.1 Results for Multiple Sources, Single-Vector Sensor

We present several results for the multiple-source model and a single-vector sensor. It is assumed that the signal and noise vectors satisfy, respectively, assumptions A5 and A6. The results are applicable to wide-band sources since a single vector sensor is used and thus A3 and A4 are not needed.

We first present results obtained by numerical evaluation concerning the localization of *two* uncorrelated sources, assuming r is known:

1. When only the electric field is measured, the information matrix is singular.
2. When the electric measurement is precise, the CRB variances are generally nonzero.
3. The MSAE_{CR}^S can increase without bound with decreasing source angular separation for sources with the same ellipticity and spin direction, but remarkably it remains bounded for sources with different ellipticities or opposite spin directions.

Properties 1 and 2 are, in general, different from the single source case. Property 1 shows that it is necessary to include both the electric and magnetic measurements to estimate the direction to more than one source. Property 3 demonstrates the great advantage of using the electromagnetic vector sensor, in that it allows high resolution of sources with different ellipticities or opposite spins. Note that this generally requires a very large aperture using a scalar sensor array.

The above result on the ability to resolve two sources that are different only in their ellipticity or spin direction appears to be new. Note also the analogy to Pauli's "exclusion principle", as in our case two narrow-band SST sources are distinguishable if and only if they have different sets of parameters. The set in our case includes wave-length, direction, ellipticity, and spin sign.

Now we present conditions for identifiability of multiple SST (or polarized) sources and a single vector sensor, which are analytically proven in [29] and [30], assuming the noise variances are known:

1. A single source is always identifiable.
2. Two sources that are not fully correlated are identifiable if they have different DOAs.
3. Two fully correlated sources are identifiable if they have different DOAs and ellipticities.
4. Three sources that are not fully correlated are identifiable if they have different DOAs and ellipticities.

Note that by identifiability we refer to both the DOA and polarization parameters.

Figures 65.6 and 65.7 illustrate the resolution of two uncorrelated equal power SST sources with a single electromagnetic vector sensor. The figures show the square root of the MSAE_{CR}^S of one of the sources for a variety of spin directions, ellipticities, and orientation angles, as a function of the separation angle between the sources. (The MSAE_{CR}^S values of the two sources are found to be equal in all the following cases.) The covariances of the signals and noise are normalized such that $P = I_2$, $\sigma_E = \sigma_H = 1$. The azimuth angle of the first source and the elevation angles of the two sources are kept constant ($\theta_1^{(1)} = \theta_2^{(1)} = \theta_2^{(2)} = 0$). The second source's azimuth is varied to give the desired separation angle $\Delta\theta_1, \theta_1^{(2)}$. In Fig. 65.6, the cases shown are of same spin directions ($\theta_4^{(1)} = \theta_4^{(2)} = \pi/12$) and opposite spin directions ($\theta_4^{(1)} = -\theta_4^{(2)} = \pi/12$), same orientation angles ($\theta_3^{(1)} = \theta_3^{(2)} = \pi/4$) and different orientation angles ($\theta_3^{(1)} = -\theta_3^{(2)} = \pi/4$). The figure shows that the resolution of the two sources with a single vector sensor is remarkably good when the sources have opposite spin directions. In particular, the MSAE_{CR}^S remains bounded even for zero separation angle and equal orientation angles! On the other hand, the resolution is not so significant when the two sources have different orientation angles but equal ellipticity angles (then, for example, the MSAE_{CR}^S tends to infinity for zero separation angle). In Fig. 65.7, the orientation angles of the sources is the same ($\theta_3^{(1)} = \theta_3^{(2)} = \pi/4$), the polarization of the first source is kept linear ($\theta_4^{(1)} = 0$) while the

FIGURE 65.6: MSAE_{CR}^S for two uncorrelated equal power SST sources and a single vector sensor as a function of the source angular separation. Upper two curves: Same spin directions ($\theta_4^{(1)} = \theta_4^{(2)} = \pi/12$). Lower two curves: Opposite spin directions ($\theta_4^{(1)} = -\theta_4^{(2)} = \pi/12$). Solid curves: Same orientation angles ($\theta_3^{(1)} = \theta_3^{(2)} = \pi/4$). Dashed curves: Different orientation angles ($\theta_3^{(1)} = -\theta_3^{(2)} = \pi/4$). Remaining parameters are $\theta_1^{(1)} = \theta_2^{(1)} = \theta_2^{(2)} = 0$, $\Delta\theta_1 \triangleq \theta_1^{(2)}$, $P = I_2$, $\sigma_E = \sigma_H = 1$.

ellipticity angle of the second source is varied ($|\theta_4^{(2)}| = \pi/12, \pi/6, \pi/4$) to illustrate the remarkable resolvability due to different ellipticities. It can be seen that the MSAE_{CR}^S remains bounded here even for zero separation angle.

Thus, Figs. 65.6 and 65.7 show that with one vector sensor it is possible to resolve extremely well two uncorrelated SST sources that have only different spin directions or different ellipticities (these sources can have the same direction of arrival and the same orientation angle). This demonstrates a great advantage of the vector sensor over scalar sensor arrays, in that the latter require large array apertures to resolve sources with small separation angle.

65.6 Concluding Remarks

An approach has been presented for the localization of electromagnetic sources using vector sensors. We summarize some of the main results of this article and give an outlook to their possible extensions.

Models: New models that include the complete electromagnetic data at each sensor have been introduced. Furthermore, new signal models and vector angular error models in the wave frame have been proposed. The wave frame model provides simple performance expressions that are easy to interpret and have only intrinsic singularities. Extensions of the proposed models may include additional structures for specific applications.

Cramér-Rao bounds and quality measures: A compact expression for the CRB for multi-vector source multi-vector sensor processing has been derived. The derivation gave rise to new block matrix operators. New quality measures in three-dimensional space, such as the MSAE for direction estimation and CVAE for direction and orientation estimation, have been defined. Explicit bounds on the MSAE and CVAE, having the desirable property of being invariant to the choice of the

FIGURE 65.7: MSAE_{CR}^s for two uncorrelated equal power SST sources and a single vector sensor as a function of the source angular separation. Sources are with the same orientation angles ($\theta_3^{(1)} = \theta_3^{(2)} = \pi/4$) and different ellipticity angles ($\theta_4^{(1)} = 0$ and $\theta_4^{(2)}$ as shown in the figure). Remaining parameters are as in Fig. 65.6.

reference coordinate frame, have been derived and can be used for performance analysis. Some generalizations of the bounds appear in [26]. These bounds are not limited to electromagnetic vector sensor processing. Performance comparisons of vector sensor processing with scalar sensor counterparts are of interest.

Identifiability: The derived bounds and the identifiability analysis of [29] and [30] were used to show that the fusion of magnetic and electric data at a single vector sensor increases the number of identifiable sources (or resolution capacity) in three-dimensional space from one source in the electric data case to up to three sources in the electromagnetic case. For a single signal transmission source, in order to get good direction estimates, the fusion of the complete data becomes more important as the polarization gets closer to linear. Finding the number of identifiable sources per sensor in a general vector sensor array is of interest. Preliminary results on this issue can be found in [29, 31].

Resolution: Source resolution using vector sensors is inherently different from scalar sensors, where the latter case is characterized by the classical Rayleigh principle. For example, it was shown that a single vector sensor can be used to resolve two sources in three-dimensional space. In particular, a vector sensor exhibits remarkable resolvability when the sources have opposite spin directions or different ellipticity angles. This is very different from the scalar sensor array case in which a plane array with large aperture is required to achieve the same goal. Analytical results on source resolution using vector sensor arrays and comparisons with their scalar counterparts are of interest.

Algorithms: A simple algorithm has been proposed and analyzed for finding the direction to a single source using a single vector sensor based on the cross-product operation. It is of interest to analyze the performance of the aforementioned variants of this algorithm and to extend them to more general source scenarios (e.g., larger number of sources). It is also of interest to develop new algorithms for the vector sensor array case.

Communication: The main considerations in communication are transmission of signals over channels with limited bandwidth and their recovery at the sensor. Vector sensors naturally fit these

considerations as they have maximum observability to incoming signals and they double the channel capacity (compared with scalar sensors) with DST signals. This has vast potential for performance improvement in cellular communications. Future goals will include development of optimum signal estimation algorithms, communication forms, and coding design with vector-sensor arrays.

Implementations: The proposed methods should be implemented and tested with real data.

Sensor development: The use of complete electromagnetic data seems to be virtually nonexistent in the literature on source localization. It is hoped that the results of this research will motivate the systematic development of high quality electromagnetic sensors that can operate over a broad range of frequencies. Recent references on this topic can be found in [14] and [15].

Extensions: The vector sensor concept can be extended to other areas and open new possibilities. An example of this can be found in [32] and [33] for the acoustic case.

Appendix A: Definitions of Some Block Matrix Operators

This appendix defines several block matrix operators that are found to be useful in this article. The following notation will be used for a blockwise partitioned matrix A :

$$A = \begin{bmatrix} A_{<11>} & \cdots & A_{<1n>} \\ \vdots & & \vdots \\ A_{<m1>} & \cdots & A_{<mn>} \end{bmatrix} \triangleq [A_{<ij>}] \quad (\text{A.1})$$

with the block entries $A_{<ij>}$ of dimensions $\mu_i \times v_j$. Define $\bar{\mu} \triangleq \sum_{i=1}^m \mu_i$, $\bar{v} \triangleq \sum_{j=1}^n v_j$, so A is a $\bar{\mu} \times \bar{v}$ matrix. Since the block entries may not be of the same size, this is sometimes called an unbalanced partitioning. The following definitions will be considered.

DEFINITION 65.6 *Block transpose.* Let A be an $m\mu \times nv$ blockwise partitioned matrix, with blocks $A_{<ij>}$ of equal dimensions $\mu \times v$. Then the block transpose A^{bT} is an $n\mu \times m\mu$ matrix defined through

$$(A^{bT})_{<ij>} = A_{<ji>} \quad (A.2)$$

DEFINITION 65.7 *Block Kronecker product.* Let A be a blockwise partitioned matrix of dimension $\bar{\mu} \times \bar{v}$, with block entries $A_{<ij>}$ of dimensions $\mu_i \times v_j$, and let B be a blockwise partitioned matrix of dimensions $\bar{\eta} \times \bar{\rho}$, with block entries $B_{<ij>}$ of dimensions $\eta_i \times \rho_j$. Also $\bar{\mu} = \sum_{i=1}^m \mu_i$, $\bar{v} = \sum_{j=1}^n v_j$, $\bar{\eta} = \sum_{i=1}^m \eta_i$, $\bar{\rho} = \sum_{j=1}^n \rho_j$. Then the block Kronecker product $A \boxtimes B$ is an $(\sum_{i=1}^m \mu_i \eta_i \times \sum_{j=1}^n v_j \rho_j)$ matrix defined through

$$(A \boxtimes B)_{<ij>} = A_{<ij>} \otimes B_{<ij>} \quad (A.3)$$

i.e., the (i, j) block entry of $A \boxtimes B$ is $A_{<ij>} \otimes B_{<ij>}$ of dimension $\mu_i \eta_i \times v_j \rho_j$.

DEFINITION 65.8 *Block Schur-Hadamard product.* Let A be an $m\mu \times nv$ matrix consisting of blocks $A_{<ij>}$ of dimensions $\mu \times v$, and let B be an $m\mu \times nv$ matrix consisting of blocks $B_{<ij>}$ of dimensions $\mu \times v$. Then the block Schur-Hadamard product $A \boxdot B$ is an $m\mu \times nv$ matrix defined through

$$(A \boxdot B)_{<ij>} = A_{<ij>} \odot B_{<ij>} \quad (A.4)$$

Thus, each block of the product is a *usual* product of a pair of blocks and is of dimension $\mu \times v$.

DEFINITION 65.9 *Block trace operator.* Let A be an $m\mu \times n\mu$ matrix consisting of blocks $A_{<ij>}$ of dimensions $\mu \times \mu$. Then the block trace matrix operator $\text{btr}[A]$ is an $m \times n$ matrix defined by

$$(\text{btr}[A])_{ij} = \text{tr } A_{<ij>} \quad (A.5)$$

66.1 Introduction

Most high resolution direction-of-arrival (DOA) estimation methods rely on subspace or eigen-based information which can be obtained from the eigenvalue decomposition (EVD) of an estimated correlation matrix, or from the singular value decomposition (SVD) of the corresponding data matrix. However, the expense of directly computing these decompositions is usually prohibitive for real-time processing. Also, because the DOA angles are typically time-varying, repeated computation is necessary to track the angles. This has motivated researchers in recent years to develop low cost eigen and subspace tracking methods. Four basic strategies have been pursued to reduce computation: (1) computing only a few eigencomponents, (2) computing a subspace basis instead of individual eigencomponents, (3) approximating the eigencomponents or basis, and (4) recursively updating the eigencomponents or basis. The most efficient methods usually employ several of these strategies.

In 1990, an extensive survey of SVD tracking methods was published by Comon and Golub [7]. They classified the various algorithms according to complexity and basically two categories emerge: $O(n^2r)$ and $O(nr^2)$ methods, where n is the snapshot vector size and r is the number of extreme eigenpairs to be tracked. Typically, $r < n$ or $r \ll n$, so the $O(nr^2)$ methods involve significantly fewer computations than the $O(n^2r)$ algorithms. However, since 1990, a number of $O(nr)$ algorithms have

been developed. This article will primarily focus on recursive subspace and eigen updating methods developed since 1990, especially, the $O(nr^2)$ and $O(nr)$ algorithms.

66.2 Background

66.2.1 EVD vs. SVD

Let $X = [x_1|x_2|\dots|x_N]$ be an $n \times N$ data matrix where the k th column corresponds to the k th snapshot vector, $x_k \in C^n$. With block processing, the correlation matrix for a zero mean, stationary, ergodic vector process is typically estimated as $R = \frac{1}{N}XX^H$ where the true correlation matrix, $\Phi = E[x_k x_k^H] = E[R]$.

The EVD of the estimated correlation matrix is closely related to the SVD of the corresponding data matrix. The SVD of X is given by $X = USV^H$ where $U \in C^{n \times n}$ and $V \in C^{N \times N}$ are unitary matrices and $S \in C^{n \times N}$ is a diagonal matrix whose nonzero entries are positive. It is easy to see that the left singular vectors of X are the eigenvectors of $XX^H = USS^T U^H$, and the right singular vectors of X are the eigenvectors of $X^H X = V S^T S V^H$. This is so because XX^H and $X^H X$ are positive definite Hermitian matrices (which have orthogonal eigenvectors and real, positive eigenvalues). Also note that the nonzero singular values of X are the positive square roots of the nonzero eigenvalues of XX^H and $X^H X$. Mathematically, the eigen information contained in the SVD of X or the EVD of XX^H (or $X^H X$) is equivalent, but the dynamic range of the eigenvalues is twice that of the corresponding singular values. With finite precision arithmetic, the greater dynamic range can result in a loss of information. For example, in rank determination, suppose the smallest singular value is ϵ where ϵ is machine precision. The corresponding eigenvalue, ϵ^2 , would be considered a machine precision zero and the EVD of XX^H (or $X^H X$) would incorrectly indicate a rank deficiency. Because of the dynamic range issue, it is generally recommended to use the SVD of X (or a square root factor of R). However, because additive sensor noise usually dominates numerical errors, this choice may not be critical in most signal processing applications.

66.2.2 Short Memory Windows for Time Varying Estimation

Ultimately, we are interested in tracking some aspect of the eigenstructure of a time varying correlation (or data) matrix. For simplicity we will focus on time varying estimation of the correlation matrix, realizing that the EVD of R is trivially related to the SVD of X . A time varying estimator must have a short term memory in order to track changes. An example of long memory estimation is an estimator that involves a growing rectangular data window. As time goes on, the estimated quantities depend more and more on the old data, and less and less on the new data. The two most popular short memory approaches to estimating a time varying correlation matrix involve (1) a moving rectangular window and (2) an exponentially faded window. Unfortunately, an unbiased, causal estimate of the true instantaneous correlation matrix at time k , $\Phi_k = E[x_k x_k^H]$, is not possible if averaging is used and the vector process is truly time varying. However, it is usually assumed that the process is varying slowly enough within the effective observation window that the process is approximately stationary and some averaging is desirable. In any event, at time k , a length N moving rectangular data window results in a rank two modification of the correlation matrix estimate, i.e.,

$$R_k^{(rect)} = R_{k-1}^{(rect)} + \frac{1}{N}(x_k x_k^H - x_{k-N} x_{k-N}^H) \quad (66.1)$$

where x_k is the new snapshot vector and x_{k-N} is the oldest vector which is being removed from the estimate. The corresponding data matrix is given by $X_k^{(rect)} = [x_k|x_{k-1}|\dots|x_{k-N+1}]$ and $R_k^{(rect)} = \frac{1}{N}X_k^{(rect)} \left(X_k^{(rect)}\right)^H$. Subtracting the rank one matrix from the correlation estimate is referred to as

a rank one downdate. Downdating moves all the eigenvalues down (or unchanged). Updating, on the other hand, moves all eigenvalues up (or unchanged). Downdating is potentially ill-conditioned because the smallest eigenvalue can move towards zero.

An exponentially faded data window produces a rank one modification in

$$R_k^{(fade)} = \alpha R_{k-1}^{(fade)} + (1 - \alpha) x_k x_k^H \quad (66.2)$$

where α is the fading factor with $0 \leq \alpha \leq 1$. In this case, the data matrix is growing in size, but the older data is de-emphasized with a diagonal weighting matrix,

$$X_k^{(fade)} = [x_k | x_{k-1} | \dots | x_1] \text{sqrt}(\text{diag}(1, \alpha, \alpha^2, \dots, \alpha^{k-1})) \text{ and } R_k^{(fade)} = (1 - \alpha) X_k^{(fade)} \left(X_k^{(fade)} \right)^H.$$

Of course, the two windows could be combined to produce an exponentially faded moving rectangular window, but this kind of hybrid short memory window has not been the subject of much study in the signal processing literature. Similarly, not much attention has been paid to which short memory windowing scheme is most appropriate for a given data model. Since downdating is potentially ill-conditioned, and since two rank one modifications usually involve more computation than one, the exponentially faded window has some advantages over the moving rectangular window. The main advantage of a (short) rectangular window is in tracking sudden changes. Assuming stationarity within the effective observation window, the power in a rectangular window will be equal to the power in an exponentially faded window when

$$N \approx \frac{1}{(1 - \alpha)} \text{ or equivalently } \alpha \approx 1 - \frac{1}{N} = \frac{N - 1}{N}. \quad (66.3)$$

Based on a Fourier analysis of linearly varying frequencies, equal frequency lags occur when [14]

$$N \approx \frac{(1 + \alpha)}{(1 - \alpha)} \text{ or equivalently } \alpha \approx \frac{N - 1}{N + 1}. \quad (66.4)$$

Either one of these relationships could be used as a rule of thumb for relating the effective observation window of the two most popular short memory windowing schemes.

66.2.3 Classification of Subspace Methods

Eigenstructure estimation can be classified as (1) block or (2) recursive. Block methods simply compute an EVD, SVD, or related decomposition based on a block of data. Recursive methods update the previously computed eigen information using new data as it arrives. We focus on recursive subspace updating methods in this article.

Most subspace tracking algorithms can also be broadly categorized as (1) modified eigen problem (MEP) methods or (2) adaptive (or non-MEP) methods. With short memory windowing, MEP methods are adaptive in the sense that they can track time varying eigen information. However, when we use the word adaptive, we mean that exact eigen information is not computed at each update, but rather, an adaptive method tends to move towards an EVD (or some aspect of an EVD) at each update. For example, gradient-based, perturbation-based, and neural network-based methods are classified as adaptive because on average they move towards an EVD at each update. On the other hand, rank one, rank k , and sphericalized EVD and SVD updates are, by definition, MEP methods because exact eigen information associated with an explicit matrix is computed at each update. Both MEP and adaptive methods are supposed to track the eigen information of the instantaneous, time varying correlation matrix.

66.2.4 Historical Overview of MEP Methods

Many researchers have studied SVD and EVD tracking problems. Golub [19] introduced one of the first eigen-updating schemes, and his ideas were developed and expanded by Bunch and co-workers in [3, 4]. The basic idea is to update the EVD of a symmetric (or Hermitian) matrix when modified by a rank one matrix. The rank-one eigen update was simplified in [37], when Schreiber introduced a transformation that makes the core eigenproblem real. Based on an additive white noise model, Karasalo [21] and Schreiber [37] suggested that the noise subspace be “sphericalized”, i.e., replace the noise eigenvalues by their average value so that deflation [4] could be used to significantly reduce computation. By deflating the noise subspace and only tracking the r dominant eigenvectors, the computation is reduced from $O(n^3)$ to $O(nr^2)$ per update. DeGroat reduced computation further by extending this concept to the signal subspace [8]. By sphericalizing and deflating both the signal and the noise subspaces, the cost of tracking the r dimensional signal (or noise) subspace is $O(nr)$ and no iteration is involved. To make eigen updating more practical, DeGroat and Roberts developed stabilization schemes to control the loss of orthogonality due to the buildup of roundoff error [10]. Further work related to eigenvector stabilization is reported in [15, 28, 29, 30]. Recently, a more stable version of Bunch’s algorithm was developed by Gu and Eisenstat [20]. In [46], Yu extended rank one eigen updating to rank k updating.

DeGroat showed in [8] that forcing certain subspaces of the correlation matrix to be spherical, i.e., replacing the associated eigenvalues with a fixed or average value, is an easy way to deflate the size of the updating problem and reduce computation. Basically, a spherical subspace (SS) update is a rank one EVD update of a sphericalized correlation matrix. Asymptotic convergence analysis of SS updating is found in [11, 13]. A four level SS update capable of automatic signal subspace rank and size adjustment is described in [9, 11]. The four level and the two level SS updates are the only MEP updates to date that are $O(nr)$ and noniterative. For more details on SS updating, see Section 66.3.6, *Spherical Subspace (SS) Updating: A General Framework for Simplified Updating*.

In [42], Xu and Kailath present a Lanczos based subspace tracking method with an associated detection scheme to track the number of sources. A reference list for systolic implementations of SVD based subspace trackers is contained in [12].

66.2.5 Historical Overview of Adaptive, Non-MEP Methods

Owsley pioneered orthogonal iteration and stochastic-based subspace trackers in [32]. Yang and Kaveh extended Owsley’s work in [44] by devising a family of constrained gradient-based algorithms. A highly parallel algorithm, denoted the inflation method, is introduced for the estimation of the noise subspace. The computational complexity of this family of gradient-based methods varies from (approximately) n^2r to $\frac{7}{2}nr$ for the adaptation equation. However, since the eigenvectors are only approximately orthogonal, an additional nr^2 flops may be needed if Gram Schmidt orthogonalization is used. It may be that a partial orthogonalization scheme (see Section 66.3.2 *Controlling Roundoff Error Accumulation and Orthogonality Errors*) can be combined with Yang and Kaveh’s methods to improve orthogonality enough to eliminate the $O(nr^2)$ Gram Schmidt computation. Karhunen [22] also extended Owsley’s work by developing a stochastic approximation method for subspace computation. Bin Yang [43] used recursive least squares (RLS) methods with a projection approximation approach to develop the projection approximation subspace tracker (PAST) which tracks an arbitrary basis for the signal subspace, and PASTd which uses deflation to track the individual eigencomponents. A multi-vector eigen tracker based on the conjugate gradient method is developed in [18]. Previous conjugate gradient-based methods tracked a single eigenvector only. Orthogonal iteration, lossless adaptive filter, and perturbation-based subspace trackers appear in [40] [36], and [5] respectively. A family of non-EVD subspace trackers is given in [16]. An adaptive subspace method that uses a linear operator, referred to as the Propagator, is given in [26]. Approximate SVD methods that are

based on a QR update step followed by a single (or partial) Jacobi sweep to move the triangular factor towards a diagonal form appear in [12, 17, 30]. These methods can be described as approximate SVD methods because they will converge to an SVD if the Jacobi sweeps are repeated.

Subspace estimation methods based on URV or rank revealing QR (RRQR) decompositions are referenced in [6]. These rank revealing decompositions can divide a set of orthonormal vectors into sets that span the signal and noise subspaces. However, a threshold (noise power) level that lies between the largest noise eigenvalue and the smallest signal eigenvalue must be known in advance. In some ways, the URV decomposition can be viewed as an approximate SVD. For example, the transposed QR (TQR) iteration [12] can be used to compute the SVD of a matrix, but if the iteration is stopped before convergence, the resulting decomposition is URV-like.

Artificial neural networks (ANN) have also been used to estimate eigen information [35]. In 1982, Oja [31] was one of the first to develop an eigenvector estimating ANN. Using a Hebbian type learning rule, this ANN adaptively extracts the first principal eigenvector. Much research has been done in this area since 1982. For an overview and a list of references, see [35].

66.3 Issues Relevant to Subspace and Eigen Tracking Methods

66.3.1 Bias Due to Time Varying Nature of Data Model

Because direction-of-arrival (DOA) angles are typically time varying, a range of spatial frequencies is usually included in the effective observation window. Most spatial frequency estimation methods yield frequency estimates that are approximately equal to the effective frequency average in the window. Consequently, the estimates lag the true instantaneous frequency. If the frequency variation is assumed to be linear within the effective observation window, this lag (or bias) can be easily estimated and compensated [14].

66.3.2 Controlling Roundoff Error Accumulation and Orthogonality Errors

Numerical algorithms are generally defined as stable if the roundoff error accumulates in a linear fashion. However, recursive updating algorithms cannot tolerate even a linear buildup of error if large (possibly unbounded) numbers of updates are to be performed. For real time processing, periodic reinitialization is undesirable. Most of the subspace tracking algorithms involve the product of at least k orthogonal matrices by the time the k th update is computed. According to Parlett [33], the error propagated by a product of orthogonal matrices is bounded as

$$|U_k U_k^H - I|_E \leq (k + 1)n^{1.5}\epsilon \quad (66.5)$$

where the $n \times n$ matrix $U_k = U_{k-1} Q_k = Q_k Q_{k-1} \dots Q_1$ is a product of k matrices that are each orthogonal to working accuracy, ϵ is machine precision, and $|\cdot|_E$ denotes the Euclidean matrix norm. Clearly, if k is large enough, the roundoff error accumulation can be significant.

There are really only two sources of error in updating a symmetric or Hermitian EVD: (1) the eigenvalues and (2) the eigenvectors. Of course, the eigenvectors and eigenvalues are interrelated. Errors in one tend to produce errors in the other. At each update, small errors may occur in the EVD update so that the eigenvalues become slowly perturbed and the eigenvectors become slowly nonorthonormal. The solution is to prevent significant errors from ever accumulating in either.

We do not expect the main source of error to be from the eigenvalues. According to Stewart [38], the eigenvalues of a Hermitian matrix are perfectly conditioned, having condition numbers of one. Moreover, it is easy to show that when exponential weighting is used, the accumulated roundoff error

is bounded by a constant, assuming no significant errors are introduced by the eigenvectors. By contrast, if exponential windowing is not used, the bound for the accumulated error builds up in a linear fashion. Thus, the fading factor not only fades out old data, but also old roundoff errors that accumulate in the eigenvalues.

Unfortunately, the eigenvectors of a Hermitian matrix are not guaranteed to be well conditioned. An eigenvector will be ill-conditioned if its eigenvalue is closely spaced with other eigenvalues. In this case, small roundoff perturbations to the matrix may cause relatively large errors in the eigenvectors. The greatest potential for nonorthogonality then is between eigenvectors with adjacent (closely spaced) eigenvalues. This observation led to the development of a partial orthogonalization scheme known as pairwise Gram Schmidt (PGS) [10] which attacks the roundoff error buildup problem at the point of greatest numerical instability — nonorthogonality of adjacent eigenvectors. If the intervening rotations (orthogonal matrix products) inherent in the eigen update are random enough, the adjacent vector PGS can be viewed as a full orthogonalization spread out over time. When PGS is combined with exponential fading, the roundoff accumulation in both the eigenvectors and the eigenvalues is controlled. Although PGS was originally designed to stabilize Bunch's EVD update, it is generally applicable to any EVD, SVD, URV, QR, or orthogonal vector update. Moonen et al. [29] suggested that the bulk of the eigenvector stabilization in the PGS scheme is due to the normalization of the eigenvectors. Simulations seem to indicate that normalization alone stabilizes the eigenvectors almost as well as the PGS scheme, but not to working precision orthogonality. Edelman and Stewart provide some insight into the normalization only approach to maintaining orthogonality [15]. For additional analysis and variations on the basic idea of spreading orthogonalization out over time, see [30] and especially [28].

Many of the $O(nr)$ adaptive subspace methods produce eigenvector estimates that are only approximately orthogonal and normalization alone does not always provide enough stabilization to keep the orthogonality and other error measures small enough. We have found that PGS stabilization can noticeably improve both the subspace estimation performance as well as the DOA (or spatial frequency) estimation performance. For example, without PGS (but with normalization only), we found that Champagne's $O(nr)$ perturbation-based eigen tracker (method PC) [5] sometimes gives spurious MUSIC-based frequency estimates. On the other hand, with PGS, Champagne's PC method produced improved subspace and frequency estimates. The orthogonality error was also significantly reduced. Similar performance boosts could be expected for any subspace or eigen tracking method (especially those that produce eigenvector estimates that are only approximately orthogonal, e.g., PAST and PASTd [43] or Yang and Kaveh's family of gradient based methods [44, 45]). Unfortunately, normalization only and PGS are $O(nr)$. Adding this kind of stabilization to an $O(nr)$ subspace tracking method could double its overall computation.

Other variations on the original PGS idea involve symmetrizing the 2×2 transformation and making the pairwise orthogonalization cyclic [28]. The symmetric transformation assumes that the vector pairs are almost orthogonal so that higher order error terms can be ignored. If this is the case, the symmetric version can provide slightly better results at a somewhat higher computational cost. For methods that involve working precision orthogonal vectors, the original PGS scheme is overkill. Instead of doing PGS orthogonalization on each adjacent vector pair, cyclic PGS orthogonalizes only one pair of vectors per update, but cycles through all possible combinations over time. Thus, cyclic PGS covers all vector pairs without relying on the randomness of intervening rotations. Cyclic PGS spreads the orthogonalization process out in time even more than the adjacent vector PGS method. Moreover, cyclic PGS (or cyclic normalization) involves $O(n)$ flops per update, but there is a small overhead associated with keeping track of the vector pair cycle.

In summary, we can say that stabilization may not be needed for a small number of updates. On the other hand, if an unbounded number of updates is to be performed, some kind of stabilization is recommended. For methods that yield nearly orthogonal vectors at each update, only a small amount of orthogonalization is needed to control the error buildup. In these cases, cyclic PGS may be best.

However, for methods that produce vectors that are only approximately orthogonal, a more complete orthogonalization scheme may be appropriate, e.g., a cyclic scheme with two or three vector pairs orthogonalized per update will produce better results than a single pair scheme.

66.3.3 Forward-Backward Averaging

In many subspace tracking problems, forward-backward (FB) averaging can improve subspace as well as DOA (or frequency) estimation performance. Although FB averaging is generally not appropriate for nonstationary processes, it does appear to improve spatial frequency estimation performance if the frequencies vary linearly within the effective observation window. Based on Fourier analysis of linearly varying frequencies, we infer that this is probably due to the fact that the average frequency in the window is identical for both the forward and the backward cases [14]. Consequently, the frequency estimates are reinforced by FB averaging. Besides improved estimation performance, FB averaging can be exploited to reduce computation by as much as 75% [24]. FB averaging can also reduce computer memory requirements because (conjugate symmetric or anti-symmetric) symmetries in the complex eigenvectors of an FB averaged correlation matrix (or the singular vectors of an FB data matrix) can be exposed through appropriate normalization.

66.3.4 Frequency vs. Subspace Estimation Performance

It has recently been shown with asymptotic analysis that a better subspace estimate does not necessarily result in a better MUSIC-based frequency estimate [23]. In subspace tracking simulations, we have also observed that some methods produce better subspace estimates, but the associated MUSIC-based frequency estimates are not always better. Consequently, if DOA estimation is the ultimate goal, subspace estimation performance may not be the best criterion for evaluating subspace tracking methods.

66.3.5 The Difficulty of Testing and Comparing Subspace Tracking Methods

A significant amount of research has been done on subspace and eigen tracking algorithms in the past few years, and much progress has been made in making subspace tracking more efficient. Not surprisingly, all of the methods developed to date have different strengths and weaknesses. Unfortunately, there has not been enough time to thoroughly analyze, study, and evaluate all of the new methods. Over the years, several tests have been devised to “experimentally” compare various methods, e.g., convergence tests [44], response to sudden changes [7], and crossing frequency tracks (where the signal subspace temporarily collapses) [8]. Some methods do well on one test, but not so well on another. It is difficult to objectively compare different subspace tracking methods because optimal operating parameters are usually unknown and therefore unused, and the performance criteria may be ill-defined or contradictory.

66.3.6 Spherical Subspace (SS) Updating — A General Framework for Simplified Updating

Most eigen and subspace tracking algorithms are based directly or indirectly on tracking some aspect of the EVD of a time varying correlation matrix estimate that is recursively updated according to Eq. (66.1) or (66.2). Since Eqs. (66.1) and (66.2) involve rank one and rank two modifications to the correlation matrix, most subspace tracking algorithms explicitly or implicitly involve rank one (or two) modification of the correlation matrix. Since rank two modifications can be computed as two rank one modifications, we will focus on rank one updating.

Basically, spherical subspace (SS) updates are simplified rank one EVD updates. The simplification involves sphericalizing subsets of eigenvalues (i.e., forcing each subset to have the same eigenlevel) so that the sphericalized subspaces can be deflated.

Based on an additive white noise signal model, Karasalo [21] and Schreiber [37] first suggested that the “noise” eigenvalues be replaced by their average value in order to reduce computation by deflation. Using Ljung’s ODE-based method for analyzing stochastic recursive algorithms [25], it has recently been shown that, if the noise subspace is sphericalized, the dominant eigenstructure of a correlation matrix asymptotically converges to the true eigenstructure with probability one (under any noise assumption) [11]. It is important to realize that averaging the noise eigenvalues yields a spherical subspace in which the eigenvectors can be arbitrarily oriented as long as they form an orthonormal basis for the subspace. A rank-one modification affects only one component of the sphericalized subspace. Thus, only one of the multiple noise eigenvalues is changed by a rank-one modification. Consequently, making the noise subspace spherical (by averaging the noise eigenvalues, or replacing them with a constant eigenlevel) deflates the eigenproblem to an $(r + 1) \times (r + 1)$ problem, which corresponds to a signal subspace of dimension r , and the single noise component whose power is changed. For details on deflation, see [4].

The analysis in [11] shows that any number of sphericalized eigenlevels can be used to track various subspace spans associated with the correlation matrix. For example, if both the noise and the signal subspaces are sphericalized (i.e., the dominant and subdominant set of eigenvalues is replaced by their respective averages), the problem deflates to a 2×2 eigenproblem that can be solved in closed form, noniteratively. We will call this doubly deflated SS update, SA2 (Signal Averaged, Two Eigenlevels) [8]. In [13] we derived the SA2 algorithm ODE and used a Lyapunov function to show asymptotic convergence to the true subspaces w.p. 1 under a diminishing gain assumption. In fact, the SA2 subspace trajectories can be described with Lie bracket notation and follow an isospectral flow as described by Brockett’s ODE [2]. A four level SS update (called SA4) was introduced in [9] to allow for information theoretic source detection (based on the eigenvalues at the boundary of the signal and noise subspaces) and automatic subspace size adjustment. A detailed analysis of SA4 and an SA4 minimum description length (SA4-MDL) detection scheme can be found in [11, 41]. SA4 sphericalizes all the signal eigenvalues except the smallest one, and all the noise eigenvalues except the largest one, resulting in a 4×4 deflated eigenproblem. By tracking the eigenvalues that are on the boundary of the signal and noise subspaces, information theoretic detection schemes can be used to decide if the signal subspace dimension should be increased, decreased, or remain unchanged. Both SA2 and SA4 are $O(nr)$ and noniterative.

The deflated core problem in SS updating can involve any EVD or SVD method that is desired. It can also involve other decompositions, e.g., the URVD [34]. To illustrate the basic idea of SS updating, we will explicitly show how an update is accomplished when only the smallest $(n - r)$ “noise” eigenvalues are sphericalized. This particular SS update is called a Signal Eigenstructure (SE) update because only the dominant r “signal” eigenvectors are tracked. This case is equivalent to that described by Schreiber [37] and an SVD version is given by Karasalo [21].

To simplify and more clearly illustrate the idea SS updating, we drop the normalization factor, $(1 - \alpha)$, and the k subscripts from Eq. (66.2) and use the eigendecomposition of $R = UDU^H$ to expose a simpler underlying structure for a single rank-one update

$$\tilde{R} = \alpha R + xx^H \quad (66.6)$$

$$= \alpha UDU^H + xx^H \quad (66.7)$$

$$= U(\alpha D + \beta\beta^H)U^H, \quad \beta = U^H x \quad (66.8)$$

$$= UG(\alpha D + \gamma\gamma^T)G^H U^H, \quad \gamma = G^H \beta \quad (66.9)$$

$$= UGH(\alpha D + \zeta\zeta^T)H^T G^H U^H, \quad \zeta = H^T \gamma \quad (66.10)$$

$$= UGH(Q\tilde{D}Q^T)H^T G^H U^H \quad (66.11)$$

$$= \tilde{U} \tilde{D} \tilde{U}^H, \quad \tilde{U} = UGHQ \quad (66.12)$$

where $G = \text{diag}(\beta_1/|\beta_1|, \dots, \beta_n/|\beta_n|)$ is a diagonal unitary transformation that has the effect of making the matrix inside the parenthesis real [37], H is an embedded Householder transformation that deflates the core problem by zeroing out certain elements of ζ (see the SE case below), and $Q\tilde{D}Q^T$ is the EVD of the simplified, deflated core matrix, $(\alpha D + \zeta\zeta^T)$. In general, H and Q will involve smaller matrices embedded in an $n \times n$ identity matrix. In order to more clearly see the details of deflation, we must concentrate on finding the eigendecomposition of the completely real matrix, $S = (\alpha D + \gamma\gamma^T)$ for a specific case. Let us consider the SE update and assume that the noise eigenvalues contained in the diagonal matrix have been replaced by their average values, $d^{(n)}$, to produce a sphericalized noise subspace. We must then apply block Householder transformations to concentrate all of the power in the new data vector into a single component of the noise subspace. The update is thus deflated to an $(r+1) \times (r+1)$ embedded eigenproblem as shown below,

$$S = (\alpha D + \gamma\gamma^T) \quad (66.13)$$

$$= H(\alpha D + \zeta\zeta^T)H^T, \quad \zeta = H^T\gamma \quad (66.14)$$

$$= \begin{bmatrix} I_r & 0 \\ 0 & H_{n-r}^{(n)} \end{bmatrix} \left(\alpha \begin{bmatrix} D_r^{(s)} & 0 \\ 0 & d^{(n)} I_{n-r} \end{bmatrix} + \zeta\zeta^T \right) \begin{bmatrix} I_r & 0 \\ 0 & H_{n-r}^{(n)} \end{bmatrix}^T \quad (66.15)$$

$$= \begin{bmatrix} I_r & 0 \\ 0 & H_{n-r}^{(n)} \end{bmatrix} \left(\begin{bmatrix} Q_{r+1} & 0 \\ 0 & I_{n-r-1} \end{bmatrix} \begin{bmatrix} \tilde{D}_r^{(s)} & 0 & 0 \\ 0 & \tilde{d}^{(n)} & 0 \\ 0 & 0 & \alpha d^{(n)} I_{n-r-1} \end{bmatrix} \begin{bmatrix} Q_{r+1} & 0 \\ 0 & I_{n-r-1} \end{bmatrix}^T \right) \begin{bmatrix} I_r & 0 \\ 0 & H_{n-r}^{(n)} \end{bmatrix}^T \quad (66.16)$$

$$= H(Q\tilde{D}Q^T)H^T \quad (66.17)$$

where

$$\zeta^T = (H^T\gamma)^T = [\gamma^{(s)}, |\gamma^{(n)}|, 0_{(n-r-1) \times 1}]^T, \quad (66.18)$$

$$H_{n-r}^{(n)} = I_{n-r} - 2 \frac{v^{(n)}(v^{(n)})^T}{(v^{(n)})^T v^{(n)}}, \quad (66.19)$$

$$H = \begin{bmatrix} I_r & 0 \\ 0 & H_{n-r}^{(n)} \end{bmatrix}, \quad (66.20)$$

$$\gamma = \begin{bmatrix} \gamma^{(s)} \\ \gamma^{(n)} \end{bmatrix} \begin{matrix} \} r \\ \} n-r \end{matrix} \quad (66.21)$$

$$v^{(n)} = \gamma^{(n)} + |\gamma^{(n)}| \begin{bmatrix} 1 \\ 0_{(n-r-1) \times 1} \end{bmatrix} \quad (66.22)$$

The superscripts (s) and (n) denote signal and noise subspace, respectively, and the subscripts denote the size of the various block matrices. In the actual implementation of the SE algorithm, the Householder transformations are not explicitly computed, as we will see below. Moreover, it should be stressed that the Householder transformation does not change the span of the noise subspace, but

merely “aligns” the subspace so that all of the new data vector, x , that projects into the noise subspace lies in a single component of the noise subspace.

The embedded (deflated) $(r + 1) \times (r + 1)$ eigenproblem,

$$E = \left(\begin{bmatrix} D^{(s)} & 0 \\ 0 & d^{(n)} \end{bmatrix} + \begin{bmatrix} \gamma^{(s)} \\ |\gamma^{(n)}| \end{bmatrix} \begin{bmatrix} \gamma^{(s)} \\ |\gamma^{(n)}| \end{bmatrix}^T \right)_{(r+1) \times (r+1)} = Q_{r+1} \tilde{D}_{r+1} Q_{r+1}^T \quad (66.23)$$

can be solved using any EVD algorithm. Or, an SVD (square root) version can be computed by finding the SVD of

$$F = \begin{bmatrix} \Sigma^{(s)} & 0 & \gamma^{(s)} \\ 0 & \sigma^{(n)} & |\gamma^{(n)}| \end{bmatrix}_{(r+1) \times (r+2)} = Q_{r+1} \tilde{\Sigma}_{r+1} P_{r+1}^T \quad (66.24)$$

where $E = FF^T$, $\Sigma^{(s)} = \text{sqrt}(D^{(s)})$, $\sigma^{(n)} = \sqrt{d^{(n)}}$ and $\tilde{\Sigma}_{r+1} = \text{sqrt}(\tilde{D}_{r+1})$. The right singular vectors, P_{r+1} , are generally not needed or explicitly computed in most subspace tracking problems.

The new signal and noise subspaces are thus given by

$$\tilde{U} = [\tilde{U}^{(s)}, \tilde{U}^{(n)}] \quad (66.25)$$

$$= UGHQ \quad (66.26)$$

$$= \left[\underbrace{U^{(s)}G^{(s)}}_{n \times r}, \underbrace{U^{(n)}G^{(n)}H^{(n)}}_{n \times (n-r)} \right] \begin{bmatrix} Q_{r+1} & 0 \\ 0 & I_{n-r-1} \end{bmatrix} \quad (66.27)$$

where $U^{(s)}$ and $U^{(n)}$ are the old signal and noise subspaces, G represents the diagonal unitary transformation that makes the rest of the problem real, H is the block Householder transformation that rotates (or more precisely, reflects) the spherical subspaces so that all of the noise power contained in the new data vector can be concentrated into a single component of noise subspace, and Q represents the evolution and interaction of the two subspaces induced by the new data vector. Basically, this update partitions the data space into two subspaces: the signal subspace is not sphericalized and all of its eigenvectors are explicitly tracked whereas the noise subspace is sphericalized and not explicitly tracked (to save computation). Using the properties of the Householder transformation, it can be shown that the single component of the noise subspace that mixes with the signal subspace via Q_{r+1} is given by

$$u^{(n)} = \text{the first column of } U^{(n)}G^{(n)}H^{(n)} \quad (66.28)$$

$$= \frac{U^{(n)}(U^{(n)})^H x}{|U^{(n)}(U^{(n)})^H x|} \quad (66.29)$$

$$= \frac{1}{|\gamma^{(n)}|} (I - U^{(s)}(U^{(s)})^H)x \quad (66.30)$$

$$= \frac{1}{|\gamma^{(n)}|} (x - U^{(s)}\gamma^{(s)}) \quad (66.31)$$

where $u^{(n)}$ is the projection of x into the noise subspace and $|\gamma^{(n)}| = |x - U^{(s)}\gamma^{(s)}|$ is the power of x projected into the noise subspace. Once the eigenvectors of the core $(r + 1) \times (r + 1)$ problem are found, the signal subspace eigenvectors can be updated as

$$\tilde{U} = [\tilde{U}^{(s)}, \tilde{u}^{(n)}] \quad (66.32)$$

$$= \left[\underbrace{U^{(s)}G^{(s)}}_{n \times r}, \underbrace{u^{(n)}}_{n \times 1} \right] Q_{r+1} \quad (66.33)$$

where updating the new noise eigenvector is not necessary (if the noise subspace is resphericalized). The complexity of the core eigenproblem is $O(r^3)$ and updating the signal eigenvectors is $O(nr^2)$. Thus, the SE update is $O(nr^2)$.

After an update is accomplished, one of the noise eigencomponents is altered by the embedded eigenproblem. To maintain noise subspace sphericity, the noise eigenvalues must be re-averaged before the next SE update can be accomplished. On the other hand, if the noise eigenvalues are not re-averaged, the SE update eventually reverts to a full eigen update.

A whole family of related SS updates is possible by simple modification of the above described process. For example, to obtain SA2, the H transformation in Eq. (66.20) would be modified by replacing the I_r with an $r \times r$ Householder matrix that deflates the signal subspace. This would make the core eigenproblem 2×2 and the Q matrix an identity with an embedded 2×2 orthogonal matrix.

66.3.7 Initialization of Subspace and Eigen Tracking Algorithms

It is impossible to give generic initialization requirements that would apply to all subspace tracking algorithms, but one feature that is common to many updating methods is a fading factor. For cold start initialization (e.g., starting from nothing) at $k = 0$, initial convergence can often be sped up by ramping up the fading factor, e.g.,

$$\alpha_k = \left(1 - \frac{1}{k+1}\right)\alpha, \quad k = 0, 1, 2, \dots \quad (66.34)$$

where α is the final steady state value for the fading factor.

66.3.8 Detection Schemes for Subspace Tracking

Several subspace tracking methods have detection schemes that were specifically designed for them. Xu and Kailath developed a strongly consistent detection scheme for their Lanczos-based method [42]. DeGroat and Dowling adapted information theoretic criteria for use with SA4 [9] and an asymptotic proof of consistency is given in [11]. Stewart proposed the URV update as a rank revealing method [39]. Bin Yang proposed that the eigenvalue estimates from PASTd be used for information theoretic-based rank estimation [43].

66.4 Summary of Subspace Tracking Methods Developed Since 1990

66.4.1 Modified Eigen Problems

An $O(n^2r)$ fast subspace decomposition (FSD) method based on the Lanczos algorithm and a strongly consistent source detection scheme was introduced by Xu and Kailath [42].

A transposed QR (TQR) iteration-based SVD update was introduced in [12]. To reduce computation to $O(nr^2)$, the noise subspace is sphericalized and deflated. Based on various performance tests, one or two TQR iterations per update yield results that are comparable to the fully converged SVD. Moreover, because the diagonalization process is taking place on a triangular factor, the partially converged, deflated TQR-SVD update is very similar to a deflated URV update [34].

DeGroat and Roberts [10] simplified Bunch's rank one eigen update [4] and proposed a partial orthogonalization scheme, called pair-wise Gram Schmidt (PGS), to stabilize the eigenvectors. Together with exponential fading to stabilize the eigenvalues, the buildup of roundoff error is essentially controlled and machine precision orthogonality is maintained. For a more complete discussion,

see Section 66.3.2 *Controlling Roundoff and Orthogonality Error*. Recently, Gu and Eisenstat [20] presented an improved version of Bunch's rank one EVD update. The new algorithm contains a more stable way to compute the eigenvectors. DeGroat and Dowling have also developed a family of sphericalized EVD and SVD updates (see Section 66.3.6 *Spherical Subspace Updating*).

66.4.2 Gradient-Based Eigen Tracking

Jar-Ferr Yang and Hui-Ju Lin [45] proposed a generalized inflation method which extends the gradient-based work of Yang and Kaveh [44]. An $O(nr^2)$ noise sphericalized and deflated conjugate gradient-based eigen tracking method is presented by Fu and Dowling in [18]. This method can be described as an SS update with a conjugate gradient-based eigen tracker at the core.

Bin Yang [43] introduced a projection approximation approach that uses RLS techniques to update the signal subspace. The projection approximation subspace tracker (PAST) algorithm computes an arbitrary basis for the signal subspace in $3nr + O(r^2)$ flops per update. The PASTd algorithm (which uses deflation to track the individual eigenvalues and vectors of the signal subspace) requires $4nr + O(n)$ flops per update. Both methods produce eigenvector estimates that are only approximately orthogonal.

Regalia and Loubaton [36] use an adaptive lossless transfer matrix (multivariable lattice filter) excited by sensor output to achieve a condition of maximum “power splitting” between two groups of output bins. The update equations resemble standard gradient descent algorithms, but they do not properly follow the gradient of the error surface. Nonetheless, the convergence speed may be a strong function of the source spectral and spatial characteristics.

Recently, Marcos and Benidir [26] introduced an adaptive subspace-based method that relies on a linear operator, referred to as the Propagator, which exploits the linear independency of the source steering vectors, and which allows the determination of the signal and noise subspaces without any eigendecomposition of the correlation matrix. Two gradient-based adaptive algorithms are proposed for the estimation of the Propagator, and then the basis of the signal subspace. The overall computational complexity of the adaptive Propagator subspace update is $O(nr^2)$.

A family of three perturbation-based EVD tracking methods (denoted PA, PB, and PC) are presented by Champagne [5]. Each method uses perturbation-based approximations to track the eigencomponents. Progressively more simplifications are used to reduce the complexity from $\frac{1}{2}n^3 + O(n^2)$ for PA to $\frac{1}{2}nr^2 + O(nr)$ for PB to $5nr + O(n)$ for PC. Both the PB and PC methods use a sphericalized noise subspace to reduce computation. Thus, PB and PC can be viewed as SS updates that use perturbation-based approximations to track the deflated core eigenproblem. The PC method achieves greater computational simplifications by assuming well-separated eigenvalues. Some special decompositions are also used to reduce the computation of the PC algorithm. Surprisingly, simulations seem to indicate that the PC method achieves good overall performance even when the eigenvalues are not well separated. Convergence rates are also very good for the PC method. However, we have noticed that occasionally spurious frequency estimates may be obtained with PC-based MUSIC. Ironically, the PC estimated subspaces tend to be closer to the true subspaces than other subspace tracking methods that do not exhibit occasionally spurious frequency estimates. Because PC only tracks approximations of the eigencomponents, the orthogonality error is typically much greater than machine precision orthogonality. Nevertheless, partial orthogonality schemes can be used to improve orthogonality and other measures of performance (see Section 66.3.2 *Controlling Roundoff Error Accumulation and Orthogonality Errors*).

Artificial neural networks (ANN) have been developed to find eigen information, e.g., see [27] and [35] as well as the references contained therein. An ANN consists of many richly interconnected simple and similar processing elements (called artificial neurons) operating in parallel. High computational rates (due to massive parallelism) and robustness (due to local neural connectivity) are

two important features of ANNs. Most of the eigenvector estimating ANNs appear under the topic of principal component analysis (PCA). The principal eigenvectors are defined as the eigenvectors associated with the larger eigenvalues.

66.4.3 The URV and Rank Revealing QR (RRQR) Updates

The URV update [39] is based on the URV decomposition (URVD) developed by G.W. Stewart as a two sided generalization of the RRQR methods. The URVD can also be viewed as a generalization of the SVD because U and V are orthogonal matrices and R is an upper triangular matrix. Clearly, the SVD is a special case of the URVD. If $X = URV^H$ is the URVD of X , then the R factor can be rank revealing in the sense that the Euclidean norm of the $n - r$ rightmost columns of R is approximately equal to the Euclidean norm of the $n - r$ smallest singular values of X . Also, the smallest singular value of the first r columns of R is approximately equal to the r th singular value of X . These two conditions effectively partition the corresponding columns of U and V into an r -dimensional dominant subspace and an $(n - r)$ -dimensional subdominant subspace that can be used as estimates for the signal and noise subspace spans. The URV update is $O(n^2)$ per update. An RRQR update [that is usually $O(n^2)$ per update] is developed by Bischof and Schroff in [1]. RRQR methods that use the traditional pivoting strategy to maintain a rank revealing structure involve $O(n^3)$ flops per update. An analysis of problems associated with RRQR methods along with a fairly extensive reference list on RRQR methods can be found in [6]. An $O(nr)$ deflated URV update is presented by Rabideau and Steinhardt in [34] (and the references contained therein).

66.4.4 Miscellaneous Methods

Strobach [40] recently introduced a family of low rank or eigensubspace adaptive filters based on orthogonal iteration. The computational complexity ranges from $O(nr^2)$ to $O(nr)$.

A family of Subspace methods Without EigenDEcomposition (SWEDE) has been proposed by Eriksson et al. [16]. With SWEDE, portions of the correlation matrix must be updated for each new snapshot vector at a cost of approximately $12nr$ flops. However, the subspace basis (which is computed from the correlation matrix partitions) need only be computed every time a DOA estimate is needed. Computing the subspace estimate is $O(nr^2)$, so if the subspace is computed every k th update, the overall complexity is $O(nr^2/k) + 12nr$ per update. At high SNR, SWEDE performs almost as well as eigen-based MUSIC.

Key References:

As previously mentioned, Comon and Golub did a nice survey of SVD tracking methods in 1990 [7]. In 1995, Reddy et al. published a selected overview of eigensubspace estimation methods, including ANN approaches [35]. For a study of URV and RRQR methods, see [6]. Partial orthogonalization schemes are studied in [28]. Finally, a special issue of Signal Processing [41] is planned for April 1996 featuring *Subspace Methods for Detection and Estimation*.

TABLE 66.1 Efficient Subspace Tracking Methods Developed Since 1990

Complexity	Subspace or eigen tracking method	Orthog. span
$O(n^2 r)$	Fast subspace decomposition (FSD) [42]	Yes ^a
$O(n^2)$	URV update [39]	Yes
	Rank revealing QR [possibly $O(n^3)$] [1]	Yes
	Approximate SVD updates [17, 30]	Yes ^a
	Neural Network Based Updates [35]	No ^a
$O(nr^2)$	Stabilized signal eigenstructure (SE) update ^b [8, 10]	Yes ^a
	Sphericalized transposed QR SVD update ^b [12]	Yes ^a
	Sphericalized conjugate gradient SVD update ^b [18]	Yes ^a
	SWEDE [16]	No
	Gradient-based EVD updates with gram schmidt orthog. [44, 45]	Yes ^a
$O(nr)$	Signal averaged 2-level (SA2) update ^b [8]	Yes
	Signal averaged 4-level (SA4) update ^b [9, 11]	Yes ^a
	Projection approximation subspace tracking (PAST) [43]	No
	PAST with deflation (PASTd) [43]	No ^a
	Sphericalized perturbation based eigen update (PC method) ^b [5]	Yes ^a
	Sphericalized URV update ^b [34]	Yes

Key: n = no. of sensors, r = rank of subspace.

^a Tracks individual eigencomponents.

^b Uses sphericalized subspaces.

Georgia Institute of Technology

The processing of signals received by sensor arrays generally can be separated into two problems: (1) detecting the number of sources and (2) isolating and analyzing the signal produced by each source. We make this distinction because many of the algorithms for separating and processing array signals make the assumption that the number of sources is known *a priori* and may give misleading results if the wrong number of sources is used [3]. A good example are the errors produced by many high resolution bearing estimation algorithms (e.g., MUSIC) when the wrong number of sources is assumed. Because, in general, it is easier to determine how many signals are present than to estimate the bearings of those signals, signal detection algorithms typically can correctly determine the number of signals present even when bearing estimation algorithms cannot resolve them. In fact, the capability of an array to resolve two closely spaced sources could be said to be limited by its ability to detect that there are actually two sources present. If we have a reliable method of determining the number of sources, not only can we correctly use high resolution bearing estimation algorithms, but we can also use this knowledge to utilize more effectively the information obtained from the bearing estimation algorithms. If the bearing estimation algorithm gives fewer source directions than we know there are sources, then we know that there is more than one source in at least one of those directions and have thus essentially increased the resolution of the algorithm. If analysis of the information provided by the bearing estimation algorithm indicates more source directions than we know there are sources, then we can safely assume that some of the directions are the results of false alarms and may be ignored, thus decreasing the probability of false alarm for the bearing estimation algorithms. In this section we will present and discuss the more common approaches to determining the number of sources.

67.1 Formulation of the Problem

The basic problem is that of determining how many signal producing sources are being observed by an array of sensors. Although this problem addresses issues in several areas including sonar, radar,

communications, and geophysics, one basic formulation can be applied to all these applications. We will give only a basic, brief description of the assumed signal structure, but more detail can be found in references such as the book by Johnson and Dudgeon [3]. We will assume that an array of M sensors observes signals produced by N_s sources. The array is allowed to have an arbitrary geometry. For our discussion here, we will assume that the sensors are omnidirectional. However, this assumption is only for notational convenience as the algorithms to be discussed will work for more general sensor responses.

The output of the m th sensor can be expressed as a linear combination of signals and noise

$$y_m(t) = \sum_{i=1}^{N_s} s_i(t - \Delta_i(m)) + n_m(t) .$$

The noise observed at the m th sensor is denoted by $n_m(t)$. The propagation delays, $\Delta_i(m)$, are measured with respect to an origin chosen to be at the geometric center of the array. Thus, $s_i(t)$ indicates the i th propagating signal observed at the origin, and $s_i(t - \Delta_i(m))$ is the same signal measured by the m th sensor. For a plane wave in a homogeneous medium, these delays can be found from the dot product between a unit vector in the signal's direction of propagation, $\vec{\zeta}_i^o$, and the sensor's location, \vec{x}_m ,

$$\Delta_i(m) = \frac{\vec{\zeta}_i^o \cdot \vec{x}_m}{c} ,$$

where c is the plane wave's speed of propagation.

Most algorithms used to detect the number of sources incident on the array are frequency domain techniques that assume the propagating signals are narrowband about a common center frequency, ω^o . Consequently, after Fourier transforming the measured signals, only one frequency is of interest and the propagation delays become phase shifts

$$Y_m(\omega^o) = \sum_{i=1}^{N_s} S_i(\omega^o) e^{-j\omega^o \Delta_i(m)} + N_m(\omega^o) .$$

The detection algorithms then exploit the form of the spatial correlation matrix, \mathbf{R} , for the array. The spatial correlation matrix is the $M \times M$ matrix formed by correlating the vector of the Fourier transforms of the sensor outputs at the particular frequency of interest

$$\mathbf{Y} = [Y_0(\omega^o) \ Y_1(\omega^o) \ \cdots \ Y_{M-1}(\omega^o)]^T .$$

If the sources are assumed to be uncorrelated with the noise, then the form of \mathbf{R} is

$$\mathbf{R} = E \{ \mathbf{Y} \mathbf{Y}' \} = \mathbf{K}_n + \mathbf{S} \mathbf{C} \mathbf{S}' ,$$

where \mathbf{K}_n is the correlation matrix of the noise, \mathbf{S} is the matrix whose columns correspond to the vector representations of the signals, \mathbf{S}' is the conjugate transpose of \mathbf{S} , and \mathbf{C} is the matrix of the correlations between the signals. Thus, the matrix \mathbf{S} has the form

$$\mathbf{S} = \begin{bmatrix} e^{-j\omega^o \Delta_1(0)} & \cdots & e^{-j\omega^o \Delta_{N_s}(0)} \\ \vdots & & \vdots \\ e^{-j\omega^o \Delta_1(M-1)} & \cdots & e^{-j\omega^o \Delta_{N_s}(M-1)} \end{bmatrix} .$$

If we assume that the noise is additive, white Gaussian noise with power σ_n^2 and that none of the signals are perfectly coherent with any of the other signals, then $\mathbf{K}_n = \sigma_n^2 \mathbf{I}_M$, \mathbf{C} has full rank, and the form of \mathbf{R} is

$$\mathbf{R} = \sigma_n^2 \mathbf{I}_M + \mathbf{S} \mathbf{C} \mathbf{S}' . \quad (67.1)$$

We will assume that the columns of \mathbf{S} are linearly independent when there are fewer sources than sensors, which is the case for most common array geometries and expected source locations. As \mathbf{C} is of full rank, if there are fewer sources than sensors, then the rank of \mathbf{SCS}' is equal to the number of signals incident on the array or, equivalently, the number of sources. If there are N_s sources, then \mathbf{SCS}' is of rank N_s and its N_s eigenvalues in descending order are $\delta_1, \delta_2, \dots, \delta_{N_s}$. The M eigenvalues of $\sigma_n^2 \mathbf{I}_M$ are all equal to σ_n^2 , and the eigenvectors are any orthonormal set of length M vectors. So the eigenvectors of \mathbf{R} are the N_s eigenvectors of \mathbf{SCS}' plus any $M - N_s$ eigenvectors which complete the orthonormal set, and the eigenvalues in descending order are $\sigma_n^2 + \delta_1, \dots, \sigma_n^2 + \delta_{N_s}, \sigma_n^2, \dots, \sigma_n^2$. The correlation matrix is generally divided into two parts: the signal-plus-noise subspace formed by the largest eigenvalues ($\sigma_n^2 + \delta_1, \dots, \sigma_n^2 + \delta_{N_s}$) and their eigenvectors, and the noise subspace formed by the smallest, equal eigenvalues and their eigenvectors. The reason for these labels is obvious as the space spanned by the signal-plus-noise subspace eigenvectors contains the signals and a portion of the noise while the noise subspace contains only that part of the noise that is orthogonal to the signals [3]. If there are fewer sources than sensors, the smallest $M - N_s$ eigenvalues of \mathbf{R} are all equal and to determine exactly how many sources there are, we must simply determine how many of the smallest eigenvalues are equal. If there are not fewer sources than sensors ($N_s \geq M$), then none of the smallest eigenvalues are equal. The detection algorithms then assume that only the smallest eigenvalue is in the noise subspace as it is not equal to any of the other eigenvalues. Thus, these algorithms can detect up to $M - 1$ sources and for $N_s \geq M$ will say that there are $M - 1$ sources as this is the greatest detectable number. Unfortunately, all that is usually known is $\hat{\mathbf{R}}$, the sample correlation matrix, which is formed by averaging N samples of the correlation matrix taken from the outputs of the array sensors. As $\hat{\mathbf{R}}$ is formed from only a finite number of samples of \mathbf{R} , the smallest $M - N_s$ eigenvalues of $\hat{\mathbf{R}}$ are subject to statistical variations and are unequal with probability one [4]. Thus, solutions to the detection problem have concentrated on statistical tests to determine how many of the eigenvalues of \mathbf{R} are equal when only the sample eigenvalues of $\hat{\mathbf{R}}$ are available.

When performing statistical tests on the eigenvalues of the sample correlation matrix to determine the number of sources, certain assumptions must be made about the nature of the signals. In array processing, both deterministic and stochastic signal models are used depending on the application. However, for the purpose of testing the sample eigenvalues, the Fourier transforms of the signals at frequency ω^o ; $S_i(\omega^o)$, $i = 1, \dots, N_s$; are assumed to be zero mean Gaussian random processes that are statistically independent of the noise and have a positive definite correlation matrix \mathbf{C} . We also assume that the N samples taken when forming $\hat{\mathbf{R}}$ are statistically independent of each other. With these assumptions, the spatial correlation matrix is still of the same form as in (67.1), except that now we can more easily derive statistical tests on the eigenvalues of $\hat{\mathbf{R}}$.

67.2 Information Theoretic Approaches

We will see that the source detection methods to be described all share common characteristics. However, we will classify them into two groups—information theoretic and decision theoretic approaches—determined by the statistical theories used to derive them. Although the decision theoretic techniques are quite a bit older, we will first present the information theoretic algorithms as they are currently much more commonly used.

67.2.1 AIC and MDL

AIC and MDL are both information theoretic model order determination techniques that can be used to test the eigenvalues of a sample correlation matrix to determine how many of the smallest eigenvalues of the correlation matrix are equal. The AIC and MDL algorithms both consist of minimizing a criterion over the number of signals that are detectable, i.e., $N_s = 0, \dots, M - 1$.

To construct these criteria, a family of probability densities, $f(\mathbf{Y}|\theta(N_s))$, $N_s = 0, \dots, M - 1$, is needed, where θ , which is a function of the number of sources, N_s , is the vector of parameters needed for the model that generated the data \mathbf{Y} . The criteria are composed of the negative of the log-likelihood function of the density $f(\mathbf{Y}|\hat{\theta}(N_s))$, where $\hat{\theta}(N_s)$ is the maximum likelihood estimate of θ for N_s signals, plus an adjusting term for the model dimension. The adjusting term is needed because the negative log-likelihood function always achieves a minimum for the highest dimension model possible, which in this case is the largest possible number of sources. Therefore, the adjusting term will be a monotonically increasing function of N_s and should be chosen so that the algorithm is able to determine the correct model order.

AIC was introduced by Akaike [1]. Originally, the “IC” stood for information criterion and the “A” designated it as the first such test, but it is now more commonly considered an acronym for the “Akaike Information Criterion.” If we have N independent observations of a random variable with probability density $g(\mathbf{Y})$ and a family of models in the form of probability densities $f(\mathbf{Y}|\theta)$ where θ is the vector of parameters for the models, then Akaike chose his criterion to minimize

$$I(g; f(\cdot|\theta)) = \int g(\mathbf{Y}) \ln g(\mathbf{Y}) d\mathbf{Y} - \int g(\mathbf{Y}) \ln f(\mathbf{Y}|\theta) d\mathbf{Y} \quad (67.2)$$

which is known as the Kullback-Leibler mean information distance. $\frac{1}{N} AIC(\theta)$ is an estimate of $-E\{\int g(\mathbf{Y}) \ln f(\mathbf{Y}|\theta) d\mathbf{Y}\}$ and minimizing $AIC(\theta)$ over the allowable values of θ should minimize (67.2). The expression for $AIC(\theta)$ is

$$AIC(\theta) = -2 \ln \left[f(\mathbf{Y}|\hat{\theta}(N_s)) \right] + 2\eta,$$

where η is the number of independent parameters in θ .

Following AIC, MDL was developed by Schwarz [6] using Bayesian techniques. He assumed that the *a priori* density of the observations comes from a suitable family of densities that possess efficient estimates [7]; they are of the form

$$f(\mathbf{Y}|\theta) = \exp(\theta \cdot p(\mathbf{Y}) - b(\theta)).$$

The MDL criterion was then found by choosing the model that is most probable *a posteriori*. This choice is equivalent to selecting the model for which

$$MDL(\theta) = -\ln \left[f(\mathbf{Y}|\hat{\theta}(N_s)) \right] + \frac{1}{2} \eta \ln N$$

is minimized. This criterion was independently derived by Rissanen [5] using information theoretic techniques. Rissanen noted that each model can be perceived as encoding the observed data and that the optimum model is the one that yields the minimum code length. Hence, the name MDL comes from “Minimum Description Length”.

For the purpose of using AIC and MDL to determine the number of sources, the forms of the log-likelihood function and the adjusting terms have been given by Wax [8]. For N_s signals the parameters that completely parameterize the correlation matrix \mathbf{R} are $\{\sigma_n^2, \lambda_1, \dots, \lambda_{N_s}, \mathbf{v}_1, \dots, \mathbf{v}_{N_s}\}$ where λ_i and \mathbf{v}_i , $i = 1, \dots, N_s$, are the eigenvalues and their respective eigenvectors of the signal-plus-noise subspace of the correlation matrix. As the vector of sensor outputs is a Gaussian random vector with correlation matrix \mathbf{R} and all the samples of the sensor outputs are independent, the log-likelihood function of $f(\mathbf{Y}|\theta)$ is

$$\ln f(\mathbf{Y}|\sigma_n^2, \lambda_1, \dots, \lambda_{N_s}, \mathbf{v}_1, \dots, \mathbf{v}_{N_s}) = \pi^{-pN} (\det \mathbf{R})^{-N} \exp \left(-N \text{tr} (\mathbf{R}^{-1} \hat{\mathbf{R}}) \right)$$

where $\text{tr}(\cdot)$ denotes the trace of the matrix, $\hat{\mathbf{R}}$ is the sample correlation matrix, and \mathbf{R} is the unique correlation matrix formed from the given parameters. The maximum likelihood estimate of the parameters are [2, 4]

$$\begin{aligned}\hat{\mathbf{v}}_i &= \mathbf{u}_i; i = 1, \dots, N_s \\ \hat{\lambda}_i &= l_i; i = 1, \dots, N_s \\ \hat{\sigma}_n^2 &= \frac{1}{M - N_s} \sum_{i=N_s+1}^M l_i = \bar{l},\end{aligned}\tag{67.3}$$

where l_1, \dots, l_M are the eigenvalues in descending order of $\hat{\mathbf{R}}$ and \mathbf{u}_i are the corresponding eigenvectors. Therefore, the log-likelihood function of $f(\mathbf{Y}|\hat{\theta}(N_s))$ is

$$\ln f(\mathbf{Y}|\bar{l}, l_1, \dots, l_{N_s}, \mathbf{u}_1, \dots, \mathbf{u}_{N_s}) = \ln \left[\frac{\prod_{i=N_s+1}^M l_i^{1/(M-N_s)}}{\frac{1}{M - N_s} \sum_{i=N_s+1}^M l_i} \right]^{(M-N_s)N}.$$

Remembering that the eigenvalues of a complex correlation matrix are real and that the eigenvectors are complex and orthonormal, the number of degrees of freedom in the parameters of the model is classically chosen to be $\eta = N_s(2M - N_s) + 1$. Noting that any constant term in the criteria which is common to the entire family of models for either AIC or MDL may be ignored, we have the criterion for AIC as

$$AIC(\hat{N}_s) = -2N \ln \left[\frac{\prod_{i=\hat{N}_s+1}^M l_i}{\left[\frac{1}{M - \hat{N}_s} \sum_{i=\hat{N}_s+1}^M l_i \right]^{M-\hat{N}_s}} \right] + 2\hat{N}_s(2M - \hat{N}_s); \hat{N}_s = 0, \dots, M-1$$

and the criterion for MDL as

$$MDL(\hat{N}_s) = -N \ln \left[\frac{\prod_{i=\hat{N}_s+1}^M l_i}{\left[\frac{1}{M - \hat{N}_s} \sum_{i=\hat{N}_s+1}^M l_i \right]^{M-\hat{N}_s}} \right] + \frac{1}{2}\hat{N}_s(2M - \hat{N}_s) \ln N; \hat{N}_s = 0, \dots, M-1.$$

For both of these methods, the estimate of the number of sources is that value of \hat{N}_s which minimizes the criterion. In [9] there is a more thorough discussion concerning determining the number of degrees of freedom and the advantages of choosing instead $\eta = N_s(2M - N_s - 1)$.

In general, MDL is considered to perform better than AIC. Schwarz [6], through his derivation of the MDL criterion, showed that if his assumptions are accepted, then AIC cannot be asymptotically optimal. He also mentioned that MDL tends toward lower-dimensional models than AIC as the model dimension term is multiplied by $\frac{1}{2} \ln N$ in the MDL criterion. Zhao et al. [14] showed that

MDL is consistent (the probability of detecting the correct number of sources, i.e., $\Pr(\hat{N}_s = N_s)$, goes to 1 as N goes to infinity), but AIC is not consistent and will tend to overestimate the number of sources as N goes to infinity. Thus, most people in array processing prefer to use MDL over AIC. Interestingly, many statisticians prefer AIC because many of their modeling problems have a very large penalty for underestimating the model order but a relatively mild penalty for overestimating it. Xu and Kaveh [12] have provided a thorough discussion of the asymptotic properties of AIC and MDL, including an examination of their sensitivities to modelling errors and bounds on the probability that AIC will overestimate the number of sources.

67.2.2 EDC

Clearly, the only difference between the implementations of AIC and MDL is the choice of the adjusting term that penalizes for choosing larger model orders. Several people have examined using other adjusting terms to arrive at other criteria. In particular, statisticians at the University of Pittsburgh [13, 14] have developed the Efficient Detection Criterion (EDC) procedure which is actually a family of criteria chosen such that they are all consistent. The general form of these criteria is

$$EDC(\theta) = -\ln \left[f \left(\mathbf{Y} | \hat{\theta}(N_s) \right) \right] + \eta C_N,$$

where C_N can be any function of N such that

- (1) $\lim_{N \rightarrow \infty} C_N/N = 0$
- (2) $\lim_{N \rightarrow \infty} C_N/\ln(\ln(N)) = \infty.$

Thus, for the array processing source detection problem the EDC procedure chooses the value of \hat{N}_s that minimizes

$$EDC(\hat{N}_s) = -N \ln \left[\frac{\prod_{i=\hat{N}_s+1}^M l_i}{\left[\frac{1}{M - \hat{N}_s} \sum_{i=\hat{N}_s+1}^M l_i \right]^{M - \hat{N}_s}} \right] + \hat{N}_s(2M - \hat{N}_s)C_N; \quad \hat{N}_s = 0, \dots, M-1.$$

In their analysis of the EDC procedure, Zhao et al. [14] showed that not only are all the EDC criteria consistent for the data assumptions we have made, but under certain conditions they remain consistent even when the data sample vectors used to form the estimate $\hat{\mathbf{R}}$ are not independent or Gaussian.

The choice of $C_N = \frac{1}{2} \ln(N)$ satisfies the restrictions on C_N and, thus, produces one of the EDC procedures. This particular criterion is identical to MDL and shows that the MDL criterion is included as one of the EDC procedures. Another relatively common choice for C_N is $C_N = \sqrt{N \ln(N)}$.

67.3 Decision Theoretic Approaches

The methods that we term decision theoretic approaches all rely on the statistical theory of hypothesis testing to determine the number of sources. The first of these that we will discuss, the sphericity test, is by far the oldest algorithm for source detection.

67.3.1 The Sphericity Test

Originally, the sphericity test was a hypothesis testing method designed to determine if the correlation (or covariance) matrix, \mathbf{R} , of a length M Gaussian random vector is proportional to the identity matrix, \mathbf{I}_M , when only $\hat{\mathbf{R}}$, the sample correlation matrix, is known. If $\mathbf{R} \propto \mathbf{I}_M$, then the contours of equal density for the Gaussian distribution form concentric spheres in M -dimensional space. The sphericity test derives its name from being a test of the sphericity of these contours.

The original sphericity test had two possible hypotheses

$$\begin{aligned} H_0 : \quad \mathbf{R} &= \sigma_n^2 \mathbf{I}_M \\ H_1 : \quad \mathbf{R} &\neq \sigma_n^2 \mathbf{I}_M \end{aligned}$$

for some unknown σ_n^2 . If we denote the eigenvalues of \mathbf{R} in descending order by $\lambda_1, \lambda_2, \dots, \lambda_M$, then equivalent hypotheses are

$$\begin{aligned} H_0 : \quad \lambda_1 &= \lambda_2 = \dots = \lambda_M \\ H_1 : \quad \lambda_1 &> \lambda_M . \end{aligned}$$

For the appropriate statistic, $T(\hat{\mathbf{R}})$, the test is of the form

$$\begin{array}{c} H_1 \\ T(\hat{\mathbf{R}}) \geq \gamma \\ H_0 \end{array}$$

where the threshold, γ , can be set according to the Neyman-Pearson criterion [7]. That is, if the distribution of $T(\hat{\mathbf{R}})$ is known under the null hypothesis, H_0 , then for a given probability of false alarm, P_F , we can choose γ such that

$$\Pr(T(\hat{\mathbf{R}}) > \gamma | H_0) = P_F.$$

Using the alternate form of the hypotheses, $T(\hat{\mathbf{R}})$ is actually $T(l_1, l_2, \dots, l_M)$, and the eigenvalues of the sample correlation matrix are a sufficient statistic for the hypothesis test. The correct form of the sphericity test statistic is the generalized likelihood ratio [4]

$$T(l_1, l_2, \dots, l_M) = \ln \left[\frac{\left(\frac{1}{M} \sum_{i=1}^M l_i \right)^M}{\prod_{i=1}^M l_i} \right]$$

which was also a major component of the information theoretic tests.

For the source detection problem we are interested in testing a subset of the smaller eigenvalues for equality. In order to use the sphericity test, the hypotheses are generally broken down into pairs of hypotheses that can be tested in a series of hypothesis tests. For testing $M - \hat{N}_s$ eigenvalues for equality, the hypotheses are

$$\begin{aligned} H_0 : \quad \lambda_1 &\geq \dots \geq \lambda_{\hat{N}_s} \geq \lambda_{\hat{N}_s+1} = \dots = \lambda_M \\ H_1 : \quad \lambda_1 &\geq \dots \geq \lambda_{\hat{N}_s} \geq \lambda_{\hat{N}_s+1} > \lambda_M . \end{aligned}$$

We are interested in finding the smallest value of \hat{N}_s for which H_0 is true, which is done by testing $\hat{N}_s = 0, \hat{N}_s = 1, \dots$ until $\hat{N}_s = M - 2$ or the test does not fail. If the test fails for $\hat{N}_s = M - 2$,

then we consider none of the smallest eigenvalues to be equal and say that there are $M - 1$ sources. If \widehat{N}_s is the smallest value for which H_0 is true, then we say that there are \widehat{N}_s sources. There is also a problem involved in setting the desired P_F . The Neyman-Pearson criterion is not able to determine a threshold for given P_F for the overall detection problem. The best that can be done is to set a P_F for each individual test in the nested series of hypothesis tests using Neyman-Pearson methods. Unfortunately, as the hypothesis tests are obviously not statistically independent and their statistical relationship is not very clear, how this P_F for each test relates to the P_F for the entire series of tests is not known.

To use the sphericity test to detect sources, we need to be able to set accurately the threshold γ according to the desired P_F , which requires knowledge of the distribution of the sphericity test statistic $T(l_{\widehat{N}_s+1}, \dots, l_M)$ under the null hypothesis. The *exact* form of this distribution is not available in a form that is very useful as it is generally written as an infinite series of Gaussian, chi-squared, or beta distributions [2, 4]. However, if the test statistic is multiplied by a suitable function of the eigenvalues of $\widehat{\mathbf{R}}$, then its distribution can be accurately approximated as being chi-squared [10]. Thus, the statistic

$$2 \left((N - 1) - \widehat{N}_s - \frac{2(M - \widehat{N}_s)^2 + 1}{6(M - \widehat{N}_s)} + \sum_{i=1}^{\widehat{N}_s} \left(\frac{l_i}{\bar{l}} - 1 \right)^{-2} \right) \ln \left[\frac{\left(\frac{1}{M - \widehat{N}_s} \sum_{i=\widehat{N}_s+1}^M l_i \right)^{M - \widehat{N}_s}}{\prod_{i=\widehat{N}_s+1}^M l_i} \right]$$

is approximately chi-squared distributed with degrees of freedom given by

$$d = (M - \widehat{N}_s)^2 - 1,$$

where $\bar{l} = \frac{1}{M - \widehat{N}_s} \sum_{i=\widehat{N}_s+1}^M l_i$.

Although the performance of the sphericity test is comparable to that of the information theoretic tests, it is not as popular because it requires selection of the P_F and calculation of the test thresholds for each value of \widehat{N}_s . However, if the received data does not match the assumed model, the ability to change the test thresholds gives the sphericity test a robustness lacking in the information theoretic methods.

67.3.2 Multiple Hypothesis Testing

The sphericity test relies on a sequence of binary hypothesis tests to determine the number of sources. However, the optimum test for this situation would be to test all hypotheses simultaneously:

$$\begin{aligned} H_0 : & \quad \lambda_1 = \lambda_2 = \dots = \lambda_M \\ H_1 : & \quad \lambda_1 > \lambda_2 = \dots = \lambda_M \\ H_2 : & \quad \lambda_1 \geq \lambda_2 > \lambda_3 = \dots = \lambda_M \\ & \quad \vdots \\ H_{M-1} : & \quad \lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{M-1} > \lambda_M \end{aligned}$$

to determine how many of the smaller eigenvalues are equal. While it is not possible to generalize the sphericity test directly, it is possible to use an approximation to the probability density function (*pdf*) of the eigenvalues to arrive at a suitable test. Using the theory of multiple hypothesis tests, we

can derive a test that is similar to AIC and MDL and is implemented in *exactly* the same manner, but is designed to minimize the probability of choosing the wrong number of sources.

To arrive at our statistic, we start with the joint probability density function (*pdf*) of the eigenvalues of the $M \times M$ sample covariance when the $M - \hat{N}_s$ smallest eigenvalues are known to be equal. We will denote this pdf by $f_{\hat{N}_s}(l_1, \dots, l_M | \lambda_1 \geq \dots \geq \lambda_{\hat{N}_s+1} = \dots = \lambda_M)$ where the l_i denote the eigenvalues of the sample matrix and the λ_i are the eigenvalues of the true covariance matrix. The asymptotic expression for $f_{\hat{N}_s}(\cdot)$ is given by Wong et al. [11] for the complex-valued data case as

$$f_{\hat{N}_s}(l_1, \dots, l_M | \lambda_1 \geq \dots \geq \lambda_{\hat{N}_s+1} = \dots = \lambda_M) \approx \frac{n^{mn - \frac{\hat{N}_s}{2}(2M - \hat{N}_s - 1)} \pi^{M(M-1) - \frac{\hat{N}_s}{2}(2M - \hat{N}_s - 1)}}{\tilde{\Gamma}_M(n) \tilde{\Gamma}_{M-\hat{N}_s}(M - \hat{N}_s)} \\ \prod_{i=1}^M \lambda_i^{-n} \prod_{i=1}^M l_i^{n-M} \exp \left\{ -n \sum_{i=1}^M \frac{l_i}{\lambda_i} \right\} \prod_{i=\hat{N}_s+1}^M \prod_{i < j}^M (l_i - l_j)^2 \\ \prod_{i=1}^{\hat{N}_s} \prod_{i < j}^{\hat{N}_s} \left(\frac{(l_i - l_j) \lambda_i \lambda_j}{\lambda_i - \lambda_j} \right) \prod_{i=1}^{\hat{N}_s} \prod_{j=\hat{N}_s+1}^M \left(\frac{(l_i - l_j) \lambda_i \lambda_j}{\lambda_i - \lambda_j} \right)$$

where $n = N - 1$ is one less than the number of samples and $\tilde{\Gamma}_N(\cdot)$ is the multivariate gamma function for complex-valued data [11]. We then form M likelihood ratios by dividing each joint pdf by $f_{M-1}(\cdot)$ to form

$$\Lambda(\hat{N}_s) = \frac{f_{\hat{N}_s}(l_1, \dots, l_M | \lambda_1 \geq \dots \geq \lambda_{\hat{N}_s+1} = \dots = \lambda_M)}{f_{M-1}(l_1, \dots, l_M | \lambda_1 \geq \dots \geq \lambda_M)}, \quad \hat{N}_s = 0, \dots, M-1.$$

Assuming that each value of \hat{N}_s is equally likely, then multiple hypothesis testing theory tells us that the value of \hat{N}_s that *maximizes* $\Lambda(\hat{N}_s)$ is the optimum choice in that it minimizes the probability of choosing the incorrect \hat{N}_s [7]. Because $\Lambda(\hat{N}_s)$ in this form requires knowledge of the unknown parameters λ_i , we must use a generalized likelihood ratio test and independently substitute the maximum likelihood estimates of the λ_i [see Eq.(67.3) for these expressions] into both $f_{\hat{N}_s}(\cdot)$, for which we assume $M - \hat{N}_s$ equal λ_i s, and $f_{M-1}(\cdot)$, for which we assume no equal λ_i s, to get our new statistics $\Lambda(\hat{N}_s)$. After much simplification including dropping terms that are common to $\Lambda(\hat{N}_s)$ for every allowable value of \hat{N}_s and then taking the natural logarithm of each $\Lambda(\hat{N}_s)$, we get the statistic

$$\Lambda(\hat{N}_s) = (n - \hat{N}_s) \ln \left[\frac{\prod_{i=\hat{N}_s+1}^M l_i}{\left(\frac{1}{M - \hat{N}_s} \sum_{i=\hat{N}_s+1}^M l_i \right)^{M - \hat{N}_s}} \right] - \frac{1}{2} \hat{N}_s (2M - \hat{N}_s - 1) \ln[n] + \\ \ln \left[\frac{\pi^{-\hat{N}_s(2M - \hat{N}_s - 1)/2}}{\tilde{\Gamma}_{M-\hat{N}_s}(M - \hat{N}_s)} \right] + \sum_{i=1}^{\hat{N}_s} \sum_{j=\hat{N}_s+1}^M \ln \left[\frac{l_i - l_j}{l_i - \bar{l}} \right] - \sum_{i=\hat{N}_s+1}^M \sum_{j=i+1}^M 2 \ln \left[\frac{(l_i l_j)^{1/2}}{l_i - l_j} \right]$$

where $\bar{l} = \frac{1}{M - \hat{N}_s} \sum_{i=\hat{N}_s+1}^M l_i$.

The terms in the first line of this equation are almost identical to the negative of the MDL criterion, especially when the degrees of freedom recommended in [9] are used. Note that the change in sign is necessary because we are finding the maximum of this criterion, not the minimum. The extra terms on the following line include both the eigenvalues being tested for equality and those not being tested. These extra terms allow this test to outperform the information theoretic techniques, since the use of all the eigenvalues for each value of \hat{N}_s being tested allows this criterion to be more adaptive.

67.4 For More Information

Most of the original papers on model order determination appeared in the statistical literature in journals such as *The Annals of Statistics* and the *Journal of Multivariate Analysis*. However, almost all of the more recent developments that apply these techniques to the source detection problem have appeared in signal processing journals such as the *IEEE Transactions on Signal Processing*. More advanced topics that have been addressed in the signal processing literature but not discussed here include: detecting coherent (i.e., completely correlated) signals, detecting sources in unknown colored noise, and developing more robust source detection methods.

68.1 Introduction and Motivation

This chapter reviews the applications of antenna array signal processing to mobile networks. Cellular networks are rapidly growing around the world and a number of emerging technologies are seen to be critical to their improved economics and performance. Among these is the use of multiple antennas and spatial signal processing at the base station. This technology is referred to as Smart Antennas or, more accurately, as Space-Time Processing (STP). STP refers to processing the antenna outputs in both space and time to maximize signal quality.

A cellular architecture is used in a number of mobile/portable communications applications. Cell sizes may range from large macrocells, which serve high speed mobiles, to smaller microcells or very small picocells, which are designed for outdoor and indoor applications. Each of these offers different channel characteristics and, therefore, poses different challenges for STP. Likewise, different service delivery goals such as grade of service and type of service: voice, data, or video, also need specific STP solutions. STP provides three processing leverages. The first is *array gain*. Multiple antennas capture more signal energy, which can be combined to improve the signal-to-noise ratio (SNR). Next is spatial diversity to combat space-selective fading. Finally, STP can reduce *co-channel*, *adjacent channel*, and inter-symbol interference.

The organization of this chapter is as follows. In Section 68.2, we describe the vector channel model for a base station antenna array. In Section 68.3 we discuss the algorithms for STP. Section 68.4 outlines the applications of STP in cellular networks. Finally, we conclude with a summary in Section 68.5.

68.2 Vector Channel Model

Channel effects in a cellular radio link arise from multipath propagation and user motion. These create special challenges for STP. A thorough understanding of channel characteristics is the key to developing successful STP algorithms. The main features of a mobile wireless channel are described below.

68.2.1 Propagation Loss and Fading

The signal radiated by the mobile loses strength as it travels to the base station. These losses arise from the mean propagation loss and from slow and fast fading. The mean propagation loss comes from square law spreading, absorption by foliage, and the effect of vertical multipath. A number of models exist for characterizing the mean propagation loss [22, 30], which is usually around 40 dB per decade. Slow fading results from shadowing by buildings and natural features and is usually characterized by a log-normal distribution with standard deviation agreed to 8 dB. Fast fading results from multipath scattering in the vicinity of the moving mobile. It is usually Rayleigh distributed. However, if there is a direct path component present, the fading will be Rician distributed.

68.2.2 Multipath Effects

Multipath propagation plays a central role in determining the nature of the channel. By channel we mean the impulse, or frequency response, of the radio channel from the mobile to the output of the antenna array. We refer to it as a *vector* channel, because we have multiple antennas and, therefore, we have a collection of channels. The mobile radiates omnidirectionally in azimuth using a vertical E-field antenna. The transmitted signal then undergoes scattering, reflection, or diffraction before reaching the base station, where it arrives from different paths, each with its own fading, propagation delay, and angle-of-arrival. This multipath propagation, in conjunction with user motion, determines the behavior of the wireless channel. Multipath scattering arises from three sources (see Fig. 68.1). There are scatterers local to the mobile, remote dominant scatterers, and scatterers local to the base. We will now describe these three scattering mechanisms and their effect on the channel.

FIGURE 68.1: Multipath propagation has three distinct classes, each of which gives rise to different channel effects.

Scatterers Local to Mobile

Scattering local to the mobile is caused by buildings in the vicinity of the mobile (a few tens of meters). Mobile motion and local scattering give rise to Doppler spread, which causes time-selective fading. For a vertical, polarized E-field antenna, it has been shown [22] that the fading signal has a characteristic *classical spectrum*. For a mobile traveling at 55 MPH, the Doppler spread is about ± 200 Hz in the 1900 MHz band. This effect results in rapid signal fluctuations also called time-selective fading. While local scattering contributes to Doppler spread, the delay spread will usually be insignificant because of the small scattering radius. Likewise, the angle spread will also be small.

Remote Scatterers

The emerging wavefront from the local scatterers may then travel directly to the base and also be scattered toward the base by remote *dominant scatterers*, giving rise to specular multipath. These remote scatterers can be terrain features or high rise buildings. Remote scattering can cause significant delay and angle spreads. Delay spread causes frequency-selective fading, and the angle spread results in space-selective fading.

Scatterers Local to Base

Once these multiple wavefronts reach the base station, they may be scattered further by local structures such as buildings or other structures that are in the vicinity of the base. Such scattering will be more pronounced for low elevation below-roof-top antennas. The scattering local to the base can cause severe angle spread.

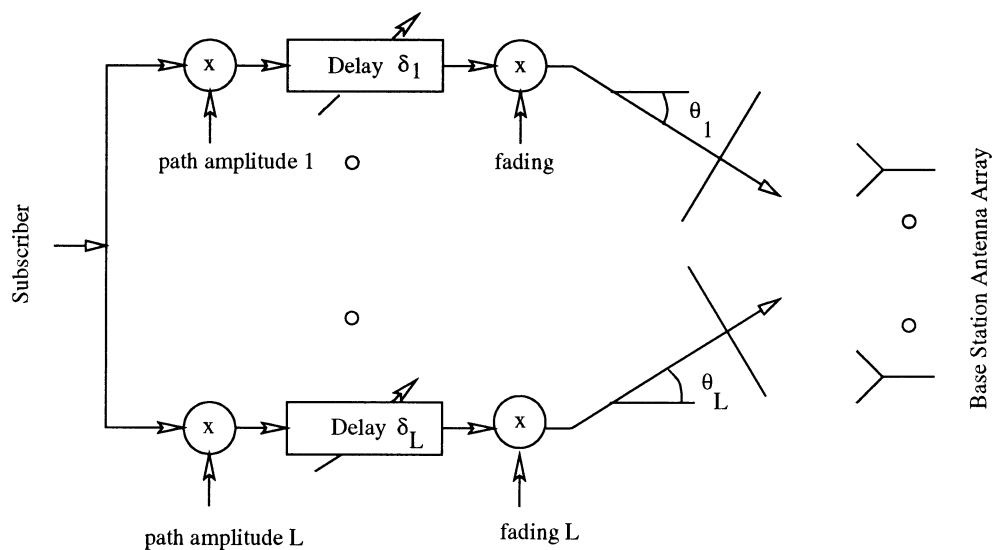

FIGURE 68.2: Multipath model.

68.2.3 Typical Channels

Measurements in macrocells indicate that up to 6 to 12 paths may be present. Typical channel delay, angle, and one-sided Doppler (1800 MHz) spreads are given in Table 68.1.

FIGURE 68.3: Channel frequency response at four different antennas for GSM in a typical hilly terrain channel at 1800 MHz. Mobile speed is 100 KPH. The response is plotted at four time instances spaced 66 μ secs apart.

TABLE 68.1 Typical Delay, Angle and Doppler Spreads in Cellular Applications

Environment	Delay spread (μ sec)	Angle spread (deg)	Doppler spread (Hz)
Flat rural (Macro)	0.5	1	190
Urban (Macro)	5	20	120
Hilly (Macro)	20	30	190
Microcell (Mall)	0.3	120	10
Picocell (Indoors)	0.1	360	5

A multipath channel structure is illustrated in Fig. 68.2. Typical path power and delay statistics can be obtained from the GSM¹ standard. Angle-of-arrival statistics have been less well studied but several results have been reported (see [1, 2, 3]). The resulting channel is shown in Fig. 68.3. We show a frequency response at each antenna for a GSM system. Since the channel bandwidth is 200 KHz, it is highly frequency-selective in a hilly terrain environment. Also, the large angle spread causes variations of the channel from antenna to antenna. The channel variation in time depends on the Doppler spread. Notice that since GSM uses a short time slot, the channel variation during the time slot is negligible.

68.2.4 Signal Model

We study the case when a single user transmits and is received at a base station with multiple antennas. The noiseless baseband signal $x_i(t)$ received by the base station at the i th element of an m element antenna array is given by

¹ Global System for Mobile communications.

$$x_i(t) = \sum_{l=1}^L a_i(\theta_l) \alpha_l^R(t) u(t - \tau_l) \quad (68.1)$$

where L is the number of multipaths, $a_i(\theta_l)$ is the response of the i th element for an l th path from direction θ_l , $\alpha_l^R(t)$ is the complex path fading, τ_l is the path delay, and $u(\cdot)$ is the transmitted signal that depends on the modulation waveform and the information data stream. In the IS-54 TDMA standard, $u(\cdot)$ is a $\pi/4$ shifted DQPSK, gray-coded signal that is modulated using a pulse with square-root raised cosine spectrum with excess bandwidth of 0.35. In GSM, a Gaussian Minimum Shift Keying (GMSK) modulation is used. See [12, 30, 55] for more details. For a linear modulation (e.g., BPSK), we can write

$$u(t) = \sum_k g(t - kT) s(k) \quad (68.2)$$

where $g(\cdot)$ is the pulse shaping waveform and $s(k)$ represents the information bits.

In the above model, we have assumed that the inverse signal bandwidth is large compared to the travel time across the array. For example, in GSM the inverse signal bandwidth is $5 \mu s$, whereas the travel time across the array is, at most, a few ns . This is the narrowband assumption in array processing. The signal bandwidth is a sum of the modulation bandwidth and the Doppler spread, with the latter being comparatively negligible. Therefore, the complex envelope of the signal received by different antennas from a given path are identical except for phase and amplitude differences that depend on the path angle-of-arrival, array geometry, and the element pattern. This angle-of-arrival dependent phase and amplitude response at the i th element is $a_i(\theta_l)$ [37].

We collect all the element responses to a path arriving from angle θ_l into an m -dimensional vector, called the *array response vector* defined as

$$\mathbf{a}(\theta_l) = [a_1(\theta_l) \ a_2(\theta_l) \ \dots \ a_m(\theta_l)]^T$$

where $(\cdot)^T$ denotes matrix transpose.

In array processing literature the array vector $\mathbf{a}(\theta)$ is also known as the *steering vector*. We can rewrite the array output at the base station as

$$\mathbf{x}(t) = \sum_{l=1}^L \mathbf{a}(\theta_l) \alpha_l^R(t) u(t - \tau_l) \quad (68.3)$$

where

$$\mathbf{x}(t) = [x_1(t) \ x_2(t) \ \dots \ x_m(t)]^T$$

and $\mathbf{x}(t)$ and $\mathbf{a}(\theta_l)$ are m -dimensional complex vectors. The fade amplitude $|\alpha^R(t)|$ is Rayleigh or Rician distributed depending on the propagation model.

The channel model described above uses physical path parameters such as path gain, delay, and angle of arrival. When the received signal is sampled at the receiver at symbol (or higher) rate, such a model may be inconvenient to use. For linear modulation schemes, it is more convenient to use a “symbol response” channel model.

Such a discrete-time signal model can be obtained easily as follows. Let the continuous-time output from the receive antenna array $\mathbf{x}(t)$ be sampled at the symbol rate at instants $t = t_o + kT$. The output may be written as

$$\mathbf{x}(k) = \mathbf{H} \mathbf{s}(k) + \mathbf{n}(k) \quad (68.4)$$

where \mathbf{H} is the symbol response channel (a $m \times N$ matrix) that captures the effects of the array response, symbol waveform, and path fading. m is the number of antennas, N is the channel length

in symbol periods, and $\mathbf{n}(k)$ is the sampled vector of additive noise. Note that $\mathbf{n}(k)$ may be colored in space and time, as will be shown later. \mathbf{H} is assumed to be time invariant, i.e., α^R is constant. $\mathbf{s}(k)$ is a vector of N consecutive elements of the data sequence and is defined as

$$\mathbf{s}(k) = \begin{bmatrix} s(k) \\ \vdots \\ s(k - N + 1) \end{bmatrix} \quad (68.5)$$

It can be shown [49] that the ij th element of the \mathbf{H} is given by

$$[\mathbf{H}]_{ij} = \sum_{l=1}^L a_l(\theta_l) \alpha_l^R g((M_d + \Delta - j)T - \tau_l), \quad i = 1 \dots, m ; \quad j = 1, \dots, N \quad (68.6)$$

where M_d is the maximum path delay and $2\Delta T$ is the duration of the pulse shaping waveform $g(t)$.

68.2.5 Co-Channel Interference

In wireless networks a cellular layout with frequency reuse is exploited to support a large number of geographically dispersed users. In TDMA and FDMA networks, when a co-channel mobile operates in a neighboring cell, co-channel interference (CCI) will be present. The average signal-to-interference power ratio (SIR), also called the protection ratio [24], depends on the reuse factor (K). It is 18.7 dB for reuse $K = 7$ (IS-54), and 13.8 dB for reuse $K = 4$ (GSM). In sectorized cells, CCI is significant mainly from cells that lie within the sector beam. The received signal at a base station will therefore be a sum of the desired signal and co-channel interference.

68.2.6 Signal-Plus-Interference Model

The overall signal-plus-interference-and-noise model at the base station antenna array can now be rewritten as

$$\mathbf{x}(k) = \mathbf{H}_s \mathbf{s}_s(k) + \sum_{q=1}^{Q-1} \mathbf{H}_q \mathbf{s}_q(k) + \mathbf{n}(k) \quad (68.7)$$

where \mathbf{H}_s and \mathbf{H}_q are channels for signal and CCI, respectively, while \mathbf{s}_s and \mathbf{s}_q are the corresponding data sequences. Note that Eq. (68.7) appears to suggest that the signal and interference are band synchronous. However, this can be relaxed and the time offsets can be absorbed into the channel \mathbf{H}_q . In multi-user cases, all the signals are desired and Eq. (68.7) can be rewritten to reflect this situation.

68.2.7 Block Signal Model

It is often convenient to handle signals in blocks. Therefore, we may collect M consecutive snapshots of $\mathbf{x}(\cdot)$ corresponding to time instants $k, \dots, k + M - 1$, (and dropping subscripts for a moment), we get

$$\mathbf{X}(k) = \mathbf{H}\mathbf{S}(k) + \mathbf{N}(k) \quad (68.8)$$

where $\mathbf{X}(k)$, $\mathbf{S}(k)$, and $\mathbf{N}(k)$ are defined as

$$\begin{aligned} \mathbf{X}(k) &= [\mathbf{x}(k) \cdots \mathbf{x}(k + M - 1)] & (m \times M) \\ \mathbf{S}(k) &= [\mathbf{s}(k) \cdots \mathbf{s}(k + M - 1)] & (N \times M) \\ \mathbf{N}(k) &= [\mathbf{n}(k) \cdots \mathbf{n}(k + M - 1)] & (m \times M) \end{aligned}$$

Note that $\mathbf{S}(k)$ by definition is constant along the diagonals and is therefore Toeplitz.

68.2.8 Spatial and Temporal Structure

Given the signal model at Eq. (68.8), an important question is whether the unknown channel, \mathbf{H} , and data, \mathbf{s} , can be determined from the observations \mathbf{X} . This leads us to examine the underlying constraints on \mathbf{H} and $\mathbf{S}(\cdot)$ which we call *structure*.

Spatial Structure

From Eq. (68.6), the j th column of \mathbf{H} is given by

$$\mathbf{H}_{1:m,j} = \sum_{l=1}^L \mathbf{a}(\theta_l) \alpha_l^R g((M_d + \Delta - j)T - \tau_l) \quad (68.9)$$

Spatial structure can help determine $\mathbf{a}(\theta_l)$ if the angles of arrival θ_l are known or can be estimated. $\mathbf{a}(\theta_l)$ lies on a *array manifold* \mathcal{A} , which is the set of all possible array response vectors indexed by θ .

$$\mathcal{A} = \{\mathbf{a}(\theta) | \theta \in \Theta\} \quad (68.10)$$

where Θ is the set of all possible values of θ . \mathcal{A} includes the effect of array geometry, element patterns, inter-element coupling, scattering from support structures, and objects near the base station.

Temporal Structure

The temporal structure relates to the properties of the signal $u(t)$ and includes modulation format, pulse-shaping function, and symbol constellation. Some typical temporal structures are

- Constant modulus (CM)

In many wireless applications, the transmitted waveform has a constant envelope (e.g., in FM modulation). A typical example of a constant envelope waveform is the GMSK modulation used in the GSM cellular system which has the following general form

$$u(t) = e^{j(\omega t + \phi(t))}$$

where $\phi(t)$ is a Gaussian-filtered phase output of a minimum shift keyed (MSK) signal [40].

- Finite alphabet (FA)

Another important temporal structure in mobile communication signals is the *finite alphabet*. This structure underlies all digitally modulated schemes. The modulated signal is a linear or nonlinear map of an underlying finite alphabet. For example, the IS-54 signal is a $\pi/4$ shifted DQPSK signal given by

$$\begin{aligned} u(t) &= \sum_p A_p g(t - pT) + j \sum_p B_p g(t - pT) \\ A_p &= \cos(\phi_p), \quad B_p = \sin(\phi_p), \quad \phi_p = \phi_{p-1} + \Delta\phi_p \end{aligned} \quad (68.11)$$

where $g(\cdot)$ is the pulse shaping function (which is a square root raised cosine function in the case of IS-54), and $\Delta\phi_p$ is chosen from a set of finite phase shifts $\{\frac{5\pi}{4}, \frac{3\pi}{4}, \frac{\pi}{4}, \frac{7\pi}{4}\}$ depending on the data $s(\cdot)$. These finite set of phase shifts represent the FA structure.

- Distance from Gaussianity

The distribution of digitally modulated signals is not Gaussian,² and this property can be exploited to estimate the channel from the higher-order moments such as cumulants, see e.g., [15, 33]. Clearly CM signals are non-Gaussian. These higher order statistics (HOS) based methods are usually slower converging than those based on second order statistics.

- Cyclostationarity

Recent theoretical results [14, 28, 39, 44] suggest that exploiting the *cyclostationary* characteristic of the communication signal can lead to second-order statistics based algorithms to identify the channel, \mathbf{H} , and therefore a more attractive approach than HOS techniques.

It can be shown [10] that the continuous-time stochastic process $x(t)$ defined in Eq. (68.1) (assuming the fade amplitude α^R is constant) is cyclostationary. Moreover, the discrete sequence $\{x_i\}$ obtained by sampling $x(t)$ at the symbol rate $\frac{1}{T}$ is wide-sense stationary, whereas the sequence obtained by temporal oversampling (i.e., at a rate higher than $1/T$) or spatial oversampling (multiple antenna elements) is cyclostationary. The cyclostationary signal consists of a number of sampling *phases* each of which is stationary. A phase corresponds to a shift in the sampling point in temporal oversampling and different antenna element in spatial oversampling.

The cyclostationary property of sampled communication signals carries important information about the channel phase, which can be exploited in several ways to identify the channel. The cyclostationarity property can also be interpreted as a *finite duration* property. Put simply, this says that the oversampling increases the number of samples in the signal $\mathbf{x}(t)$ and phases in the channel, \mathbf{H} , but does not change the value of the data for the duration of the symbol period. This allows \mathbf{H} to become tall (more rows than columns) and full column rank. Also, the stationarity of the channel makes \mathbf{H} Toeplitz (or rather block Toeplitz). Tallness and Toeplitz properties are key to the blind estimation of \mathbf{H} .

- The temporal manifold

Just as the array manifold captures spatial wavefront information, the *temporal manifold* captures the temporal pulse-shaping function information [48, 49]. We define the temporal manifold $\mathbf{k}(\tau)$ as the sampled response of a receiver to an incoming pulse with delay τ . Unlike the array manifold, the temporal manifold can be estimated with good accuracy because it depends only on our knowledge of the pulse-shaping function. Table 68.2 summarizes the duality between the array and the temporal manifold.

TABLE 68.2 The Duality Between the Array and the Time Manifold

Manifold	Indexed by:	Characterizes:
Array	Angle θ	Antenna array response
Time	Delay τ	Transmitted pulse shape

The different structures and properties inherent in the signal model are depicted in Fig. 68.4

²The distribution may, however, approach Gaussian when constellation shaping is used for spectral efficiency [56].

FIGURE 68.4: Space-time structures.

68.3 Algorithms for STP

The history of array signal processing goes back nearly four decades to adaptive antenna combining techniques using phase-lock loops for antenna tracking. An important beginning was made by Howells [21], when he proposed the sidelobe canceller for adaptive nulling, and later Applebaum developed a feedback control algorithm for maximizing SINR. Another significant advance was the LMS algorithm proposed by Widrow [54]. Yet another important milestone was the work of Capon who proposed an adaptive antenna system [8] using a look direction constraint that resulted in the minimum variance distortionless beamformer. Further advances were made by Frost [13] and Griffiths and Jim [17] among several others. See [50] for a review on spatial filtering.

Because of significant delay spread in the channel, array processing in mobile communications can be greatly leveraged by processing the signals in space and in time (STP) to minimize *both* co-channel interference and inter symbol interference while maximizing SNR. See [35] for a review of channel equalization.

We begin with the single-user case where we are only interested in demodulating the signal of interest. We therefore treat interference from other users as unknown additive noise. This is an interference-suppression approach [53]. Later in the section, we will discuss multi-user detection which jointly detects all impinging signals.

68.3.1 Single-User ST-ML and ST-MMSE

The first criterion for optimality in space-time processing is Maximum Likelihood (ML) or is usually referred to as *Maximum Likelihood Sequence Estimation* (MLSE). ST-MLSE seeks to estimate the data sequence that is most likely to have been sent given the received vector signal. Another frequently used criterion is *Minimum Mean Square Error* (MMSE). In ST-MMSE we obtain an estimate of the transmitted signal as a space-time weighted sum of the received signal and seek to minimize the mean square error between the estimate and the true signal at every time instant.

We present ST-MLSE and ST-MMSE in a form that is a space-time extension of the well-known ML and MMSE algorithms.

ST-MLSE

With the channel model described by Eq. (68.8), we assume that the noise \mathbf{N} is spatially and temporally white and Gaussian, and that there is *no interference*. The MLSE problem can be shown to reduce to finding \mathbf{S} so as to satisfy the following criterion:

$$\min_{\mathbf{S}} \|\mathbf{X} - \mathbf{H}\mathbf{S}\|_F^2 \quad (68.12)$$

where the channel \mathbf{H} is assumed to be known and $\|\cdot\|_F$ denotes Frobenius norm. This is a generalization of the standard MLSE problem where the channel is now defined in space and time. We can, therefore, use a space-time generalization of the well-known Viterbi algorithm (VA) to carry out the search in Eq. (68.12) efficiently as is shown in Fig. 68.5. See [34] for a discussion on the VA methods.

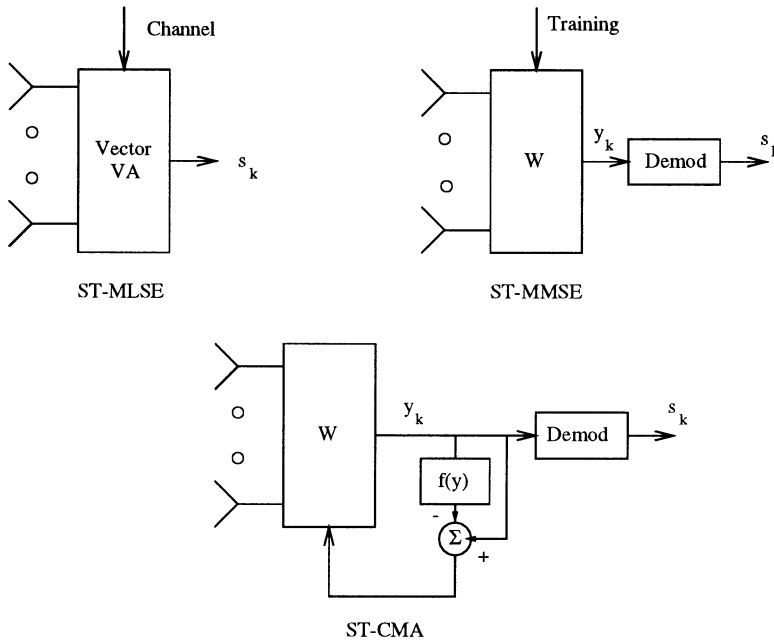

FIGURE 68.5: Different structures for space-time processing.

In the presence of co-channel interference, which is likely to be both spatially and temporally correlated (due to delay spread), the MLSE criterion can be reformulated with a new metric to address the problem. However, the temporal correlation due to delay spread in CCI complicates the implementation of the Viterbi equalizer.

ST-MMSE

In the presence of CCI with delay spread, a ST-MMSE receiver is more attractive. This receiver combines the input in space and time to generate an output that minimizes the error between itself and the desired signal (see Fig. 68.5). Before proceeding further, we need to introduce some preliminaries.

In a space-time filter (equalizer cum beamformer), \mathbf{W} has the following form:

$$\mathbf{W}(k) = \begin{bmatrix} w_{11}(k) & \cdots & w_{1M}(k) \\ \vdots & \cdots & \vdots \\ w_{m1}(k) & \cdots & w_{mM}(k) \end{bmatrix} \quad (68.13)$$

In order to obtain a convenient formulation for the space-time filter output, we introduce the quantities $W(k)$ and $X(k)$ as follows:

$$\begin{aligned} X(k) &= \text{vec}(\mathbf{X}(k)) \quad (mM \times 1) \\ W(k) &= \text{vec}(\mathbf{W}(k)) \quad (mM \times 1) \end{aligned} \quad (68.14)$$

where the operator $\text{vec}(\cdot)$ is defined as:

$$\text{vec}([\mathbf{v}_1 \cdots \mathbf{v}_M]) = \begin{bmatrix} \mathbf{v}_1 \\ \vdots \\ \mathbf{v}_M \end{bmatrix}$$

The scalar equalizer output $y(k)$ can then be written as

$$y(k) = W^H(k)X(k) = \text{Tr}(\mathbf{W}^H(k)\mathbf{X}(k)) \quad (68.15)$$

where $(\cdot)^H$ denotes complex conjugate transpose.

The ST-MMSE filter chooses the space-time filter weights to approach the minimum mean square error, i.e.,

$$\min_W E \left\| W^H X(k) - s(k - \zeta) \right\|_2^2 \quad (68.16)$$

where ζ is a delay chosen to center the space-time filter (the choice of this parameter strongly affects performance). The solution to this least-squares (LS) problem follows from the well-known projection theorem

$$E \left(X(k)(X^H(k)W - s^*(k - \zeta)) \right) = 0 \quad (68.17)$$

This leads to

$$W = \left\{ E \left(X(k)X^H(k) \right) \right\}^{-1} E \left(X(k)s^*(k - \zeta) \right) \quad (68.18)$$

where superscript $*$ denotes complex conjugate. If the interference and noise are independent of the signal, the transmitted bit sequence is white, and $M > N$

$$E \left(X(k)s^*(k - \zeta) \right) = \left[0 \cdots 0 \text{vec}^T(\mathbf{H}) 0 \cdots 0 \right]^T = \overline{H} \quad (68.19)$$

where the number of zeros preceding and succeeding $\text{vec}^T(\mathbf{H})$ depends on the choice of ζ . Defining the space-time $mN \times mN$ covariance matrix $\mathbf{R}_{XX} = E(XX^H)$, Eq. (68.18) takes the familiar form

$$W = \mathbf{R}_{XX}^{-1} \overline{H} \quad (68.20)$$

Note that when $M = N$, $\overline{H} = \text{vec}(\mathbf{H})$. A number of techniques are available in order to solve Eq. (68.20), such as the least mean square (LMS) [54] or the recursive least square (RLS) [29]. These have different tradeoffs of computational complexity, tracking capability and steady-state error. See [29] for a discussion. Alternatively, if a block method is used, we can explicitly calculate \mathbf{R}_{XX}^{-1} and then use \overline{H} to find W . This is known as Sample Matrix Inversion (SMI).

The relative performance of ST-MLSE and ST-MMSE schemes is influenced by the dominance of CCI and ISI, and the nature of the channel. When the channel is CCI dominated and contains multipath, a Viterbi equalizer is complicated to implement. In this case, the MMSE approach appears desirable. On the other hand, in an ISI-dominated large delay spread scenario, an MLSE has natural advantages.

Having reviewed the basic approaches to space-time processing, we will now study two important issues: blind vs. non-blind and single vs. multi-user approaches.

Training Signal Methods

In many mobile communications standards such as GSM and IS-54, explicit training signals are inserted inside the TDMA data bursts. These training signals can be used to estimate the channel needed for the MLSE or MMSE receivers.

Let \mathbf{T} be the training sequence arranged in a matrix form (again \mathbf{T} is Toeplitz). Then, during the training burst, the received data is given by

$$\mathbf{X} = \mathbf{HT} + \mathbf{N} \quad (68.21)$$

Clearly \mathbf{H} can be estimated using LS

$$\mathbf{H} = \mathbf{XT}^\dagger \quad (68.22)$$

where $\mathbf{T}^\dagger = \mathbf{T}^H (\mathbf{TT}^H)^{-1}$.

In a ST-MMSE receiver, we need \mathbf{W} and this can be computed readily from \mathbf{H} using Eq. (68.20).

Blind Methods

The term “blind” methods (other names are “self-recovering” or “unsupervised”), do not need training signals and rather exploit the temporal structure such as non-Gaussianity; constant modulus (CM); finite alphabet (FA); cyclostationarity, or the spatial structure, such as the array manifold. The performance of blind methods will, of course, be sensitive to the validity of structural properties assumed.

Spatial Structure or DOA-Based Methods These techniques use DOA estimates as a basis for determining the optimum beamformer. These methods were developed vigorously in the 1980s in military applications for reception of unknown or noise-like signals. The modern era in DOA estimation began with the MUSIC algorithm first proposed in 1979 by Schmidt and independently by Bienvenu and Kopp [6, 36], thus launching the “subspace era” in signal processing. See [52] for a survey. Another class of DOA estimation techniques was launched when Paulraj et al. proposed the ESPRIT algorithm which has striking advantages when compared to MUSIC but needs a special array geometry. See [23] for a survey.

DOA-based methods suffer from serious drawbacks in cellular applications. First, DOA estimation requires an accurate knowledge of the array manifold. This needs expensive calibration support. Next, the number of antennas at cellular base stations vary from four to eight per sector, an insufficient number for the multipath and interference rich cellular environments. Finally, these methods do not exploit the knowledge of the modulation format of the communication signal and the time delay relationship between multipath signals.

A *subspace approach* can be used to estimate the directions-of-arrival of the impinging wavefronts. The signal model is given by

$$\mathbf{x}(t) = \mathbf{A}\mathbf{u}(t) + \mathbf{n}(t) \quad (68.23)$$

where \mathbf{A} is an $m \times Q$ matrix whose columns are the array response vectors for each wavefront (assuming no multipath)

$$\mathbf{A} = [\mathbf{a}(\theta_1) \quad \cdots \quad \mathbf{a}(\theta_Q)],$$

$\mathbf{u}(t)$ contains the fading signals from the Q users

$$\mathbf{u}(t) = [\alpha_1(t)u_1(t - \tau_1) \quad \cdots \quad \alpha_Q(t)u_Q(t - \tau_Q)]^T$$

and

$$u_q(t) = \sum_k s_q(k)g(t - kT)$$

The sampled block signal model then takes the following form

$$\mathbf{X} = \mathbf{A} \mathbf{S} + \mathbf{N} \quad (68.24)$$

In the subspace approach, we seek to estimate \mathbf{A} from the array data by exploiting the underlying array manifold structure. When the number of antennas, m , is greater than the number of signals, Q , the signal $\mathbf{x}(t)$ in the absence of noise is confined to a subspace, referred to as the *signal subspace*.

We first estimate this signal subspace from the received data \mathbf{X} . We then search for an $m \times Q$ matrix \mathbf{A} whose *columns lie on the array manifold* and whose (column) subspace matches the estimated signal subspace. A good estimate of the signal subspace is given by the first Q dominant eigenvectors of the space-only $m \times m$ covariance matrix $\mathbf{R}_{xx} = E(\mathbf{x}\mathbf{x}^H)$. If \mathbf{E}_s is a matrix of these eigenvectors, then the subspace fitting approach estimates \mathbf{A} to minimize the following criterion

$$\min_{\mathbf{A}} \|\mathbf{E}_s - \mathbf{A}\mathbf{Z}\|_F^2$$

where \mathbf{Z} is an arbitrary $Q \times Q$ square matrix.

Once \mathbf{A} is estimated, we have the array vector for the desired signal. The MMSE and ML estimators (assuming no multipath) of $u_q(t)$ are identical [7] and are given by

$$\mathbf{w}_q = \mathbf{R}_{xx}^{-1} \mathbf{a}(\theta_q) \quad (68.25)$$

\mathbf{w}_q is a (space-only) beamformer that has been studied extensively.

When multipath and delay spread is present, the solution in Eq. (68.25) will have a poor performance and improved techniques are needed. If we use a ST-MMSE structure, we can extend the above subspace methods to compute the optimum beamformer given in Eq. (68.20).

Temporal Structure Methods These techniques include a vast range that spans from the well-studied CM and HOS methods to the more recent second order methods that exploit the cyclostationarity of the received signal.

The fading and dynamics of the mobile propagation channel create special problems for blind techniques, and their performance in mobile channels is only recently gaining attention. A widely known class of simple blind algorithms is the so-called Bussgang class that contains, among others, the CM 1-2, CM 2-2, Sato, and Decision-Directed (DD) algorithms. See [11, 19, 20] for a survey of blind algorithms.

Contrary to non-blind techniques, where a training signal drives the recursive algorithms, in the CM approach, we replace the training signals by a modulus corrected version of the output signal. The CM 2-2 minimizes the following cost function

$$\min_W J(W) = E[|y(k)|^2 - 1]^2 \quad (68.26)$$

where $y(k)$ is the output of the ST filter [see Eq. (68.15)].

The resulting LMS-type algorithm is given by

$$W(k+1) = W(k) - \mu X^*(k) y(k) (|y(k)|^2 - 1) \quad (68.27)$$

$W(k+1)$, under the right conditions, approaches the optimum ST-MMSE solution in Eq. (68.20).

Important performance issues for blind algorithms are speed of convergence, ability to reach the global optimum solution, and capacity to track time varying mobile channels.

Polyphase Methods Following the path-breaking paper by Tong, et al. [44] that presented a blind channel identification method using oversampling and relying only on second order statistics, a number of techniques that exploit cyclostationarity have since dominated the blind-deconvolution literature.

Polyphase methods provide a blind solution by starting with the data

$$\mathbf{X}(k) = \mathbf{H}\mathbf{S}(k) + \mathbf{N}(k) \quad (68.28)$$

or its second order statistics. They then extract \mathbf{H} and \mathbf{S} by exploiting the tallness structure (obtained via oversampling) of \mathbf{H} [28, 29]. See [25] for a tutorial presentation of polyphase techniques.

68.3.2 Multi-User Algorithms

In multi-user (MU) algorithms, we address the problem of extracting multiple co-channel user signals arriving at an antenna array. Such problems occur in channel reuse within cell (RWC) applications or in situations where we attempt to demodulate the interference signal in order to improve interference suppression. The data model is once again

$$\mathbf{X} = \mathbf{H}\mathbf{S} + \mathbf{N} \quad (68.29)$$

where \mathbf{H} and \mathbf{S} are suitably defined to include multiple users and are of dimensions $m \times NQ$ and $NQ \times M$, respectively.

We have several approaches that parallel the single-user case. We begin with the ML and MMSE prototypes and then explain in more detail some recently developed blind techniques.

Multi-User MLSE and MMSE

If the channels for all arriving signals are known, then we can extend the earlier MLSE to jointly demodulate all the user data sequences. Starting with the data model in Eq. (68.29), we can then search for multiple user data sequences that minimize the ML cost function in Eq. (68.12). The multi-user MLSE will have a large number of states in the trellis. Efficient techniques for implementing a Viterbi equalizer need to be developed.

In multi-user MMSE, we usually estimate each user signal separately using the single-user MMSE processor given in Eq. (68.20). In this case, the MMSE treats other user signals as interference with unknown structure. Multi-user techniques either need training signals for all the users or adopt blind methods. The multiple training signals should be designed to have low cross correlation properties so as to minimize cross coupling in the channel estimates.

Multi-User Blind Methods

Once again, the techniques are parallel to the single-user spatial and temporal blind methods. The spatial structure multi-user algorithms are again applicable under the conditions discussed in Section 68.3.1. The approach is identical; we first estimate \mathbf{A} using subspace methods, and the beamformer \mathbf{w}_q for each user follows from Eq. (68.25).

We briefly describe some illustrative algorithms.

Finite Alphabet (FA) Method

This approach exploits the FA property of the digitally modulated signals. Assuming no delay spread and perfect multi-user symbol synchronization, the channel model is given by Eq. (68.24), which we repeat here for convenience:

$$\mathbf{X} = \mathbf{A}\mathbf{S} + \mathbf{N} \quad (68.30)$$

where both \mathbf{A} and \mathbf{S} are unknown and the additive noise is assumed to be white and Gaussian. The joint ML criterion for this reduces to the familiar minimization problem

$$\min_{\mathbf{A}, \mathbf{S}} \|\mathbf{X} - \mathbf{A}\mathbf{S}\|_F^2 \quad (68.31)$$

This is a joint ML problem where both the channel and data are unknown. The FA property allows us to solve Eq. (68.31) and estimate both \mathbf{A} and \mathbf{S} . Since the ML criterion is separable with respect to the unknowns, one approach to minimize the cost function in Eq. (68.31) is alternating projections. Starting with an initial estimate of \mathbf{A} , we minimize Eq. (68.31) with respect to \mathbf{S} , keeping \mathbf{A} fixed. This is a data detection problem. With an estimate of \mathbf{S} , an improved estimate of \mathbf{A} can be obtained by minimizing Eq. (68.31) with respect to \mathbf{A} , keeping \mathbf{S} fixed. This is a standard least-squares problem. We continue this iterative process until a fixed point is reached. The global solution is a fixed point of the iteration. In order to avoid a computationally expensive search, two suboptimal iterative techniques, ILSP and ILSE [42, 43], can be used to make this minimization tractable.

Note that the joint ML problem can also be formulated for the single user case where we estimate the channel and the data jointly using the FA or other signal properties. Joint ML methods are also known as adaptive ML.

Finite Alphabet – Oversampling (FA-OS) Method

In the presence of delay spread (and unsynchronized symbols), the FA algorithm has to be modified to estimate the space-time channel \mathbf{H} as against the spatial channel \mathbf{A} described earlier. An attractive technique to estimate the temporal channel using polyphase or oversampling method was proposed recently in [47].

We therefore first need to extend the multi-user data model in Eq. (68.30) to incorporate oversampling. Assuming oversampling at P samples per symbol, we define a new $mP \times M$ data matrix \mathbf{X} where each entry is a vector of P data samples per symbol period.

This results once again in the familiar model

$$\mathbf{X} = \mathbf{H}\mathbf{S} + \mathbf{N} \quad (68.32)$$

Note that now the dimensions of \mathbf{X} , \mathbf{H} , and \mathbf{S} are $mP \times M$, $mP \times NQ$, and $NQ \times M$, respectively. As noted earlier, \mathbf{H} is tall, full column rank and has a block Toeplitz structure.

Once again we can estimate \mathbf{H} and \mathbf{S} using a Joint-ML approach. This reduces to minimizing

$$\min_{\mathbf{H}, \mathbf{S}} \|\mathbf{X} - \mathbf{H}\mathbf{S}\|_F^2 \quad (68.33)$$

A direct approach to Eq. (68.33) is computationally prohibitive. The approach in [47] breaks up the joint problem into two smaller subproblems. First, the channels are equalized by enforcing the low rank and block-Toeplitz structure of \mathbf{H} . This yields the row subspace of \mathbf{S} . The FA property can now be enforced to determine the symbols in \mathbf{S} .

Multi-User CM

While the FA approach exploits the FA property, CM is another structure for multi-user signal separation. When the channel has no delay spread, we have a standard source separation problem, which can be dealt with the so-called *constant modulus array* [4, 16, 26]. The resulting algorithms are space-only multi-user counterparts of the temporal CM algorithms: instead of combatting the channel ISI in order to retrieve the single-user signal, they try to combat the channel CCI and demodulate the different user signals.

Recent advances in multi-user CM include an analytical CM (ACM) [32, 45], a multi-stage CM algorithm [38], and related approaches [5] and [9]. The extension to a delay spread environment was proposed in [31].

68.3.3 Simulation Example

Figure 68.6 illustrates the effect of STP in a mobile environment. The channel model chosen was a typical urban channel. A four element linear array with $\frac{\lambda}{2}$ spacing was employed. The desired and interference signals arrived from mean directions of 0° and 45° , respectively. An IS-54 channel interface was used. Section (a) shows the received signal constellation for a simple antenna. Note that this implies that the eye is completely closed. Section (b) shows the constellation after STP, using a ST-MMSE equalizer employing training signals. Note the dramatic improvement in the received constellation.

FIGURE 68.6: Interference cancellation using STP.

68.4 Applications of Spatial Processing

In this section, we briefly describe three applications of antennas and STP in cellular base stations.

68.4.1 Switched Beam Systems

Switched Beam Systems (SBS) consist of a beamformer in the RF stage that forms multiple (non-adaptive) beams, a “sniffer” that determines the beam that has the best SINR and a switch that is used to select the best or best two beams for the receiver. These systems are used as an appliqué unit, where the existing diversity antennas are replaced by a switch-beam antenna system. The SBS operates by sniffer scanning the beamformer outputs to detect the best two beams which are then

switched through to the receiver. In order to reduce the probability of incorrect beam selection, the beam outputs are validated by checking the color code (for example CDVCC in IS-54 or SAT tone in AMPS) prior to determining the best beam.

The main advantage of using SBS is the improvement in cell coverage on the reverse link due to the array gain and improved voice quality due to reduced interference. Since the pre-formed beams are narrower than the sector beamwidth, reduction in interference power is obtained when the desired signal and the interference are separated in angle and fall into different beams. This SINR improvement offers better voice quality and may also allow use of a smaller reuse factor and therefore improve capacity.

The performance of SBS depends on a number of factors, including angle spread of multipath, relative angles-of-arrival of the signals and interference, and the array topology. Performance gains in SBS come from array gain, diversity gain, reduced interference, and trunking efficiency.

68.4.2 Space-Time Filtering

Space-time filtering (STF) applies space-time processing to maximize signal power and minimize intersymbol and co-channel interference. As is evident from earlier sections, space-time processing will be very different for each air interface standard. In GSM, the slot duration is 0.577 ms with 26 training bits and the symbol period is 3.7 μ secs. Channel equalization is, of course, necessary. The presence of controlled ISI further complicates the equalization problem. It is reasonable to assume that the signal and interference channels are invariant across a slot. In IS-54, the slot duration is 6.66 ms, resulting in substantial variation of the channel over the slot. However, the symbol period is 41.6 μ secs, and therefore channel equalization is usually not needed. Thus, the STF architectures must find some means to track the signal and interference channels across the burst, using blind techniques, as those described earlier in this chapter.

68.4.3 Channel Reuse Within Cell

Reuse within cell (RWC) refers to the reuse of a channel or radio resource *within* a cell by exploiting differences in the channels. This is akin to spectrum reuse in cellular systems, where a channel or a spectrum resource used in one cell is reused in another cell separated by sufficient *distance* such that the co-channel interference is sufficiently small.

When RWC is used in TDMA or FDMA, a cell supports two or more users in a given channel, as against a single user in conventional cells. Antenna arrays and space-time processing is used for joint demodulation of multiple users, assuming such users are sufficiently separated in channels (directions). When two or more users become closely aligned in their channels, they will no longer be separable, and one of the users should be handed off to another frequency or time slot. RWC needs to work on both forward and reverse links, therefore, signal separability must be achieved on both links.

The principal challenge in RWC when used with TDMA or FDMA is to estimate and track the reverse and forward channels to a high degree of accuracy. The problem is further complicated by the near-far problem resulting in power imbalance between users. The ability to estimate and track the reverse link channel depends on angle, delay, and Doppler spreads. The higher these spreads, the higher the sources of channel estimation errors. Therefore, flat rural environments with low angle and delay spreads score over urban and microcells which use antennas below roof top. Also, fixed wireless applications score over mobile applications. In the forward link, we need to once again predict the channel accurately. We can do this by an open loop method, i.e., use the reverse link channel to predict forward channel. Alternatively, we can use feedback from the mobile to estimate the forward channel. For the open loop method, in FDD, angle spread is a source of error and in TDD the Doppler spread is a source of error. Due to these complications, RWC is not a promising

technology in most TDMA and FDMA applications.

68.5 Summary

Use of array signal processing or STP is emerging as a powerful tool for improving cellular wireless networks. STP can improve cell coverage, enhance link quality, and increase system capacity. The rapidly varying mobile channel with large multipath delay and angle spreads offer a significant challenge to STP. Effective solutions have to be specific to each air interface and the propagation environment. More work is needed to develop robust STP techniques and to characterize their performance. See [1, 2, 3] for a review of the current state of the art in smart antennas technology.

69.1 Introduction

The classical definition of a beamformer basically specifies its goal: to estimate the signal waveform arriving at the array from a given direction. Beamformers are spatial processors that combine the signals impinging on an array of captors. Combining the outputs of the captors forms a narrow beam pointing towards the direction of the source (look direction). This narrow beam can discriminate between sources spatially located at distinct sites. This important property of beamformers is used to design techniques that localize active or passive sources particularly in RADAR/ SONAR systems.

In the last two decades, beamforming methods have had significant theoretical and practical advances. This, together with other technological advances, has broadened the application of sophisticated beamforming techniques to a diversity of areas, including imaging, geophysical and oceanographic exploration, astrophysical exploration, and biomedical. See [19, 20] for an excellent overview of modern beamforming techniques and applications.

Communications is another attractive application area for beamforming. In fact, beamforming has been widely used for directional transmission and reception as well as for sector broadcasting in satellite communications systems. More recently, due to the drastic increase of users in cellular

¹Initial date of submission of this article September 28, 1995.

radio systems [10, 15, 18], including indoors and outdoors mobile systems, it is increasingly being recognized that the design of base station and mobile antennas based on beamforming methods improves significantly the system's spectrum efficiency [1, 11]. In turn, this enables accommodating larger numbers of users [3, 16]. The most striking argument in favor of using advanced beamforming techniques such as adaptive or blind beamforming for mobile communications is based on the idea of Space Division Multiple Access (SDMA) schemes. With SDMA, several mobiles share simultaneously the same frequency channel by creating virtual channels in the spatial domain. Another important argument in favor of using beamforming in cellular radio is that beamforming yields flexible signal processing schemes that properly handle multipath effects which are typical in radio communications. Multipath is the term given when the same signal arrives at the destination through different paths. This may arise when signals bounce off obstacles in their path of propagation. At the receiver, these arrivals are correlated. Their recombination causes severe signal distortions and fading. In limiting cases, the power of the received signal can become so small that the reliability of the data communications link is completely lost.

In this section we design a multichannel beamformer to combat multipath effects. The receiver uses a base station antenna array which handles several radio links operating simultaneously at the same carrier frequency, while preserving the reliability of the communications. The approach relies on statistical signal processing methods, yielding a solution that operates in a blind mode with respect to the parameters that specify the propagation channel. This means that, except for a few quantities related to system specifications, e.g., link budget and array geometry, the receiver that we describe here does not assume any prior knowledge about the locations of the sources and of the structures of the ray arrivals, including directions of arrival and correlations. The simulation results show the excellent performance of this multichannel beamformer in SDMA schemes.

The chapter is organized as follows. In Section 69.2 we introduce the beamforming problem (see also [20]), and classical beamformers such as the delay-and-sum beamformer, the minimum output noise power beamformer, and the minimum variance beamformer. We show that these beamformers present severe drawbacks when operating in multipath environments. Section 69.3 presents a solution to the beamforming problem for the case of correlated arrivals. This solution is based on a minimum mean square error (MMSE) approach. We compare the performance of this beamformer with the performance of the beamformers introduced in Section 69.2. We emphasize, in particular, the case of multipath propagation. In this section, we also discuss issues regarding the implementation of the minimum mean square error beamformer. In Section 69.4, we describe a method to implement the minimum mean square error beamformer in the context of a digital mobile communications system. The method operates in a blind mode and strongly exploits the structure of the received multipath data. Since the propagation channel parameters, e.g., angles of arrivals of the multiple paths, are not known, we estimate them with a maximum likelihood approach supported on a finite mixture distribution model of the array data. We maximize the likelihood function with an iterative scheme. We describe an efficient procedure to initialize the iterative algorithm. In general, this procedure converges rapidly to the global maximum of the likelihood function. Section 69.5 presents simulation results obtained with data synthesized by a simple mobile communications simulator. These results confirm the excellent performance of the MMSE beamformer described in the paper.

69.2 Beamforming

Beamforming is an array processing technique for estimating a desired signal waveform impinging on an array of sensors from a given direction. This technique applies to both narrowband and wideband signals. Here, we will consider only the narrowband case.

Let $s(t)$ be the complex envelope of the source radiated signature. Under the farfield assumption the signal at the receiving array is a planar wavefront, see Fig. 69.1. In this case, and according to the

FIGURE 69.1: Source/receiver geometry.

model derived in [20], the complex envelope of the signal received at each sensor of a uniform and linear array of N omnidirectional sensors is

$$s_n(t) = s(t - \tau_n) e^{-j\omega_0 \tau_n} , \quad (69.1)$$

where ω_0 is the carrier frequency and τ_n is the intersensor propagation delay. Let d , c , and θ_0 be, respectively, the distance between sensors, the propagation velocity, and the direction of arrival (DOA). The intersensor delays are then

$$\tau_n = \frac{(n-1)d}{c} \sin \theta_0, \quad n = 1, 2, \dots, N . \quad (69.2)$$

Because of the narrowband assumption, we can make the simplification

$$s(t - \tau_n) \simeq s(t)$$

in Eq. (69.1). This means that, for the values of τ_n of interest, the source complex envelope $s(t)$ is slowly varying when compared with the carrier $e^{j\omega_0 t}$.

We model each array sensor by a quadrature receiver, its output being given by

$$z_n(t) = s_n(t) + n_n(t), \quad (69.3)$$

where $s_n(t)$ is the complex envelope of the signal component and $n_n(t)$ is a complex additive disturbance, such as sensor noise, ambient noise, or another signal interfering with the desired one. Collecting in a vector $\mathbf{z}(t)$ all the responses of the N sensors of the array to a narrowband source coming at the array from the DOA = θ_0 , we get the N -dimensional complex vector

$$\mathbf{z}(t) = \mathbf{a}(\theta_0) s(t) + \mathbf{n}(t) . \quad (69.4)$$

The vector $\mathbf{a}(\theta_0)$ is referred to as the steering vector for the DOA θ_0 .

The elements of the steering vector $\mathbf{a}(\theta_0)$ are given by $a_n(\theta_0) = e^{-j\omega_0 \tau_n}$, $n = 1, 2, \dots, N$. The noise vector $\mathbf{n}(t)$ is an N -dimensional complex vector collecting the N sensor noises $n_n(t)$. In general, it includes components correlated with the desired signal as in multipath propagation environments. With multipath, several replicas of the same signal, each one propagating along a different path, arrive at the array with distinct DOAs.

In beamforming, the goal is to estimate the source signal $s(t)$ given $\mathbf{a}(\theta_0)$. The narrowband beamformer is illustrated in Fig. 69.2. The output of the beamformer is

$$y(t) = \mathbf{w}^H \mathbf{z}(t) , \quad (69.5)$$

where $\mathbf{w} = [w_1, w_2, w_3, \dots, w_N]^T$ is a vector of complex weights. We use the notation $\{\cdot\}^T$ to denote vector and matrix transposition, and $\{\cdot\}^H$ for transposition followed by complex conjugation. The beamformer is completely specified by the vector of weights \mathbf{w} .

FIGURE 69.2: Narrowband beamformer.

In the absence of the noise term $\mathbf{n}(t)$ in (69.4), it is readily seen that choosing

$$\mathbf{w} = (1/N)\mathbf{a}(\theta_0) ,$$

the beamformer output is $y(t) = s(t)$. This corresponds to the simplest implementation of the narrowband beamformer, known as the delay-and-sum (DS) beamformer: it combines coherently the signal replicas received at each sensor after compensating for their corresponding relative delays.

The interpretation of the DS beamformer operation is rather intuitive. However, we may ask ourselves the following question: is DS the best we can do to estimate the desired signal when the disturbance $\mathbf{n}(t)$ is present? To answer the question satisfactorily, we begin by noting that, in the presence of noise, the output of the DS beamformer is

$$y(t) = s(t) + (1/N)\mathbf{a}^H(\theta_0)\mathbf{n}(t) .$$

The influence of the error term on the estimate $y(t)$ of $s(t)$ depends basically on the structure of $\mathbf{n}(t)$. The optimal design of beamformers depends now on the choice of an adequate optimization criterion that takes into account the disturbance vector, with the goal of improving in some sense the quality of the desired estimate. In the sequel, we will consider several cases of practical interest.

69.2.1 Minimum Output Noise Power Beamforming (MNP)

To reduce the effect of the error term at the beamformer output, we formulate the beamforming problem as follows:

find the weight vector \mathbf{w} such that the noise output power $E\left\{|\mathbf{w}^H\mathbf{n}(t)|^2\right\}$ is minimized subject to the constraint $\mathbf{w}^H\mathbf{a}(\theta_0) = 1$,

where $E\{\cdot\}$ denotes the statistical average. The cost function is

$$E\left\{|\mathbf{w}^H\mathbf{n}(t)|^2\right\} = \mathbf{w}^H\mathbf{R}_n\mathbf{w} \quad (69.6)$$

with \mathbf{R}_n the covariance matrix of the disturbance vector $\mathbf{n}(t)$, i.e., $\mathbf{R}_n = E\{\mathbf{n}(t)\mathbf{n}^H(t)\}$. The constraint guarantees that the signal along the look direction θ_0 is not distorted.

The solution to this constrained optimization problem is obtained by Lagrange multipliers techniques. It is given by

$$\mathbf{w} = (\mathbf{a}^H(\theta_0)\mathbf{R}_n^{-1}\mathbf{a}(\theta_0))^{-1}\mathbf{R}_n^{-1}\mathbf{a}(\theta_0) . \quad (69.7)$$

The vector \mathbf{w} in Eq. (69.7) is the gain of the MNP beamformer [20].

When the source signal is uncorrelated with the disturbance,

$$E\{s(t)\mathbf{n}^H(t)\} = \mathbf{0} ,$$

it can be shown that the weight vector (69.7) of the MNP beamformer takes the form

$$\mathbf{w} = (\mathbf{a}^H(\theta_0)\mathbf{R}^{-1}\mathbf{a}(\theta_0))^{-1}\mathbf{R}^{-1}\mathbf{a}(\theta_0), \quad (69.8)$$

where

$$\mathbf{R} = \mathbf{E} \left\{ \mathbf{z}(t)\mathbf{z}^H(t) \right\} \quad (69.9)$$

is the covariance matrix of the array data vector \mathbf{z} . The vector \mathbf{w} in Eq. (69.8) is the gain of the minimum variance (MV) beamformer [20]. The MV beamformer minimizes the total output power

$$\mathbf{E} \left\{ \left| \mathbf{w}^H \mathbf{z}(t) \right|^2 \right\} = \mathbf{w}^H \mathbf{R} \mathbf{w}$$

subject to $\mathbf{w}^H \mathbf{a}^H(\theta_0) = 1$. The MV beamformer presents an important advantage over the MNP beamformer. While to implement the MNP beamformer we need to know the covariance matrix $\mathbf{R}_{\mathbf{n}}$ of the disturbance vector \mathbf{n} , in general, to implement the MV beamformer it is sufficient to estimate the array covariance matrix \mathbf{R} using the available data \mathbf{z} .

We discuss how to estimate \mathbf{R} . Let T time samples (snapshots) of the array response vector $\mathbf{z}(t)$ be available. An estimate of \mathbf{R} is the data sample covariance matrix \mathbf{R}_s :

$$\mathbf{R}_s = \frac{1}{T} \sum_{t=1}^T \mathbf{z}(t)\mathbf{z}^H(t). \quad (69.10)$$

Under technical conditions that we will not discuss here, the sample covariance matrix, \mathbf{R}_s , converges (in the appropriate sense) to the array covariance matrix \mathbf{R} when T approaches infinity. This means that, for a large enough number T of snapshots, we can replace \mathbf{R} in Eq. (69.8) by \mathbf{R}_s , without a significant performance degradation.

We provide an alternative interpretation to the MNP beamformer. Using Eq. (69.7) in Eq. (69.5), and taking into account Eq. (69.4), we see that the output of the MNP beamformer has a signal component $s(t)$ and an error term $\mathbf{w}^H \mathbf{n}(t)$ with average power

$$P_o = \mathbf{w}^H \mathbf{E} \left\{ \mathbf{n}(t)\mathbf{n}^H(t) \right\} \mathbf{w} = \left(\mathbf{a}^H(\theta_0)\mathbf{R}_{\mathbf{n}}^{-1}\mathbf{a}(\theta_0) \right)^{-1}. \quad (69.11)$$

Since the power of the signal is preserved and the MNP beamformer minimizes the power of the noise at its output, the MNP beamformer maximizes the output signal-to-noise ratio (SNR).

FIGURE 69.3: (a) Single source in white noise; (b) uncorrelated interference; (c) correlated interference.

We will not discuss in detail the behavior of the MNP and MV beamformers. The reader is referred to the work in [2]. We list some of the properties of the MNP and MV beamformers in two scenarios of practical interest.

Case 1: Single Source in White Noise

Here (see Fig. 69.3(a)), we assume that the noise $\mathbf{n}(t)$ is sensor noise. We model it as $\mathbf{n}(t) = \mathbf{u}(t)$ where the components of $\mathbf{u}(t)$ are jointly independent and identically distributed samples of zero mean white noise sequences with variance σ^2 , i.e.,

$$\mathbf{R}_n = \mathbf{R}_u = \sigma^2 \mathbf{I},$$

where \mathbf{I} is the identity matrix. The sensor noise models the thermal noise generated at each receiver and is assumed independent of (thus, uncorrelated with) the source signal. If S is the power of the desired signal, the SNR at each sensor is $\text{SNR}_i = S/\sigma^2$. Also, from Eq. (69.7), we conclude that when the additive noise is white, as in this case, the MNP beamformer reduces to the DS beamformer.

Moreover, computing the power at the output of the beamformer with Eq. (69.11) for this particular situation yields $P_o = \sigma^2/N$. This means that, at the output of the beamformer, the signal-to-noise ratio is $\text{SNR}_o = N \text{SNR}_i$.

We conclude, for the case of a single source in white noise, that the DS beamformer is optimum in the sense of maximizing the output signal-to-noise ratio SNR_o . Further, SNR_o increases linearly with the number N of array sensors.

Case 2: Directional Interferences and White Noise

Now, we assume that the disturbance $\mathbf{n}(t)$ is the superposition of possibly several directional interferences and white noise. Without loss of generality, we consider the case of a single interferer:

$$\mathbf{n}(t) = \mathbf{a}(\theta_i)i(t) + \mathbf{u}(t), \quad (69.12)$$

where $i(t)$ is the signal radiated by the interferer, θ_i is the DOA of the interference signal, and $\mathbf{u}(t)$ is the white noise vector. In general, we assume that $\mathbf{u}(t)$ is uncorrelated with $i(t)$.

Case 2.1: Uncorrelated Arrivals

This is the case where the desired signal and the interference are generated by distinct sources, see Fig. 69.3(b). It is clear that under this assumption, $s(t)$ and $\mathbf{n}(t)$ are uncorrelated. As we emphasized before, this is the situation where the MNP beamformer (69.7) is equivalent to the MV beamformer (69.8).

The covariance of the noise $\mathbf{n}(t)$ is now

$$\mathbf{R}_n = \mathbf{a}(\theta_i)S_i\mathbf{a}^H(\theta_i) + \sigma^2\mathbf{I},$$

where S_i is the average power of the interference $i(t)$. At the DOA θ_i , the beamformer has an amplitude response

$$|\mathbf{w}^H \mathbf{a}(\theta_i)| = \frac{|\beta|}{1 + (1 - |\beta|^2)\text{INR}}, \quad (69.13)$$

where

$$\text{INR} = S_i/(\sigma^2/N)$$

is the interference-to-noise ratio (INR), and $\beta = (1/N)\mathbf{a}^H(\theta_i)\mathbf{a}(\theta_0)$ measures the spatial coherence between the desired source and the interference.

Well Separated Arrivals

When the signal and interference are well separated, their spatial coherence is small, i.e., $|\beta| \ll 1$. In Eq. (69.13), the denominator is approximately given by $1 + \text{INR}$. The net effect is that the beamformer output along the interference direction decreases when INR increases. In other words, the MNP and the MV beamformers direct a beam with gain 1 towards the DOA of the desired signal

and *null* the interference. The interference canceling property is reflected on the average power of the beamformer output error which is evaluated to

$$P_o = \frac{\sigma^2}{N} \frac{1}{1 - |\beta^2| \frac{\text{INR}}{1 + \text{INR}}} . \quad (69.14)$$

For large INR and well-separated DOAs, $P_o \simeq (\sigma^2/N)$. This means that the interference contributes little to the estimation error at the output of the beamformer.

Close Arrivals

When the source and the interferer are spatially close, their spatial coherence is large, $|\beta| \simeq 1$, and the output at the interference DOA is $\simeq 1$. This means that the MNP and MV beamformers no longer have the ability to discriminate the two sources.

We conclude from the simple analysis of these two cases that the DOA discrimination capability is strongly related to the *spatial resolution* of the array geometry through the parameter β . In practice, to improve upon the resolution of a linear and uniform array, we increase, when feasible, the number N of sensors. This results in narrower beamwidths which can resolve closer arrivals.

Case 2.2: Correlated Arrivals

This is the case where the interference $i(t)$ is correlated with the desired signal $s(t)$, i.e.,

$$\text{E}\{s(t)i^*(t)\} = \rho = |\rho|e^{j\phi_\rho} \neq 0 .$$

We denote complex conjugate by $(\cdot)^*$.

With reference to Fig. 69.3(c), we discuss a simple example where the interference results from a secondary path generated by a reflector (multipath propagation)

$$i(t) = \gamma s(t) . \quad (69.15)$$

The complex parameter, γ , accounts for the relative attenuation and delay of the reflected path. The correlation factor, ρ , between $i(t)$ and $s(t)$ is, in this case, given by

$$\rho = \gamma/|\gamma| .$$

The desired signal and the disturbance vector $\mathbf{n}(t)$ are now correlated and the MV beamformer is no longer equivalent to the MNP beamformer. Recall that the MV beamformer attempts to minimize the total output power under the constraint of a unitary gain at the DOA of the desired source. As the array output vector has a correlated signal component at a different DOA, to minimize the output power may cause the desired signal itself to be strongly attenuated. This is the *signal cancellation* effect, typical of MV beamforming when operating in multipath environments like the one just considered. On the contrary, the behavior of the MNP beamformer is independent of the correlation degree between the desired signal and the disturbance: the MNP beamformer filters out correlated arrivals just as if they were uncorrelated interferences.

To implement the MNP beamformer, besides the DOA of the desired signal, we also need to know the covariance matrix \mathbf{R}_n of the disturbance vector. In general, this covariance is not known *a priori*. It has to be estimated using the available data, and this can be a rather complicated task, not discussed here.

In this section, we discussed the MNP solution to the beamforming problem. The MNP beamformer is optimum in the sense of maximizing the output SNR. When the noise is white, the DS beamformer is recovered as the optimum solution for the single source case. It points a beam towards the source DOA and reduces the sensor noise power by a factor of N , see Fig. 69.4(a). We also saw

that, in the more general situation where the disturbance vector includes directional interferences, the MNP beamformer acts like an interference canceler: it points a beam towards the DOA of the desired signal, while nulling the remaining arrivals regardless of their correlation degrees, see Figs. 69.4(b) and (c).

FIGURE 69.4: Artistic representation of alternative solutions to the beamforming problem.

We comment on the adequacy of the MNP solution to the correlated arrivals scenario. By treating the correlated arrivals as an interference, the MNP beamformer neglects the information about the desired signal that may be provided by the reflected path. It is clear that any solution that can combine coherently the information contents of all the correlated arrivals will be more effective in recovering the desired signal from the background noise. This type of solution should behave as a combiner of the outputs of different beams steered towards the DOAs of the correlated replicas of the desired signal, see Fig. 69.4(d). In the following section, we will see how this solution can be designed using a different optimization criterion when solving the beamforming problem.

69.3 MMSE Beamformer: Correlated Arrivals

In this section, we study a different beamforming technique that, as we will see, is specially suited to multipath propagation environments. The approach is similar to that used in the previous section. The beamformer is still given by Eq. (69.5), but we choose a different optimization criterion to solve the beamforming problem. We formulate the problem in the following way:

find the weight vector \mathbf{w} such that the output error power $E \left\{ |\mathbf{w}^H \mathbf{z}(t) - s(t)|^2 \right\}$ is minimized ,

i.e., we want to find the weight vector \mathbf{w} that minimizes the mean square error between the beamformer output $\mathbf{y}(t) = \mathbf{w}^H \mathbf{z}(t)$ and the desired signal $s(t)$. The general solution, which we call the Wiener solution, is [2]

$$\mathbf{w} = \mathbf{R}^{-1} \mathbf{r}_{zs} , \quad (69.16)$$

where $\mathbf{r}_{zs} = E\{\mathbf{z}(t)s^*(t)\}$ is the correlation between the array vector response $\mathbf{z}(t)$ and the desired signal $s(t)$. To understand the behavior of the MMSE beamformer (69.16), we address the same alternative configurations considered in Case 2 of the previous section.

Directional Interference and White Noise

In this scenario, the disturbance $\mathbf{n}(t)$ is like in Eq. (69.12), so the received array signal is

$$\mathbf{z}(t) = \mathbf{a}(\theta_0)s(t) + \mathbf{a}(\theta_i)i(t) + \mathbf{u}(t) ,$$

where, as before, $i(t)$ and $\mathbf{u}(t)$ are the interference and the array sensor noise vector, respectively.

Uncorrelated Arrivals

The signal $s(t)$ and the interference $i(t)$ are uncorrelated. The correlation between the array vector and the desired signal is

$$\mathbf{r}_{zs} = \mathbf{a}(\theta_0)S,$$

where S is the average power of $s(t)$. The MMSE beamformer weight vector in Eq. (69.16) takes the particular form

$$\mathbf{w} = S\mathbf{R}^{-1}\mathbf{a}(\theta_0). \quad (69.17)$$

Comparing (69.17) with (69.8), we conclude that in the present situation, except for a scale factor, the MMSE and the MNP (or MV) beamformers are equivalent. Thus, the MMSE beamformer cancels uncorrelated interferences and directs a beam towards the DOA of the desired signal. However, contrary to what happens with the MNP (or MV) beamformer, the gain of the MMSE beamformer at the look direction is not unity. On the other hand, the MMSE beamformer provides a stronger noise rejection and a smaller output error power than the MNP beamformer. In fact, it can be shown [2] that

$$P_o(\text{MMSE}) \leq \frac{\text{SNR}_o}{1 + \text{SNR}_o} P_o(\text{MNP}), \quad (69.18)$$

where $\text{SNR}_o = S/(\sigma^2/N)$, and $P_o(\text{MNP})$ is the average power of the MNP beamformer output error given by (69.14). Equation (69.18) is particularly significant in low SNR environments.

Correlated Arrivals

We take again the interference to be like in Eq. (69.15), i.e., $i(t) = \gamma s(t)$. It leads to the correlation

$$\mathbf{r}_{zs} = (\mathbf{a}(\theta_0) + \gamma\mathbf{a}(\theta_i))S$$

and to the weight vector

$$\mathbf{w} = S\mathbf{R}^{-1}\mathbf{a}(\theta_0) + S\gamma\mathbf{R}^{-1}\mathbf{a}(\theta_i). \quad (69.19)$$

It is clear from Eq. (69.19) that the MMSE beamformer directs distinct beams towards the DOAs θ_0 and θ_i of the correlated arrivals in order to combine coherently their respective outputs. If \mathbf{R} has contributions of other sources uncorrelated with $s(t)$, then these will be filtered out by both beams. This simple example shows how the MMSE beamformer uses the correlated arrivals to improve the output error power.

To have an idea of how the behavior of the MMSE beamformer compares with that of the MNP beamformer, we represent in Fig. 69.5 the output error power as a function of the INR and the SNR, for the case of spatially close arrivals. We see from Fig. 69.5 that the MMSE beamformer outperforms the MNP beamformer in all scenarios considered. This is particularly apparent in the limiting case of coherent arrivals, when the correlation between the signal and the interference is such that $|\rho| = 1$. The upper and lower bounds of the output error power shown in the figure are determined by $-1 \leq \cos(\phi_\rho) \leq 1$.

To implement the MMSE beamformer in a multipath propagation environment, we need to know the correlation vector \mathbf{r}_{zs} or, alternatively, the DOAs of all correlated replicas of the desired signal as well as their relative attenuations and propagation delays. In practice, \mathbf{r}_{zs} can only be estimated from the data if we have available a reference signal whose correlation with the array vector is similar to that of the desired signal. This is the basic idea underlying adaptive implementations (least mean squares approach); see, e.g., [8, 9]. In these implementations, a time sequence, which is known by the receiver, is transmitted by the source and used to adapt the beamforming weights until some error threshold is achieved. In many applications, a reference signal is not available or, as in communications, the

FIGURE 69.5: Output error power. (a) As a function of INR; (b) as a function of SNR. (Source: Barroso, V.A.N. and Moura, J.M.F., l_2 and l_1 Beamformers: recursive implementation and performance analysis, *IEEE Trans. on Signal Processing*, SP-42(6), 1323–1334, June 1994. © 1994 IEEE. Used with permission).

transmission of a reference signal may represent a significant waste of the channel capacity. In the next section, we explain how to implement the MMSE beamformer without the need of a reference signal. We do this in the context of a wireless digital communication system.

69.4 MMSE Beamformer for Mobile Communications

In this section, we discuss the implementation of the MMSE beamformer in the context of a digital wireless communication system. The users are mobiles transmitting simultaneously in the same frequency channel. This precludes the use of time/frequency methods to discriminate between the source signals. Here, we assume that the multipath propagation delays are smaller than the baud period (symbol time interval). We develop a multiple output or multichannel MMSE beamformer for this application.

Each mobile is assigned to a specific beamforming processing channel that has the following capabilities:

- Combine the multipath arrivals generated by its assigned mobile.
- Cancel all the arrivals generated by other mobiles.

We illustrate the development of the array receiver in the simple context of Fig. 69.6. We consider two mobiles, M_1 and M_2 , each one generating a direct path ($dm, m = 1, 2$) and a reflected path ($rm, m = 1, 2$). The propagation channel used by each mobile is characterized by four parameters:

FIGURE 69.6: Example of a mobile communications scenario.

two complex numbers, γ_{dm} and γ_{rm} , accounting for the attenuation and the propagation delay in each path, and two DOAs θ_{dm} and θ_{rm} . We model all the parameters that characterize the propagation channels as deterministic unknown parameters. Furthermore, and in contrast with what we assumed in the previous sections, the *DOAs of the desired signals are not known a priori*. The receiver itself has to track the sources while they are moving. In a mobile communications system, we can safely assume that we know the number of mobiles, their transmitted power, and the sensor noise variance. The number of mobiles is determined by some higher layer of the receiver architecture (e.g., handover procedures to establish the connection between the receiver and each mobile), while the power and the noise variance are system parameters specified by the *link budget*.

69.4.1 Model of the Array Output

Let $\mathbf{h}_m, m = 1, 2$, be the single input/multiple output complex transfer function describing, for each source, the channel/receiving array system. Each \mathbf{h}_m is $N \times 1$, where N is the number of array sensors. We write

$$\mathbf{h}_1 = \gamma_{d1}\mathbf{a}(\theta_{d1}) + \gamma_{r1}\mathbf{a}(\theta_{r1})$$

$$\mathbf{h}_2 = \gamma_{d2}\mathbf{a}(\theta_{d2}) + \gamma_{r2}\mathbf{a}(\theta_{r2}) ,$$

where $\mathbf{a}(\cdot)$ represents the array steering vector. Let $s_1(t)$ and $s_2(t)$ be the baseband signals transmitted by the mobiles. They are assumed to be independent binary sequences taking the values $+1$ and -1 with equal probability. Thus, the signal vector $\mathbf{s}(t) = [s_1(t), s_2(t)]^T$ has zero mean and covariance matrix $\mathbf{S} = \mathbf{I}$. Defining the $(N \times 2)$ matrix $\mathbf{H} = [\mathbf{h}_1, \mathbf{h}_2]$, the array output vector is

$$\mathbf{z}(t) = \mathbf{H}\mathbf{s}(t) + \mathbf{u}(t) , \quad (69.20)$$

where $\mathbf{u}(t)$ represents the complex sensor noise vector. The noise $\mathbf{u}(t)$ will be assumed to be zero mean Gaussian with known covariance matrix $\sigma^2\mathbf{I}$. The goal is to estimate the signal vector $\mathbf{s}(t)$ using a MMSE beamformer which, as we saw in Section 69.3, is the appropriate approach for multipath propagation environments. However, to implement the MMSE beamformer (69.16), we need to know the correlation between the array output $\mathbf{z}(t)$ and the signal vector $\mathbf{s}(t)$ which in this case is

$$\mathbf{r}_{zs} = E\{\mathbf{z}(t)\mathbf{s}^H(t)\} = \mathbf{H} .$$

The matrix \mathbf{H} is parameterized by all the unknown θ and γ parameters of our model. Thus, it has to be estimated from the available data. Once we have the estimate of \mathbf{H} , we can use it to compute a

structured estimate of the array covariance matrix. In this case, where $\mathbf{S} = \mathbf{I}$, this estimate is

$$\mathbf{R} = \mathbf{H}\mathbf{H}^H + \sigma^2\mathbf{I}. \quad (69.21)$$

This estimate is better than the sample covariance matrix computed by Eq. (69.10) because it avoids eventual mismatches between the estimate of \mathbf{H} and its actual value embedded in \mathbf{R}_s . In the following section, we will describe a method that provides accurate estimates of \mathbf{H} .

69.4.2 Maximum Likelihood Estimation of \mathbf{H}

Suppose that T is the number of snapshots, i.e., samples, of the array output that are available for estimating the matrix \mathbf{H} , while tracking the mobiles. The choice of T should strike a balance between the two following conflicting requirements:

- T should be large enough to guarantee in the appropriate sense a good estimate of \mathbf{H} .
- T should be small enough so that we can safely model \mathbf{H} as time invariant.

Fortunately, these two conditions are easily met in the application under study. High data rates usually will be involved in mobile communications. For example, data rates of 2 Mbps or higher are envisaged for the UMTS (Universal Mobile Telecommunications System) and the MBS (Mobile Broadband System), systems presently under development in Europe. These high data rates, the typical velocities of the mobiles (less than 100 Km/h), and the typical mobile/receiver distances ensure that a large amount of data can be collected over a time period during which \mathbf{H} can be considered to be approximately constant. In other words, the geometry is very slowly varying when compared to the transmission data rates.

Under the assumptions used to establish the model of the array output vector, the *likelihood function* is

$$L(\mathbf{H}) = \prod_{t=1}^T \sum_{i=1}^4 \text{Gauss}_i(\mathbf{H}, \mathbf{z}(t)), \quad (69.22)$$

where the unnormalized Gauss function is

$$\text{Gauss}_i(\mathbf{H}, \mathbf{z}(t)) = \exp\left(-\frac{|\mathbf{z}(t) - \mathbf{H}\mathbf{s}_i|^2}{\sigma^2}\right),$$

and $\{\mathbf{s}_i\}_{i=1}^4$ spans the finite alphabet of the sources, i.e., the four possible realizations of $\mathbf{s}(t)$. In Eq. (69.22), we assume that the sampling of the received signals is synchronized with the symbol clock. This is a very strong requirement as time synchronization may be a very difficult problem, specially when the sampling rate equals the data rate. However, the sensitivity of the receiver with respect to timing errors is, in general, efficiently reduced when the sampling rate is made larger than the symbol rate. Although we do not discuss this issue here, the algorithm that we present is easily extended to this case. The value of \mathbf{H} that maximizes the likelihood function $L(\mathbf{H})$ makes the collected data more likely from a probabilistic point of view. The maximization of Eq. (69.22) with respect to \mathbf{H} is not an easy task. Equation (69.22) is strongly non-linear in \mathbf{H} which precludes the analytical solution of the optimization problem. On the other hand, the parameterization of \mathbf{H} in terms of the channel parameters does not help much because optimization over these parameters requires a multidimensional search approach, which may be excessively time consuming.

The EM Algorithm

To maximize Eq. (69.22) with respect to \mathbf{H} , we use an algorithm based on the EM (Expectation-Maximization) approach [17]. This approach yields an iterative algorithm that, under some technical

conditions that are beyond the scope of this paper, is known to converge to the true maximum likelihood estimate. The EM iteration is

$$\mathbf{H}_{l+1} = \left(\sum_{t=1}^T \mathbf{z}(t) \frac{\sum_{i=1}^4 \text{Gauss}_i(\mathbf{H}_l, \mathbf{z}(t)) \mathbf{s}_i^H}{\sum_{i=1}^4 \text{Gauss}_i(\mathbf{H}_l, \mathbf{z}(t))} \right) \left(\sum_{t=1}^T \frac{\sum_{i=1}^4 \text{Gauss}_i(\mathbf{H}_l, \mathbf{z}(t)) \mathbf{s}_i \mathbf{s}_i^H}{\sum_{i=1}^4 \text{Gauss}_i(\mathbf{H}_l, \mathbf{z}(t))} \right)^{-1}. \quad (69.23)$$

To run this iterative algorithm, we must be aware of two important aspects:

- In general, this algorithm has a very slow convergence rate.
- Due to strong non-linearities, it can easily get trapped in a local maximum.

These two aspects reflect a high sensitivity of the EM algorithm with respect to the initial estimate. Special care has to be taken to specify the initial estimate \mathbf{H}_0 . Next, we describe how to obtain this initial condition, such that the EM iteration converges in just a few iterations to the global maximum of the likelihood function.

Initialization of the EM Algorithm

In this paragraph, we do not go into the detailed derivation of the initialization procedure. The interested reader is referred to [4]. Here, we describe the basic idea underlying the initialization procedure and present the steps necessary to implement it.

Recall the structure of \mathbf{H} defined in Section 69.4.1. For the simple example that we have been considering, we write

$$\mathbf{H} = \mathbf{A}(\theta)\Gamma, \quad (69.24)$$

where

$$\mathbf{A}(\theta) = [\mathbf{a}(\theta_{d1}), \mathbf{a}(\theta_{r1}), \mathbf{a}(\theta_{d2}), \mathbf{a}(\theta_{r2})] \quad (69.25)$$

is the $(N \times 4)$ matrix of the steering vectors associated with each incoming path, θ being the vector of the unknown DOAs. The remaining unknown parameters of our model are collected in

$$\Gamma = \begin{bmatrix} \gamma_{d1} & 0 \\ \gamma_{r1} & 0 \\ 0 & \gamma_{d2} \\ 0 & \gamma_{r2} \end{bmatrix}. \quad (69.26)$$

The problem of estimating the initial condition \mathbf{H}_0 is decomposed in two steps: (1) estimation of θ , and (2) estimation of Γ .

Step (1): Estimation of θ

DOA estimation is a well-studied problem in array processing. The classical approach is based on the MV beamformer [6, 12]. The main idea consists in detecting the maxima of the output power, when a set of quantized values of the possible angles of arrival (in the range $[-\pi/2, \pi/2]$ in the case of a linear array) is scanned by varying the look direction specified by the complex weights of the MV beamformer. One of the problems with this approach is that angular resolution is mainly determined by the beamwidth. A narrow beam requires a large number of array sensors. To overcome this limitation, we might use the MUSIC algorithm, a well-known high resolution technique [5, 12, 13] based on the eigenvalue decomposition of the sample covariance matrix. The angular resolution of the MUSIC algorithm improves as the sample covariance matrix approaches the array covariance matrix. However, these two techniques (MV beamformer and MUSIC) fail when the arrivals are

correlated as is the case in mobile communications. The spatial smoothing method [12, 14] extends MUSIC to correlated arrivals. The goal of spatial smoothing is to decorrelate the arrivals. It breaks the original array into subarrays. The problem is that the performance of spatial smoothing depends strongly on the correlation degree of the arrivals. To improve the efficiency of spatial smoothing, we have to use a large number of spatial samples, i.e., a larger array.

To circumvent all these difficulties, keeping the array size manageable, and achieving acceptable performance, we use a different approach which is insensitive to the correlation degree of the arrivals. This technique is similar to MUSIC but, rather than relying on the sample covariance matrix (second order statistics), it is based on first order statistics (statistical average) of the array data, see [12] for a detailed derivation of the algorithm. We show how the method is used in the mobile communications problem.

Looking at Eq. (69.20), and recalling the assumptions on $\mathbf{s}(t)$ and $\mathbf{u}(t)$, we conclude that $E\{\mathbf{z}(t)\} = \mathbf{0}$. This seems to contradict our goal of using first order statistics of the array data to estimate the DOAs. However, a more careful analysis of the structure of our model shows that the array samples can be partitioned into a number of sets equal to the cardinality of the source's alphabet (4, in the example that is being used). Each of the sets, \mathbf{Z}_i , in the partition has samples of the form

$$\mathbf{z}_i(t) = \mathbf{H}\mathbf{s}_i + \mathbf{u}(t), \quad i = 1, \dots, 4. \quad (69.27)$$

The statistical average of these samples is

$$\mathbf{x}_i = \mathbf{H}\mathbf{s}_i, \quad i = 1, \dots, 4. \quad (69.28)$$

This means that the array data is organized in clusters, \mathbf{Z}_i , of points centered about each \mathbf{x}_i .

To estimate the DOAs, we need to use only one of the \mathbf{x}_i 's. Therefore, we are left with finding a scheme to determine one of the sets in the partition of the array data. In a statistical sense, the distance between any two samples of the array data is minimum if the two samples belong to the same partition. In other words, for any pair of time instants, t_l and t_k , $\mathbf{z}(t_l)$ and $\mathbf{z}(t_k)$ belong to the same partition \mathbf{Z}_i if the source signal vectors $\mathbf{s}(t_l)$ and $\mathbf{s}(t_k)$ have the same realization \mathbf{s}_i . In this case,

$$\Delta = E\left\{|\mathbf{z}(t_l) - \mathbf{z}(t_k)|^2\right\} = 2N\sigma^2. \quad (69.29)$$

To find one set \mathbf{Z}_i of the partition, after choosing randomly one array sample $\mathbf{z}(t_l)$, we look for all other samples whose distance to $\mathbf{z}(t_l)$ is below some threshold appropriately related with Δ . Once we obtain the set \mathbf{Z}_i in the partition, we estimate the statistical average \mathbf{x}_i of the points in the set by its sample mean.

At the end of this step, we have calculated the first order statistics and are ready to apply the first order statistics algorithm to estimate the DOAs θ [4]. Having the estimate $\hat{\theta}$ of the DOAs, we estimate the matrix of the steering vectors \mathbf{A} in Eq. (69.25) by $\hat{\mathbf{A}} = \mathbf{A}(\hat{\theta})$.

Step (2): Estimation of Γ

Recall from Eq. (69.24) that $\mathbf{H} = \mathbf{A}(\theta)\Gamma$. Step (1) estimated \mathbf{A} as $\hat{\mathbf{A}} = \mathbf{A}(\hat{\theta})$. We now proceed with the estimation of Γ . To estimate Γ , we use the estimate $\hat{\mathbf{A}} = \mathbf{A}(\hat{\theta})$ just obtained, as well as the cluster center \mathbf{x}_i on which that estimate was based.

Denote the left pseudoinverse of a matrix \mathbf{A} by \mathbf{A}^\dagger . It is defined by

$$\mathbf{A}^\dagger = (\mathbf{A}^H \mathbf{A})^{-1} \mathbf{A}^H.$$

Recall that the matrix of steering vectors \mathbf{A} defined in Eq. (69.25) is a rank 4 ($N \times 4$) matrix.

We now motivate how to estimate Γ . Define the matrix

$$\mathbf{Q} = \hat{\mathbf{A}}^\dagger (\mathbf{R} - \sigma^2 \mathbf{I}) \hat{\mathbf{A}}^{H\dagger}. \quad (69.30)$$

From Eq. (69.21), we get

$$\mathbf{R} - \sigma^2 \mathbf{I} = \mathbf{H}\mathbf{H}^H.$$

Substituting this equation in (69.30), we get

$$\mathbf{Q} = \hat{\mathbf{A}}^\dagger \mathbf{H}\mathbf{H}^H \hat{\mathbf{A}}^{H^\dagger}.$$

But by (69.24)

$$\mathbf{Q} = \hat{\mathbf{A}}^\dagger \mathbf{A} \Gamma \Gamma^H \mathbf{A}^H \hat{\mathbf{A}}^{H^\dagger}. \quad (69.31)$$

Clearly, if $\hat{\mathbf{A}} = \mathbf{A}$, then

$$\mathbf{Q} = \Gamma \Gamma^H. \quad (69.32)$$

Apparently, to estimate Γ , we should compute \mathbf{Q} and then find a factorization of the form (69.32). This is not so easy because, in general, a unique factorization of a Hermitian matrix like \mathbf{Q} does not exist. Nevertheless, \mathbf{Q} plays a key role in the procedure for estimating Γ . This is essentially based on the singular value decomposition of \mathbf{Q} , as we see now. Notice that \mathbf{Q} can be computed from the data using the data sample covariance matrix \mathbf{R}_s given by Eq. (69.10) instead of the array data covariance matrix \mathbf{R} .

Recalling from Eq. (69.26) the structure of Γ , we conclude that \mathbf{Q} should be a (4×4) Hermitian matrix of rank 2. This means that \mathbf{Q} should only have two nonzero eigenvalues (in fact, because \mathbf{Q} is Hermitian, these eigenvalues of \mathbf{Q} are real and positive). The singular value factorization of \mathbf{Q} is

$$\mathbf{Q} = \mathbf{V} \Lambda \mathbf{V}^H, \quad (69.33)$$

where Λ is a diagonal matrix whose elements are the nonzero singular values, in this case the eigenvalues of \mathbf{Q} , and \mathbf{V} is a matrix whose columns are the orthonormal eigenvectors associated to these eigenvalues.

From Eq. (69.26) defining Γ , we see that Γ has itself orthogonal columns. In general, the columns of Γ have different norms. Using the eigenvalue decomposition in Eq. (69.33), we conclude that, except for a phase difference, the columns of $\mathbf{V} \Lambda^{1/2}$ equal the columns of Γ . Thus, we can conclude that

$$\mathbf{Q}^{1/2} = \mathbf{V} \Lambda^{1/2} \quad (69.34)$$

$$= \Gamma \mathbf{Diag}(e^{j\phi_m}) \quad (69.35)$$

where $\mathbf{Diag}(\cdot)$ is a diagonal matrix and the ϕ_m , $m = 1, 2$, measure the phase uncertainty of the columns of $\mathbf{Q}^{1/2}$ with respect to the columns of Γ . The last equality in Eq. (69.35) is true only when $\hat{\mathbf{A}} = \mathbf{A}$.

We now consider how to resolve this phase uncertainty. We show that this uncertainty can be resolved up to a sign difference. This means that, at least theoretically, we can achieve an estimate $\hat{\Gamma}$ whose columns are colinear with those of Γ . Using Eq. (69.34) and Eq. (69.28), it can be shown after some algebra that

$$\mathbf{f} = \mathbf{Q}^{1/2} \hat{\mathbf{A}}^\dagger \mathbf{x}_i \left(= \mathbf{Diag}(e^{-j\phi_m}) \mathbf{s}_i \right). \quad (69.36)$$

The elements of the vector \mathbf{f} have the form $e^{-j\phi_m} \mathbf{s}_{im}$, $m = 1, 2$. Defining \mathbf{F} as the diagonal matrix formed with the elements of \mathbf{f} , we define the estimate $\hat{\Gamma}$ of Γ as

$$\hat{\Gamma} = \mathbf{Q}^{1/2} \mathbf{F} \left(= \Gamma \mathbf{Diag}(\mathbf{s}_i) \right). \quad (69.37)$$

Recalling that the elements of \mathbf{s}_i are $+1$ or -1 , we see that, ideally, the columns of Γ are estimated just with a sign uncertainty. In our application, this sign uncertainty is not relevant. To see this, suppose

that one of the columns of $\hat{\Gamma}$ has its sign changed. This sign change is equivalent to an inversion of the data stream generated by one of the mobiles. This inversion of the data stream can be solved using a differential encoding scheme of the transmitted data.

In summary, the algorithm to estimate Γ is as follows:

- use \mathbf{R}_s to compute \mathbf{Q} as defined by Eq. (69.30);
- compute the singular value decomposition of \mathbf{Q} and then form the matrix $\mathbf{Q}^{1/2}$ as given by Eq. (69.34);
- compute \mathbf{f} as given by Eq. (69.36) and use its elements to form the diagonal matrix \mathbf{F} ;
- compute $\hat{\Gamma}$ defined in Eq. (69.37).

Using the results of Steps (1) and (2), we compute the estimate used to initialize the EM iteration as:

$$\mathbf{H}_0 = \mathbf{A}(\hat{\theta})\hat{\Gamma}.$$

In practice, it will be shown in the following section by computer simulations that this initial condition enables the EM algorithm to converge to the global maximum of the likelihood function with a small number of iterations. This behavior is maintained even with critical scenarios arising under very specific geometries, see Section 69.5.

The apparent drawback of the proposed initialization procedure is its computational complexity. However, this is not really a problem because we are processing blocks of data with time length T during which the geometry remains, for all practical purposes, unchanged. Also, the changes in geometry between adjacent blocks are small. This means that, except in specific situations, the EM iteration can be initialized using the estimate of \mathbf{H} obtained with the previous block of data. Hence, the algorithm is seldom reinitialized, e.g., when the number of sources present in the cell is changed.

69.5 Experiments

In this section, we present the results obtained with the array receiver designed in the previous section. The context is a cell in a cellular radio mobile communications system. The system is operating at a carrier frequency $f_0 = 1$ GHz and accommodates transmission rates of 1 Mbps with differential encoding binary phase shift keying modulation [7]. All the mobiles present in the cell generate signals that are transmitted simultaneously in the same frequency band. The power emitted by each mobile is assumed to be unity.

The receiving array is a horizontal linear, uniform array, with $N = 19$ identical omnidirectional captors. These captors are separated by half wavelength, i.e., $d = \lambda_0/2$, where $\lambda_0 = c/f_0 = 30$ cm is the center frequency wavelength, yielding an array length of 2.7 m. The geometry of the scenario is similar to that depicted in Fig. 69.6, where the reflector is parallel to the array. The reflector is located at a distance of 50 m from the array. The reflector absorbs half of the impinging power. The two mobiles M_1 and M_2 describe circular trajectories around the receiver, from right to left (counterclockwise). Their velocities are 18 Km/h for M_1 and 19 Km/h for M_2 . These are typical speeds for city traffic with slow automobiles circling a rotary. The radii of these trajectories are 30 m and 45 m, respectively. Comparing these distances with the array length, we conclude that we can safely make the planar wavefront assumption; in other words, the received signals across the array are planar wavefronts. Finally, the receiver SNR equals 10 dB for the case of the direct path generated by M_1 . This means that all the remaining paths have smaller SNRs.

In Fig. 69.7, we illustrate examples of the geometries for which we ran the multichannel MMSE beamformer. The data synthesized by the simulator was collected during each second. The data blocks have length 1 Mbit per mobile. The matrix \mathbf{H} is estimated using 3 Kbit (per mobile). In

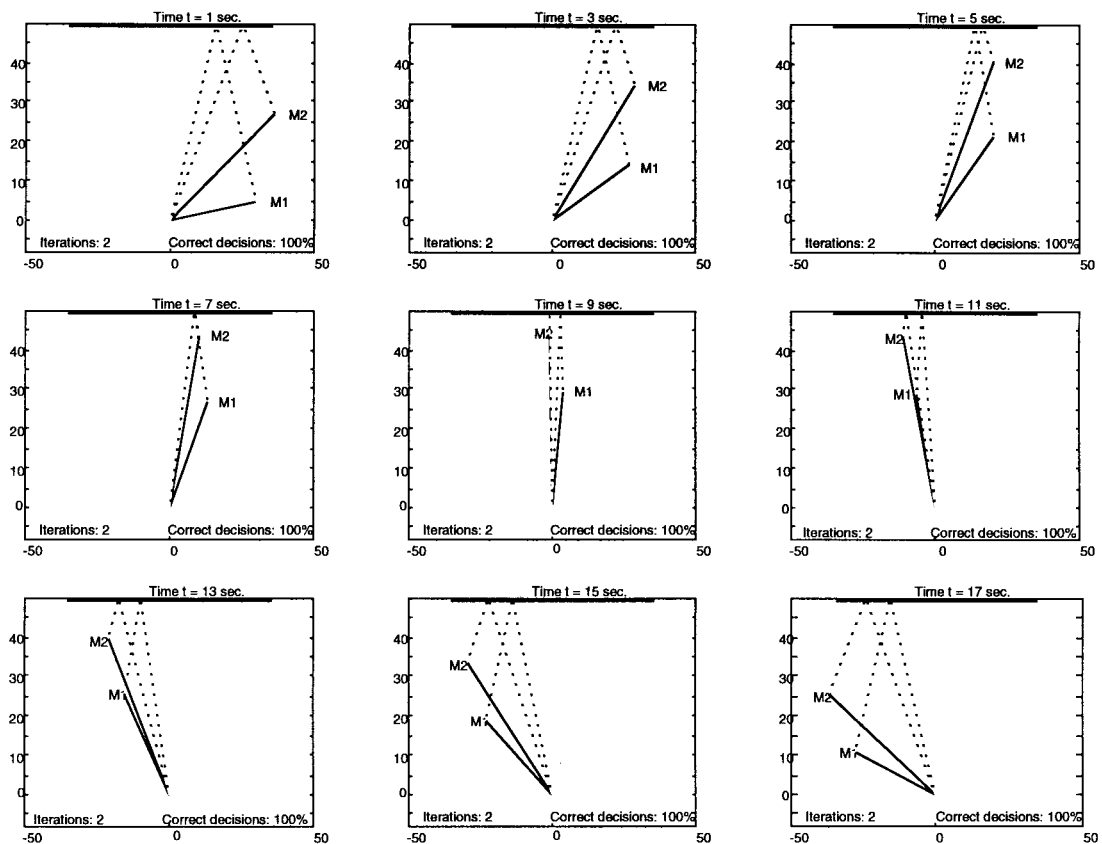

FIGURE 69.7: Simulation scenarios.

practically all scenarios that we tested, we observed that the EM algorithm converges in just two iterations. The multichannel MMSE beamforming achieved 100% of correct symbol detections for the outputs of both channels. The initialization procedure described in Section 69.4 was necessary only for the first data block (beginning at time $t = 0$). Except for the first data block, the EM algorithm was initialized with the estimate of \mathbf{H} obtained with the last adjacent data block. Notice that even for scenarios $t = 11$ and $t = 13$, where the DOAs of the direct paths are very close to each other, the EM algorithm was able to keep tracking of the columns of \mathbf{H} . In fact, each column of \mathbf{H} , representing the channel/receiving array transfer function, captures the global structure of the multipath propagation channel used by each mobile, which does not depend explicitly on the DOAs. For illustrative purposes, we show in Fig. 69.8 the amplitude response of the MMSE and the MNP beamformers as a function of the angle of arrival (beampatterns). The MMSE beampatterns were computed using the weights obtained from the synthesized data, while in the case of the MNP we used the ideal weights. We see that the behavior of both beamformers confirm what was predicted by the simple analysis carried out in Sections 69.2 and 69.3. The MMSE beamformer directs distinct beams towards the arrivals generated by the mobile being tracked and nulls all the remaining arrivals. On the contrary, the MNP beamformer cancels all the incoming wavefronts except the one corresponding to the direct path. The simulations also confirmed the improvement in the output SNR achieved by the MMSE beamformer when compared with the MNP beamformer. In our experiments, a gain close to 3 dB was obtained in almost all scenarios considered.

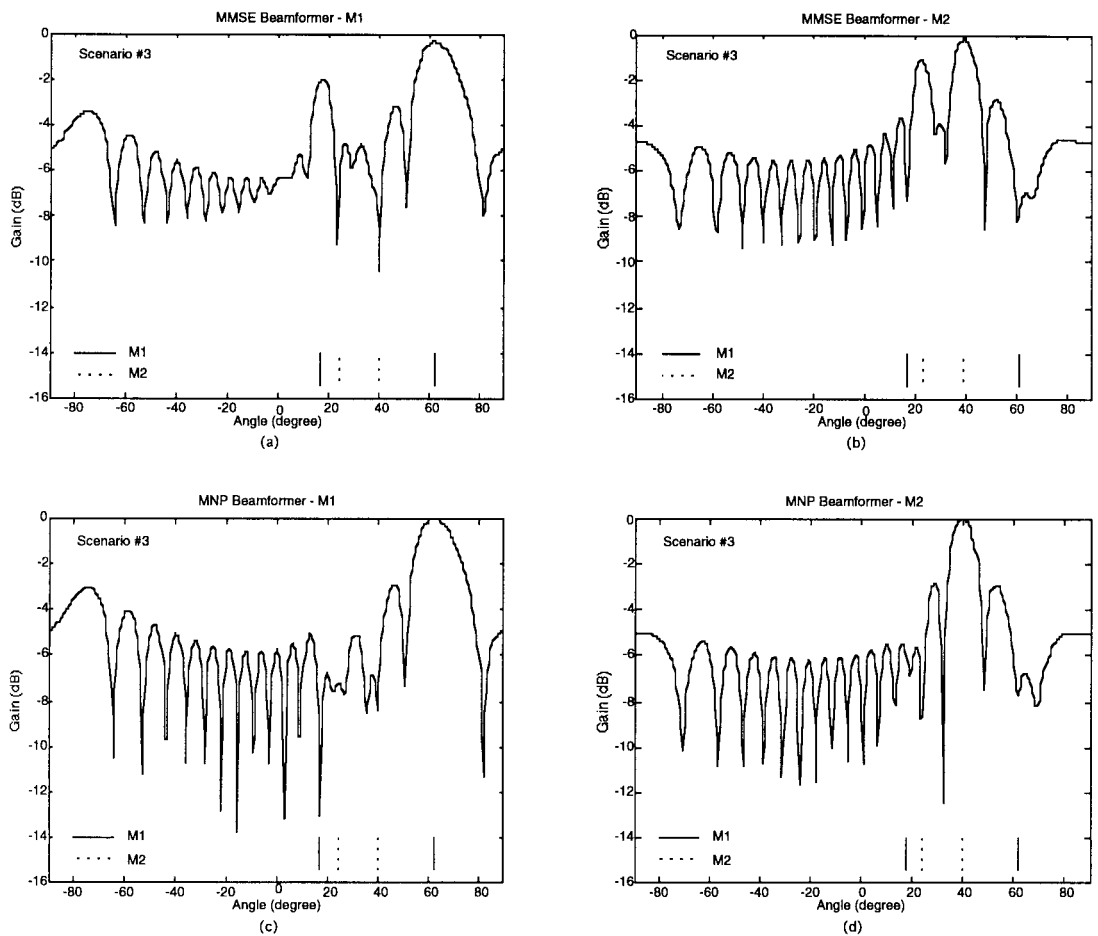

FIGURE 69.8: MMSE and MNP beampatterns: (a), (c)-channel M_1 ; (b), (d)-channel M_2 .

In this section, we showed the adequacy of the multichannel MMSE beamformer for combating multipath propagation effects as occurring in mobile communications systems. The simulations illustrated the efficiency of the implementation proposed in Section 69.4.

69.6 Conclusions

In this article, we addressed the problem of designing beamforming arrays specially suited to operate in multipath environments. The problem is motivated in the context of cellular mobile communication systems. This is a field where array processing is being recognized as a powerful technology that has the potential to improve significantly the traffic capacity of such systems. As we saw, beamforming is an efficient technique for handling several mobiles in the same cell transmitting simultaneously in the same frequency channel. Moreover, specific beamformers can be designed to optimize the receiver with respect to distortions introduced by channels, such as multipath propagation and interferences.

We proposed a solution based on the MMSE beamformer. The study presented in Section 69.3 emphasized the relevant properties of this method. In particular, it was shown that the minimum mean square error (MMSE) beamformer has an important advantage over the minimum output

noise power beamformer (MNP) introduced in Section 69.2: it combines coherently the correlated signal replicas generated by one source, while canceling the remaining interferences. Recall that the MNP beamformer nulls the secondary multipath arrivals as if they were uncorrelated interferences. Thus, the output SNR of the MMSE beamformer is always better than that of the MNP beamformer, particularly in multipath environments.

We identified the difficulties of implementing the MMSE beamformer. In particular, we pointed out that, except for the case of uncorrelated arrivals, knowledge of the direction of arrival (DOA) of the desired signal is not sufficient to implement the MMSE beamformer. We showed that, in most cases of interest, we need to know the cross-correlation between the desired signal and the array observations. In general, this cross-correlation is not previously known. It is necessary to estimate it from the available data. In other words, it is necessary to perform a blind estimation of the propagation channel. In Section 69.4 we presented a new method for estimating that correlation. It can be applied in situations where the array data have non-zero first order statistics. The method is insensitive to the correlation degree of the incoming wavefronts. This is the case that is relevant in mobile communications. Basically, the method that we described exploits the finite mixture distribution of the array data, which is organized in clusters with non-zero averages. We used a maximum likelihood approach based on the finite mixture model, the global maximum of the likelihood function being obtained by an EM iterative algorithm. As discussed, initialization of the EM algorithm is a critical issue. For a poor initial guess, the algorithm can diverge or, at most, converge to a local maximum. We provided a technique to initialize the EM algorithm. This initialization method enables the EM algorithm to converge fast to the global maximum of the likelihood function.

We tested the multichannel MMSE beamforming receiver using a simulator for a mobile communications system. We generated a simple scenario with moving sources and multiple replicas. Our results illustrated the efficiency of the receiver. In particular, the results confirm that, under the conditions studied which are typical in cellular communications, the reliability of the system is high. This is a consequence of the way we designed the MMSE beamformer which minimizes the power of the error at the output of the receiver. The MMSE beamformer relies on the accuracy of the blind estimation of the radio propagation channel. The algorithm we described can do a good job of estimating the propagating channel as long as the receiver has the ability to properly track the mobiles. In normal operation, the EM algorithm is initialized using the channel estimates obtained with the previous data block. The receiver is globally reinitialized only in very specific situations, for instance when the number of mobiles is changed. This fact simplifies the computational effort associated with the receiver. Our studies showed that the receiver converges so fast that it operates practically in real time.

Space-Time Adaptive Processing (STAP) is a multi-dimensional filtering technique developed for minimizing the effects of various kinds of interference on target detection with a pulsed airborne surveillance radar. The most common dimensions, or filtering domains, generally include the azimuth angle, elevation angle, polarization angle, doppler frequency, etc. in which the relatively weak target signal to be detected and the interference have certain differences. In the following, the STAP principle will be illustrated for filtering in the joint azimuth angle (space) and doppler frequency (time) domain only.

STAP has been a very active research and development area since the publication of Reed et al.'s seminal paper [1]. With the recently completed Multichannel Airborne Radar Measurement project (MCARM) [2]–[5], STAP has been established as a valuable alternative to the traditional approaches, such as ultra-low sidelobe beamforming and Displaced Phase Center Antenna (DPCA) [6]. Much of STAP research and development efforts have been driven by the needs to make the system affordable, to simplify its front-hardware calibration, and to minimize the system's performance loss in severely nonhomogeneous environments. Figure 70.1 is a general configuration of STAP functional blocks [5, 7] whose principles will be discussed in the following sections.

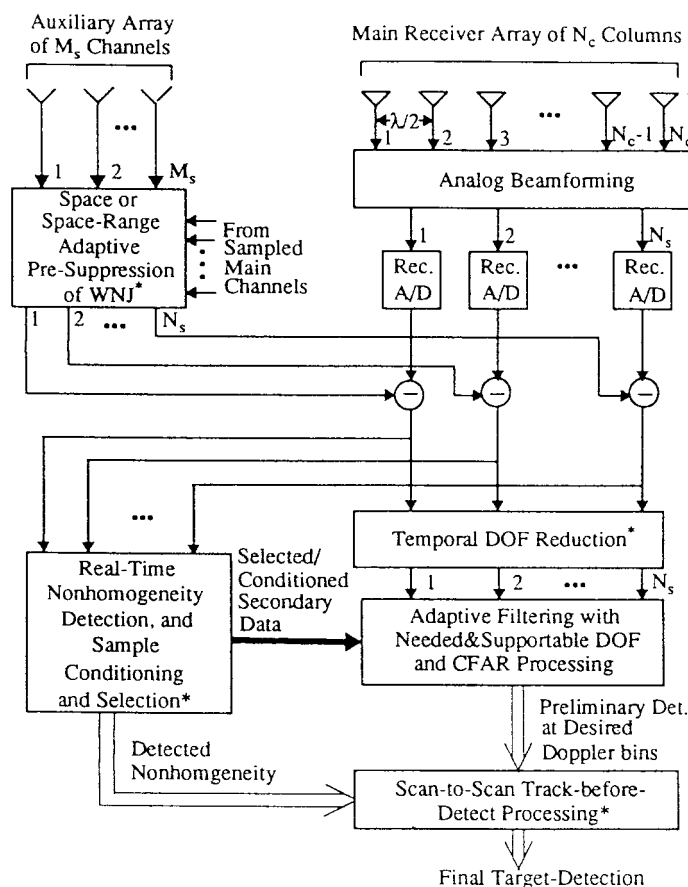

FIGURE 70.1: A general STAP configuration with auxiliary and main arrays.

70.1 Main Receive Aperture and Analog Beamforming

For conceptual clarity, the STAP configuration of Fig. 70.1 separates a possibly integrated aperture into two parts: the main aperture which is most likely shared by the radar transmitter, and an auxiliary array of spatially distributed channels for suppression of Wideband Noise Jammers (WNJ). For convenience of discussion, the main aperture is assumed to have N_c columns of elements, with the column spacing equal to a half wavelength and elements in each column being combined to produce a pre-designed, nonadaptive elevation beam-pattern.

The size of the main aperture in terms of the system's chosen wavelength is an important system parameter, usually determined by the system specifications of the required transmitter power-aperture product as well as azimuth resolution. Typical aperture size spans from a few wavelengths for some short-range radars to over 60 wavelengths for some airborne early warning systems. The analog beamforming network combines the N_c columns of the main aperture to produce N_s receiver channels whose outputs are digitized for further processing. One should note that the earliest STAP approach presented in [1], i.e., the so-called "element space" approach, is a special case of Fig. 70.1 when $N_s = N_c$ is chosen.

The design of the analog beamformer affects

1. the system's overall performance (especially in nonhomogeneous environments),
2. implementation cost,
3. channel calibration burden,
4. system reliability, and
5. controllability of the system's response pattern.

The design principle will be briefly discussed in Section 70.9; and because of the array's element error, column-combiner error, and column mutual-coupling effects, it is quite different from what is available in the adaptive array literature such as [8], where already digitized, perfectly matched channels are generally assumed.

Finally, it should be pointed out that the main aperture and analog beamforming network in Fig. 70.1 may also include nonphased-array hardware, such as the common reflector-feed as well as the hybrid reflector and phased-array feed [9]. Also, subarraying such as [10] is considered as a form of analog beamforming of Fig. 70.1.

70.2 Data to be Processed

Assume that the radar transmits, at each look angle, a sequence of N_t uniformly spaced, phase-coherent RF pulses as shown in Fig. 70.2 for its envelope only. Each of N_s receivers typically consists of a front-end amplifier, down-converter, waveform-matched filter, and A/D converter with a sampling frequency at least equal to the signal bandwidth. Consider the k th sample of radar return over the N_t pulse repetition intervals (PRI) from a single receiver, where the index “ k ” is commonly called the range index or cell. The total number of range cells, K_0 is approximately equal to the product of the PRI and signal bandwidth. The coherent processing interval (CPI) is the product of the PRI and N_t ; and since a fixed PRI can usually be assumed at a given look angle, CPI and N_t are often used interchangeably.

FIGURE 70.2: A sequence of N_t phase-coherent RF pulses (only envelope shown) transmitted at a given angle. The pulse repetition frequency (PRF) is $1/T$.

With N_s receiver channels, the data at the k th range cell can be expressed by a matrix X_k , $N_s \times N_t$, for $k = 1, 2, \dots, K_0$. The total amount of data visually forms a “cube” shown in Fig. 70.3, which is the raw data cube to be processed at a given look angle. It is important to note from Fig. 70.3 that the term “time” is associated with the CPI for any given range cell, i.e., across the multiple PRI, while the term “range” is used within a PRI. Therefore, the meaning of the frequency corresponding to the time is the so-called doppler frequency, describing the rate of the phase-shift progression of a return component with respect to the initial phase of the phase-coherent pulse train. The doppler frequency of a return, e.g., from a moving target, depends on the target velocity and direction as well as the airborne radar's platform velocity and direction, etc.

FIGURE 70.3: Raw data at a given look angle and the space, time, and range axes.

70.3 The Processing Needs and Major Issues

At a given look angle, the radar is to detect the existence of targets of unknown range and unknown doppler frequency in the presence of various interference. In other words, one can view the processing as a mapping from the data cube to a range-doppler plane with sufficient suppression of unwanted components in the data. Like any other filtering, the interference suppression relies on the differences between wanted target components and unwanted interference components in the angle-doppler domain. Figure 70.4 illustrates the spectral distribution of potential interference in the spatial and temporal (doppler) frequency domain before the analog beamforming network, while Fig. 70.5 shows a typical range distribution of interference power. As targets of interest usually have unknown doppler frequencies and unknown distances, detection needs to be carried out at sufficiently dense doppler frequencies along the look angle for each range cell within the system's surveillance volume. For each cell at which target detection is being carried out, some of surrounding cells can be used to produce an estimate of interference statistics (usually up to the second order), i.e., providing "sample support", under the assumption that all cells involved have an identical statistical distribution. Figure 70.4 also shows that, in terms of their spectral differences, traditional wideband noise jammers, whether entering the system through direct path or multipath (terrain scattering/near-field scattering), require spatial nulling only; while clutter and chaff require angle-doppler coupled nulling. Coherent repeater jammers (CRJ) represent a nontraditional threat of a target-like spectral feature with randomized ranges and doppler frequencies, making them more harmful to adaptive systems than to conventional nonadaptive systems [11].

Although Fig. 70.5 has already served to indicate that the interference is nonhomogeneous in range, i.e., its statistics vary along the range axis, recent airborne experiments have revealed that its severeness may have long been underestimated, especially over land [3]. Figure 70.6 [5, 7] summarizes the sources of various nonhomogeneity together with their main features. As pointed out in [12], a serious problem associated with any STAP approach is its basic assumption that there is a sufficient amount of sample support for its adaptive learning, which is most often void in real environments even in the absence of any nonhomogeneity type of jammers such as CRJ. Therefore, a crucial issue for the success of STAP in real environments is the development of data-efficient STAP approaches, in conjunction with the selection of reasonably identically distributed samples before estimating interference statistics. To achieve a sufficient level of the data efficiency in nonhomogeneous environments, the three most performance- and cost-effective methods are temporal degrees-of-freedom (DOF) reduction, analog beamforming to control the spatial DOF creation, and pre-suppression of WNJ as shown in Fig. 70.1.

Another crucial issue is the affordability of STAP-based systems. As pointed out in [9], phased-arrays, especially those active ones (i.e., with the so-called T/R modules), remain very expensive despite the 30-year research and development. For multichannel systems, the cost of adding more

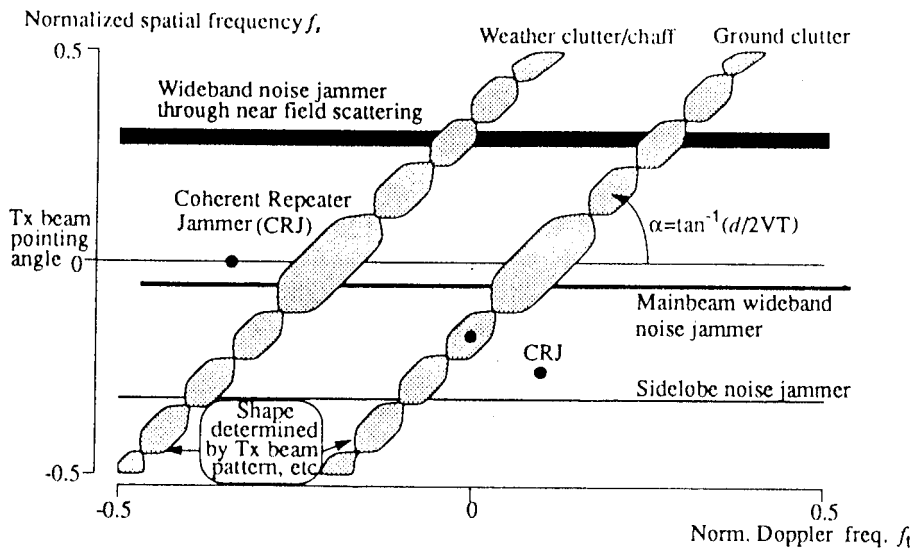

FIGURE 70.4: Illustration of interference spectral distribution for a side-mounted aperture.

receivers and A/D converters with a sufficient quality makes the affordability even worse.

Of course, more receiver channels mean more system's available spatial DOF. However, it is often the case in practice that the excessive amount of the DOF, e.g., obtained via one receiver channel for each column of a not-so-small aperture, is not necessary to the system. Ironically, excessive DOF can make the control of the response pattern more difficult, even requiring significant algorithm constraints [8]; and after all, it has to be reduced to a level supportable by the available amount of reasonably identically distributed samples in real environments. An effective solution, as demonstrated in a recent STAP experiment [13], is via the design of the analog beamformer that does not create unnecessary spatial DOF from the beginning — a sharp contrast to the DOF reduction/constraint applied in the spatial domain.

Channel calibration is a problem issue for many STAP approaches. In order to minimize performance degradation, the channels with some STAP approaches must be matched across the signal band, and steering vectors must be known to match the array. Considering the fact that channels generally differ in both elevation and azimuth patterns (magnitude as well as phase) even at a fixed frequency, the calibration difficulty has been underestimated as experienced in recent STAP experiments [5]. It is still commonly wished that the so-called “element-space” approaches, i.e., the special case of $N_s = N_c$ in Fig. 70.1, with an adaptive weight for each error-bearing “element” which hopefully can be modeled by a complex scalar, could solve the calibration problem at a significantly increased system-implementation cost as each element needs a digitized receiver channel. Unfortunately, such a wish can rarely materialize for a system with a practical aperture size operated in nonhomogeneous environments. With a spatial DOF reduction required by these approaches to bring down the number of adaptive weights to a sample-supportable level, the element errors are no longer directly accessible by the adaptive weights, and thus the wishful “embedded robustness” of these element-space STAP approaches is almost gone. In contrast, the MCARM experiment has demonstrated that, by making best use of what has already been excelled in antenna engineering [13], the channel calibration problem associated with STAP can be largely solved at the analog beamforming stage, which will be discussed in Section 70.9.

The above three issues all relate to the question: “What is the minimal spatial and temporal DOF

FIGURE 70.5: Illustration of interference-power range distribution, where Δ_h indicates the radar platform height.

required?" To simplify the answer, it can be assumed first that clutter has no Doppler spectral spread caused by its internal motion during the CPI, i.e., its spectral width cut along the doppler frequency axis of Fig. 70.4 equals to zero. For WNJ components of Fig. 70.4, the required minimal spatial DOF is well established in array processing, and the required minimal temporal DOF is zero as no temporal processing can help suppress these components. The CRJ components appear only in isolated range cells as shown in Fig. 70.5, and thus they should be dealt with by sample conditioning and selection so that the system response does not suffer from their random disturbance. With the STAP configuration of Fig. 70.1, i.e., pre-suppression of WNJ and sample conditioning and selection for CRJ, the only interference components left are those angle-doppler coupled clutter/chaff spectra of Fig. 70.4. It is readily available from the two-dimensional filtering theory [14] that suppression of each of these angle-doppler coupled components only requires one spatial DOF and one temporal DOF of the joint domain processor! In other words, a line of infinitely many nulls can be formed with one spatial DOF and one temporal DOF on top of one angle-doppler coupled interference component under the assumption that there is no clutter internal motion over the CPI. It is also understandable that, when such an assumption is not valid, one only needs to increase the temporal DOF of the processor so that the null width along the doppler axis can be correspondingly increased.

For conceptual clarity, $N_s - 1$ will be called the system's available spatial DOF and $N_t - 1$ the system's available temporal DOF. While the former has a direct impact on the implementation cost, calibration burden, and system reliability, the latter is determined by the CPI length and PRI with little cost impact, etc. Mainly due to the nonhomogeneity-caused sample support problem discussed earlier, the adaptive joint domain processor may have its spatial DOF and temporal DOF, denoted by N_{ps} and N_{pt} respectively, different from the system's availables by what is so-called DOF reduction. However, the spatial DOF reduction should be avoided by establishing the system's available spatial DOF as close to what is needed as possible from the beginning.

70.4 Temporal DOF Reduction

Typically an airborne surveillance radar has N_t anywhere between 8 and 128, depending on the CPI and PRI. With the processor's temporal DOF, N_{pt} , needed for the adjustment of the null width, normally being no more than $2 \sim 4$, huge DOF reduction is usually performed for the reasons of the sample support and better response-pattern control explained in Section 70.3.

FIGURE 70.6: Typical nonhomogeneities.

An optimized reduction could be found, given N_t , N_{pt} , and the interference statistics which are still unknown at this stage of processing in practice [7]. There are several non-optimized temporal DOF reduction methods available, such as the Doppler-domain (joint domain) localized processing (DDL/JDL) [12, 15, 16] and the PRI-staggered Doppler-decomposed processing (PRI-SDD) [17], which are well behaved and easy to implement. The DDL/JDL principle will be discussed below.

The DDL/JDL consists of unwindowed/untapered DFT of (at least) N_t -point long, operated on each of the N_s receiver outputs. The same $N_{pt} + 1$ most adjacent frequency bins of the DFTs of the N_s receiver outputs form the new data matrix at a given range cell, for detection of a target whose Doppler frequency is equal to the center bin. Figure 70.7 shows an example for $N_s = 3$, $N_t = 8$, and $N_{pt} = 2$. In other words, the DDL/JDL transforms the raw data cube of $N_s \times N_t \times K_0$ into (at least) N_t smaller data cubes, each of $N_s \times (N_{pt} + 1) \times K_0$ for target detection at the center doppler bin.

The DDL/JDL is noticeable for the following features.

1. There is no so-called signal cancellation, as the unwindowed/untapered DFT provides no desired signal components in the adjacent bins (i.e., reference “channel”) for the assumed target doppler frequency.
2. The grouping of $N_{pt} + 1$ most adjacent bins gives a high degree of correlation between the interference component at the center bin and those at the surrounding bins — a feature important to cancellation of any spectrum-distributed interference such as clutter. The cross-spectral algorithm [18] also has this feature.
3. The response pattern can be well controlled as N_{pt} can be kept small — just enough for the needed null-width adjustment; and N_{pt} itself easily can be adjusted to fit different clutter spectral spread due to its internal motion.
4. Obviously the DDL/JDL is suitable for parallel processing.

While the DDL/JDL is a typical transformation-based temporal DOF reduction method, other methods involving the use of DFTs are not necessarily transformation-based. An example is the PRI-SDD [17] which applies time-domain temporal DOF reduction on each doppler component. This explains why the PRI-SDD requires N_{pt} times more DFTs that should be tapered. It also serves

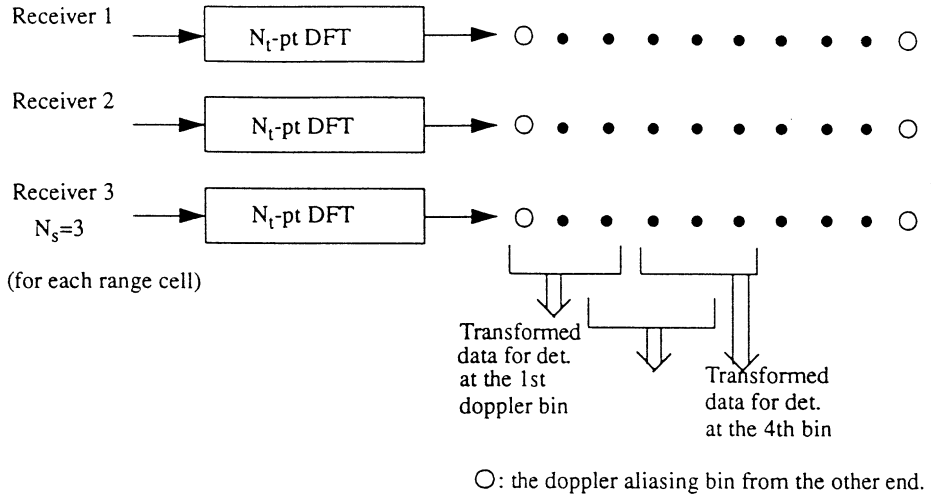

FIGURE 70.7: The DDL/JDL principle for temporal DOF reduction illustrated with $N_s = 3$, $N_t = 8$, and $N_{pt} = 2$.

as an example that an algorithm classification by the existence of the DFT use may cause a conceptual confusion.

70.5 Adaptive Filtering with Needed and Sample-Supportable DOF and Embedded CFAR Processing

After the above temporal DOF reduction, the dimension of the new data cube to be processed at a given look angle for each doppler bin is $N_s \times (N_{pt} + 1) \times K_0$. Consider a particular range cell at which target detection is being performed. Let \mathbf{x} , $N_s(N_{pt} + 1) \times 1$, be the stacked data vector of this range cell, which is usually called the primary data vector. Let $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_k$, all $N_s(N_{pt} + 1) \times 1$ and usually called the secondary data, be the same-stacked data vectors of the K surrounding range cells, which have been selected and/or conditioned to eliminate any significant nonhomogeneities with respect to the interference contents of the primary data vector. Let \mathbf{s} , $N_s(N_{pt} + 1) \times 1$, be the target-signal component of \mathbf{x} with the assumed angle of arrival equal to the look angle and the assumed doppler frequency corresponding to the center doppler bin. In practice, a look-up table of the “steering vector” \mathbf{s} for all look-angles and all doppler bins usually has to be stored in the processor, based on updated system calibration. A class of STAP systems with the steering-vector calibration-free feature has been developed, and an example from [13] will be presented in Section 70.9.

There are two classes of adaptive filtering algorithms: one with a separately designed constant false alarm rate (CFAR) processor, and the other with embedded CFAR processing. The original sample matrix inversion algorithm (SMI) [1] belongs to the former, which is given by

$$\eta_{SMI} = \left| \hat{\mathbf{w}}_{SMI}^H \mathbf{x} \right|^2 \underset{H_0}{\overset{H_1}{>}} \eta_0 \quad (70.1)$$

where

$$\mathbf{w}_{SMI} = \hat{\mathbf{R}}^{-1} \mathbf{s}, \quad (70.2)$$

and

$$\hat{\mathbf{R}} = \frac{1}{K} \sum_{k=1}^K \mathbf{y}_k \mathbf{y}_k^H \quad (70.3)$$

The SMI performance under the Gaussian noise/interference assumption has been analyzed in detail [1], and in general it is believed that acceptable performance can be expected if the data vectors are independent and identically distributed (iid) with K , the number of the secondary, being at least two times $N_s(N_{pt} + 1)$. Detection performance evaluation using a SINR-like measure deserves some care when K is finite, even under the iid assumption [19, 20].

If the output of an adaptive filter, when directly used for threshold detection, produces a probability of false alarm independent of the unknown interference correlation matrix under a set of given conditions, the adaptive filter is said to have an embedded CFAR. Under the iid Gaussian condition, two well-known algorithms with embedded CFAR are the Modified SMI [21] and Kelly's generalized likelihood ratio detector (GLR) [22], both of which are linked to the SMI as shown in Fig. 70.8. The

FIGURE 70.8: The link among the SMI, modified SMI (MSMI), and GLR where $N = (N_{ps} + 1)(N_{pt} + 1) \times 1$.

GLR has the following interesting features:

1. $0 < \frac{1}{K} \eta_{GLR} < 1$, which is a necessary condition for robustness in nongaussian interference [23].
2. Invariance with respect to scaling all data or scaling \mathbf{s} .
3. One cannot express η_{GLR} as $\hat{\mathbf{w}}^H \mathbf{x}$; and with a finite K , an objective definition of its output SINR becomes questionable.

Table 70.1 summarizes the modified SMI and GLR performance, based on [21, 24].

It should be noted that the use of the scan-to-scan track-before-detect processor (SSTBD to be discussed in Section 70.6) does not make the CFAR control any less important because the SSTBD itself is not error-free even with the assumption that almost infinite computing power would be available. Moreover, the initial CFAR thresholding can actually optimize the overall performance, in addition to a dramatic reduction of the computation load of the SSTBD processor. Traditionally, filter and CFAR designs have been carried out separately, which is valid as long as the filter is not data-dependent. Therefore, such a traditional practice becomes questionable for STAP, especially when K

TABLE 70.1 Performance Summary of Modified SMI and GLR

Performance compared	GLR	Modified SMI
Gaussian interference suppression	Similar performance	
Nongaussian interference suppression	More robust	Less robust
Rejection of signals mismatched to the steering vector	Better	Worse

is not very large with respect to $N_s(N_{pt} + 1)$, or when some of the secondary data depart from the iid Gaussian assumption that will affect both filtering and CFAR portions. The GLR and Modified SMI start to change the notion that “CFAR is the other guy’s job”, and their performance has been evaluated in some nongaussian interference [21] as well as in some nonhomogeneities [25]. Finally, it should be pointed out that performance evaluation of STAP algorithms with embedded CFAR by an output SINR-like measure may result in underestimating the effects of some nonhomogeneity such as the CRJ [11].

70.6 Scan-To-Scan Track-Before-Detect Processing

The surveillance volume is usually visited by the radar many times, and the output data collected over multiple scans (i.e., revisits) are correlated and should be further processed together for the updated and improved final target-detection report. For example, random threshold-crossings over multiple scans due to the noise/interference suppression residue can rarely form a meaningful target trajectory and therefore their effect can be deleted from the final report with a certain level of confidence (but not error-free).

For a conventional ground-based radar, scan-to-scan track-before-detect processing (SSTBD) has been well studied and a performance demonstration can be found in [26]. With a STAP-based airborne system, however, much remains to be researched. One crucial issue, coupled with the initial CFAR control, is to answer what is the optimal or near optimal setting of the first CFAR threshold, given an estimate of the current environment including the detected nonhomogeneity. Further discussion of this subject seems out of the scope of this book and still premature.

70.7 Real-Time Nonhomogeneity Detection and Sample Conditioning and Selection

Recent experience with MCARM Flight 5 data has further demonstrated that successful STAP system operation over land heavily relies on the handling of the nonhomogeneity contamination of samples [3, 5], even without intentional nonhomogeneity producing jammers such as CRJ. It is estimated that the total number of reasonably good samples over land may be as few as $10 \sim 20$. Although some system approaches to obtaining more good samples are available, such as multiband signaling [27, 28], it is still essential that a system has the capability of real-time detection of nonhomogeneities, selection of sufficiently good samples to be used as the secondary, and conditioning not-so-good samples in the case of a severe shortage of the good samples. The development of a nonhomogeneity detector can be found in [3], and its integration into the system remains to be a research issue.

Finally, it should be pointed out that the utilization of a sophisticated sample selection scheme makes it nearly unnecessary to look into the so-called training strategy such as sliding window, sliding hole, etc. Also, desensitizing a STAP algorithm via constraints and/or diagonal loading has been found to be less effective than the sample selection [28].

70.8 Space or Space-Range Adaptive Pre-Suppression of Jammers

Wideband noise jammers (WNI) have a flat or almost flat Doppler spectrum which means that without multipath/terrain-scattering (TS), only spatial nulling is necessary. Although STAP could handle, at least theoretically, the simultaneous suppression of WNI and clutter simply with an increase of the processor's spatial DOF (N_{ps}), doing so would unnecessarily raise the size of the correlation matrix which, in turn, requires more samples for its estimation. Therefore, spatial adaptive pre-suppression (SAPS) of WNI, followed by STAP-based clutter suppression, is preferred for systems to be operated in severely nonhomogenous environments. Space-range adaptive processing (SRAP) may become necessary in the presence of multipath/TS to exploit the correlation between the direct path and indirect paths for better suppression of the total WNI effects on the system performance.

The idea of cascading SAPS and STAP itself is not new, and the original work can be found in [29], with other names such as “two step nulling (TSN)” used in [30]. A key issue in applying this idea is the acquisition of the necessary jammer-only statistics for adaptive suppression, free from strong clutter contamination. Available acquisition methods include the use of clutter-free range-cells for low PRF systems, clutter-free Doppler bins for high PRF systems, or receive-only mode between two CPIs. All of these techniques require jammer data to be collected within a restricted region of the available space-time domain, and may not always be able to generate sufficient jammer-only data. Moreover, fast-changing jamming environments and large-scale PRF hopping can also make these techniques unsuitable. Reference [31] presents a new technique that makes use of frequency sidebands close to, but disjointed from, the radar's mainband, to estimate the jammer-only covariance matrix. Such an idea can be applied to a system with any PRF, and the entire or any appropriate portion of the Range Processing Interval (RPI) could be used to collect jammer data. It should be noted that wideband jammers are designed to sufficiently cover the radar's mainband, making sidebands, of more or less bandwidth, containing their energy always available to the new SAPS technique.

The discussion of the sideband-based STAP can be carried out with different system configurations, which determine the details on the sideband-to-mainband jammer information conversion, as well as the mainband jammer-cancellation signal generation. Reference [31] chooses a single array-based system, while a discussion involving an auxiliary-main array configuration can be found in [7].

70.9 A STAP Example with a Revisit to Analog Beamforming

In the early stage of STAP research, it is always assumed that $N_s = N_c$, i.e., each column consumes a digitized receiver channel, regardless of the size of the aperture. More recent research and experiments have revealed that such an “element-space” set up is only suitable for sufficiently small apertures, and the analog beamforming network has become an important integrated part of STAP-based systems with more practical aperture sizes.

The theoretically optimized analog beamformer design could be carried out for any given N_s , which yields a set of N_s nonrealizable beams once the element error, column-combiner error, and column mutual-coupling effects are factored in. A more practical approach is to select, from what antenna design technology has excelled, those beams that also meet the basic requirements for successful adaptive processing, such as the “signal blocking” requirement developed under the generalized sidelobe canceller [32]. Two examples of proposed analog beamforming methods for STAP applications are (1) multiple shape-identical Fourier beams via the Butler matrix [12], and (2) the sum and difference beams [13]. Both selections have been shown to enable the STAP system to achieve near optimal performance with N_s very close to the theoretical minimum of two for clutter suppression.

In the following, the clutter suppression performance of a STAP with the sum(Σ)-difference(Δ) beams is presented using the MCARM Flight 2 data. The clutter in this case was collected from a rural area in the eastern shore region south of Baltimore, Maryland. A known target signal was injected at

a Doppler frequency slightly offset from mainlobe clutter and the results compared for the factored approach (FA-STAP) [16] and $\Sigma\Delta$ -STAP. A Modified SMI processor was used in each case to provide a known threshold level based on a false alarm probability of 10^{-6} . As seen in Figs. 70.9 and 70.10, the injected target lies below the detection threshold for FA-STAP, but exceeds the threshold in the case of $\Sigma\Delta$ -STAP. This performance was obtained using far fewer samples for covariance estimation in the case of $\Sigma\Delta$ -STAP. Also, the $\Sigma\Delta$ -STAP uses only 2 receiver channels, while the FA-STAP consumes all 16 channels.

FIGURE 70.9: Range-Doppler plot of MCARM data, factored approach.

In terms of calibration burden, the $\Sigma\Delta$ -STAP uses two different channels to begin with and its corresponding signal (steering) vector easily remains the simplest form as long as the null of the Δ beam is correctly placed (a job in which antenna engineers have excelled already). In that sense, the $\Sigma\Delta$ -STAP is both channel calibration-free and steering-vector calibration-free. On the other hand, keeping the 16 channels of FA-STAP calibrated and updating its steering vector look-up table have been a considerable burden during the MCARM experiment [4].

Another significant affordability issue is the applicability of $\Sigma\Delta$ -STAP to existing radar systems, both phased array and continuous aperture. Adaptive clutter rejection in the joint angle-doppler domain can be incorporated into existing radar systems by digitizing the difference channel, or making relatively minor antenna modifications to add such a channel. Such a relatively low cost add-on can significantly improve the clutter suppression performance of an existing airborne radar system, whether its original design is based on low sidelobe beamforming or $\Sigma\Delta$ -DPCA.

While the trend is toward more affordable computing hardware, STAP processing still imposes a considerable burden which increases sharply with the order of the adaptive processor and radar bandwidth. In this respect, $\Sigma\Delta$ -STAP reduces computational requirements in matrix order N^3 adaptive problems. Moreover, the signal vector characteristic (mostly zero) can be exploited to

FIGURE 70.10: Range-Doppler plot of MCARM data, $\Sigma\Delta$ -STAP.

further reduce test statistic numerical computations.

Finally, it should be pointed out that more than one Δ -beam can be incorporated if needed for clutter suppression [33].

70.10 Summary

Over the 22 years from a theoretical paper [1] to the MCARM experimental system, STAP has been established as a valuable alternative to the traditional airborne surveillance radar design approaches. Initially, STAP was viewed as an expensive technique only for newly designed phased-arrays with many receiver channels; and now it has become much more affordable for both new and some existing systems. Future challenges lie in the area of real system design and integration, to which the MCARM experience is invaluable.

TRADITIONALLY, SIGNAL PROCESSING as a discipline has relied heavily on a theoretical foundation of linear time-invariant system theory in the development of algorithms for a broad range of applications. In recent years a considerable broadening of this theoretical base has begun to take place. In particular, there has been substantial growth in interest in the use

of a variety of nonlinear systems with special properties for diverse applications. Promising new techniques for the synthesis and analysis of such systems continue to emerge. At the same time, there has also been rapid growth in interest in systems that are not constrained to be time-invariant. These may be systems that exhibit temporal fluctuations in their characteristics, or, equally importantly, systems characterized by other invariance properties, such as invariance to scale changes. In the latter case, this gives rise to systems with fractal characteristics.

In some cases, these systems are directly applicable for implementing various kinds of signal processing operations such as signal restoration, enhancement, or encoding, or for modeling certain kinds of distortion encountered in physical environments. In other cases, they serve as mechanisms for generating new classes of signal models for existing and emerging applications. In particular, when autonomous or driven by simpler classes of input signals, they generate rich classes of signals at their outputs. In turn, these new classes of signals give rise to new families of algorithms for efficiently exploiting them in the context of applications.

The spectrum of techniques for nonlinear signal processing is extremely broad, and in this chapter we make no attempt to cover the entire array of exciting new directions being pursued within the community. Rather, we present a very small sampling of several highly promising and interesting ones to suggest the richness of the topic.

A brief overview of the specific chapters comprising this section is as follows.

Chapters 71 and 72 discuss the chaotic behavior of certain nonlinear dynamical systems and suggest ways in which this behavior can be exploited. In particular, Chapter 71 focuses on continuous-time chaotic systems characterized by a special self-synchronization property that makes them potentially attractive for a range of secure communications applications. Chapter 72 describes a family of discrete-time nonlinear dynamical and chaotic systems that are particularly attractive for use in a variety of signal processing applications ranging from signal modeling in power converters to pseudorandom number generation and error-correction coding in signal transmission applications.

Chapter 73 discusses fractal signals which arise out of self-similar system models characterized by scale-invariance. These represent increasingly important models for a range of natural and man-made phenomena in applications involving both signal synthesis and analysis. Multidimensional fractals also arise in the state-space representation of chaotic signals, and the fractal properties in this representation are important in the identification, classification, and characterization of such signals.

Chapter 74 focuses on morphological signal processing, which encompasses an important class of nonlinear filtering techniques together with some powerful associated signal representations. Morphological signal processing is closely related to a number of classes of algorithms including order-statistics filtering, cellular automata methods for signal processing, and others. Morphological algorithms are currently among the most successful and widely used nonlinear signal processing techniques in image processing and vision for such tasks as noise suppression, feature extraction, segmentation, and others.

Chapter 75 discusses the analysis and synthesis of soliton signals and their potential use in communication applications. These signals arise in systems satisfying certain classes of nonlinear wave equations. Because they propagate through those equations without dispersion, there has been longstanding interest in their use as carrier waveforms over fiber-optic channels having the appropriate nonlinear characteristics. As they propagate through these systems, they also exhibit a special type of reduced-energy superposition property that suggests an interesting multiplexing strategy for communications over linear channels.

Finally, Chapter 76 discusses nonlinear representations for stochastic signals in terms of their higher-order statistics. Such representations are particularly important in the processing of non-Gaussian signals for which more traditional second-moment characterizations are often inadequate. The associated tools of higher-order spectral analysis find increasing application in many signal detection, identification, modeling, and equalization contexts, where they have led to new classes of powerful signal processing algorithms.

Again, these articles are only representative examples of the many emerging directions in this active area of research within the signal processing community, and developments in many other important and exciting directions can be found in the community's journal and conference publications.

71.1 Introduction

Signals generated by chaotic systems represent a potentially rich class of signals both for detecting and characterizing physical phenomena and in synthesizing new classes of signals for communications, remote sensing, and a variety of other signal processing applications.

In classical signal processing a rich set of tools has evolved for processing signals that are deterministic and predictable such as transient and periodic signals, and for processing signals that are stochastic. Chaotic signals associated with the homogeneous response of certain nonlinear dynamical systems do not fall in either of these classes. While they are deterministic, they are not predictable in any practical sense in that even with the generating dynamics known, estimation of prior or future values from a segment of the signal or from the state at a given time is highly ill-conditioned. In many ways these signals appear to be noise-like and can, of course, be analyzed and processed using classical techniques for stochastic signals. However, they clearly have considerably more structure than can be inferred from and exploited by traditional stochastic modeling techniques.

The basic structure of chaotic signals and the mechanisms through which they are generated are described in a variety of introductory books, e.g., [1, 2] and summarized in [3].

Chaotic signals are of particular interest and importance in experimental physics because of the wide range of physical processes that apparently give rise to chaotic behavior. From the point of view of signal processing, the detection, analysis, and characterization of signals of this type present a significant challenge. In addition, chaotic systems provide a potentially rich mechanism for signal design and generation for a variety of communications and remote sensing applications.

71.2 Modeling and Representation of Chaotic Signals

The state evolution of chaotic dynamical systems is typically described in terms of the nonlinear state equation $\dot{x}(t) = F[x(t)]$ in continuous time or $x[n] = F(x[n-1])$ in discrete time. In a signal processing context, we assume that the observed chaotic signal is a nonlinear function of the state and would typically be a scalar time function. In discrete-time, for example, the observation equation would be $y[n] = G(x[n])$. Frequently the observation $y[n]$ is also distorted by additive noise, multipath effects, fading, etc.

Modeling a chaotic signal can be phrased in terms of determining from clean or distorted observations, a suitable state space and mappings $F(\cdot)$ and $G(\cdot)$ that capture the aspects of interest in the observed signal y . The problem of determining from the observed signal a suitable state space in which to model the dynamics is referred to as the embedding problem. While there is, of course, no unique set of state variables for a system, some choices may be better suited than others. The most commonly used method for constructing a suitable state space for the chaotic signal is the method of delay coordinates in which a state vector is constructed from a vector of successive observations.

It is frequently convenient to view the problem of identifying the map associated with a given chaotic signal in terms of an interpolation problem. Specifically, from a suitably embedded chaotic signal it is possible to extract a codebook consisting of state vectors and the states to which they subsequently evolve after one iteration. This codebook then consists of samples of the function F spaced, in general, non-uniformly throughout state space. A variety of both parametric and nonparametric methods for interpolating the map between the sample points in state space have emerged in the literature, and the topic continues to be of significant research interest. In this section we briefly comment on several of the approaches currently used. These and others are discussed and compared in more detail in [4].

One approach is based on the use of locally linear approximations to F throughout the state space [5, 6]. This approach constitutes a generalization of autoregressive modeling and linear prediction and is easily extended to locally polynomial approximations of higher order. Another approach is based on fitting a global nonlinear function to the samples in state space [7].

A fundamentally rather different approach to the problem of modeling the dynamics of an embedded signal involves the use of hidden Markov models [8, 9, 10]. With this method, the state space is discretized into a large number of states, and a probabilistic mapping is used to characterize transitions between states with each iteration of the map. Furthermore, each state transition spawns a state-dependent random variable as the observation $y[n]$. This framework can be used to simultaneously model both the detailed characteristics of state evolution in the system and the noise inherent in the observed data. While algorithms based on this framework have proved useful in modeling chaotic signals, they can be expensive both in terms of computation and storage requirements due to the large number of discrete states required to adequately capture the dynamics.

While many of the above modeling methods exploit the existence of underlying nonlinear dynamics, they do not explicitly take into account some of the properties peculiar to *chaotic* nonlinear dynamical systems. For this reason, in principle, the algorithms may be useful in modeling a broader class of signals. On the other hand, when the signals of interest are truly chaotic, the special properties of chaotic nonlinear dynamical systems ought to be taken into account, and, in fact, may often be exploited to achieve improved performance. For instance, because the evolution of chaotic systems is acutely sensitive to initial conditions, it is often important that this numerical instability be reflected in the model for the system. One approach to capturing this sensitivity is to require that the reconstructed dynamics exhibit Lyapunov exponents consistent with what might be known about the true dynamics. The sensitivity of state evolution can also be captured using the hidden Markov model framework since the structural uncertainty in the dynamics can be represented in terms of the probabilistic state transactions. In any case, unless sensitivity of the dynamics is taken

into account during modeling, detection and estimation algorithms involving chaotic signals often lack robustness.

Another aspect of chaotic systems that can be exploited is that the long term evolution of such systems lies on an attractor whose dimension is not only typically non-integral, but occupies a small fraction of the entire state space. This has a number of important implications both in the modeling of chaotic signals and ultimately in addressing problems of estimation and detection involving these signals. For example, it implies that the nonlinear dynamics can be recovered in the vicinity of the attractor using comparatively less data than would be necessary if the dynamics were required everywhere in state space.

Identifying the attractor, its fractal dimension, and related invariant measures governing, for example, the probability of being in the neighborhood of a particular state on the attractor, are also important aspects of the modeling problem. Furthermore, we can often exploit various ergodicity and mixing properties of chaotic systems. These properties allow us to recover information about the attractor using a single realization of a chaotic signal, and assure us that different time intervals of the signal provide qualitatively similar information about the attractor.

71.3 Estimation and Detection

A variety of problems involving the estimation and detection of chaotic signals arises in potential application contexts. In some scenarios, the chaotic signal is a form of noise or other unwanted interference signal. In this case, we are often interested in detecting, characterizing, discriminating, and extracting known or partially known signals in backgrounds of chaotic noise. In other scenarios, it is the chaotic signal that is of direct interest and which is corrupted by other signals. In these cases we are interested in detecting, discriminating, and extracting known or partially known chaotic signals in backgrounds of other noises or in the presence of other kinds of distortion.

The channel through which either natural or synthesized signals are received can typically be expected to introduce a variety of distortions including additive noise, scattering, multipath effects, etc. There are, of course, classical approaches to signal recovery and characterization in the presence of such distortions for both transient and stochastic signals. When the desired signal in the channel is a chaotic signal, or when the distortion is caused by a chaotic signal, many of the classical techniques will not be effective and do not exploit the particular structure of chaotic signals.

The specific properties of chaotic signals exploited in detection and estimation algorithms depend heavily on the degree of *a priori* knowledge of the signals involved. For example, in distinguishing chaotic signals from other signals, the algorithms may exploit the functional form of the map, the Lyapunov exponents of the dynamics, and/or characteristics of the chaotic attractor such as its structure, shape, fractal dimension and/or invariant measures.

To recover chaotic signals in the presence of additive noise, some of the most effective noise reduction techniques proposed to date take advantage of the nonlinear dependence of the chaotic signal by constructing accurate models for the dynamics. Multipath and other types of convolutional distortion can best be described in terms of an augmented state space system. Convolution or filtering of chaotic signals can change many of the essential characteristics and parameters of chaotic signals. Effects of convolutional distortion and approaches to compensating for it are discussed in [11].

71.4 Use of Chaotic Signals in Communications

Chaotic systems provide a rich mechanism for signal design and generation, with potential applications to communications and signal processing. Because chaotic signals are typically broadband, noise-like, and difficult to predict, they can be used in various contexts in communications. A particularly useful class of chaotic systems are those that possess a self-synchronization property [12, 13, 14].

This property allows two identical chaotic systems to synchronize when the second system (receiver) is driven by the first (transmitter). The well-known Lorenz system is used below to further describe and illustrate the chaotic self-synchronization property.

The Lorenz equations, first introduced by E. N. Lorenz as a simplified model of fluid convection [15], are given by

$$\begin{aligned}\dot{x} &= \sigma(y - x) \\ \dot{y} &= rx - y - xz \\ \dot{z} &= xy - bz,\end{aligned}\tag{71.1}$$

where σ , r , and b are positive parameters. In signal processing applications, it is typically of interest to adjust the time scale of the chaotic signals. This is accomplished in a straightforward way by establishing the convention that \dot{x} , \dot{y} , and \dot{z} denote $dx/d\tau$, $dy/d\tau$, and $dz/d\tau$, respectively, where $\tau = t/T$ is normalized time and T is a time scale factor. It is also convenient to define the normalized frequency $\omega = \Omega T$, where Ω denotes the angular frequency in units of rad/s. The parameter values $T = 400 \mu\text{sec}$, $\sigma = 16$, $r = 45.6$, and $b = 4$ are used for the illustrations in this chapter.

Viewing the Lorenz system (71.1) as a set of transmitter equations, a dynamical receiver system that will synchronize to the transmitter is given by

$$\begin{aligned}\dot{x}_r &= \sigma(y_r - x_r) \\ \dot{y}_r &= rx(t) - y_r - x(t)z_r \\ \dot{z}_r &= x(t)y_r - bz_r.\end{aligned}\tag{71.2}$$

In this case, the chaotic signal $x(t)$ from the transmitter is used as the driving input to the receiver system. In Section 71.4.1, an identified equivalence between self-synchronization and asymptotic stability is exploited to show that the synchronization of the transmitter and receiver is global, i.e., the receiver can be initialized in any state and the synchronization still occurs.

71.4.1 Self-Synchronization and Asymptotic Stability

A close relationship exists between the concepts of self-synchronization and asymptotic stability. Specifically, self-synchronization in the Lorenz system is a consequence of globally stable error dynamics. Assuming that the Lorenz transmitter and receiver parameters are identical, a set of equations that govern their error dynamics is given by

$$\begin{aligned}\dot{e}_x &= \sigma(e_y - e_x) \\ \dot{e}_y &= -e_y - x(t)e_z \\ \dot{e}_z &= x(t)e_y - be_z.\end{aligned}\tag{71.3}$$

where

$$\begin{aligned}e_x(t) &= x(t) - x_r(t) \\ e_y(t) &= y(t) - y_r(t) \\ e_z(t) &= z(t) - z_r(t).\end{aligned}$$

A sufficient condition for the error equations to be globally asymptotically stable at the origin can be determined by considering a Lyapunov function of the form

$$E(\mathbf{e}) = \frac{1}{2} \left(\frac{1}{\sigma} e_x^2 + e_y^2 + e_z^2 \right).$$

Since σ and b in the Lorenz equations are both assumed to be positive, E is positive definite and \dot{E} is negative definite. It then follows from Lyapunov's theorem that $\mathbf{e}(t) \rightarrow 0$ as $t \rightarrow \infty$. Therefore,

synchronization occurs as $t \rightarrow \infty$ regardless of the initial conditions imposed on the transmitter and receiver systems.

For practical applications, it is also important to investigate the sensitivity of the synchronization to perturbations of the chaotic drive signal. Numerical experiments are summarized in Section 71.4.2, which demonstrates the robustness and signal recovery properties of the Lorenz system.

71.4.2 Robustness and Signal Recovery in the Lorenz System

When a message or other perturbation is added to the chaotic drive signal, the receiver does not regenerate a perfect replica of the drive; there is always some synchronization error. By subtracting the regenerated drive signal from the received signal, successful message recovery would result if the synchronization error was small relative to the perturbation itself. An interesting property of the Lorenz system is that the synchronization error is *not* small compared to a narrowband perturbation; nevertheless, the message can be recovered because the synchronization error is nearly *coherent* with the message. This section summarizes experimental evidence for this effect; a more detailed explanation has been given in terms of an approximate analytical model [16].

The series of experiments that demonstrate the robustness of synchronization to white noise perturbations and the ability to recover speech perturbations focus on the synchronizing properties of the transmitter Eqs. (71.1) and the corresponding receiver equations,

$$\begin{aligned}\dot{x}_r &= \sigma(y_r - x_r) \\ \dot{y}_r &= rs(t) - y_r - s(t)z_r \\ \dot{z}_r &= s(t)y_r - bz_r.\end{aligned}\tag{71.4}$$

Previously, it was stated that with $s(t)$ equal to the transmitter signal $x(t)$, the signals x_r , y_r , and z_r will asymptotically synchronize to x , y , and z , respectively. Below, we examine the synchronization error when a perturbation $p(t)$ is added to $x(t)$, i.e., when $s(t) = x(t) + p(t)$.

First, we consider the case where the perturbation $p(t)$ is Gaussian white noise. In Fig. 71.1, we show the perturbation and error spectra for each of the three state variables vs. normalized frequency ω . Note that at relatively low frequencies, the error in reconstructing $x(t)$ slightly exceeds the perturbation of the drive but that for normalized frequencies above 20 the situation quickly reverses. An analytical model closely predicts and explains this behavior [16]. These figures suggest that the sensitivity of synchronization depends on the spectral characteristics of the perturbation signal. For signals that are bandlimited to the frequency range $0 < \omega < 10$, we would expect that the synchronization errors will be larger than the perturbation itself. This turns out to be the case, although the next experiment suggests there are additional interesting characteristics as well.

In a second experiment, $p(t)$ is a low-level speech signal (for example a message to be transmitted and recovered). The normalizing time parameter is $400 \mu\text{sec}$ and the speech signal is bandlimited to 4 kHz or equivalently to a normalized frequency ω of 10. Figure 71.2 shows the power spectrum of a representative speech signal and the chaotic signal $x(t)$. The overall chaos-to-perturbation ratio in this experiment is approximately 20 dB.

To recover the speech signal, the regenerated drive signal is subtracted at the receiver from the received signal. In this case, the recovered message is $\hat{p}(t) = p(t) + e_x(t)$. It would be expected that successful message recovery would result if $e_x(t)$ was small relative to the perturbation signal. For the Lorenz system, however, although the synchronization error is not small compared to the perturbation, the message can be recovered because $e_x(t)$ is nearly coherent with the message. This coherence has been confirmed experimentally and an explanation has been developed in terms of an approximate analytical model [16].

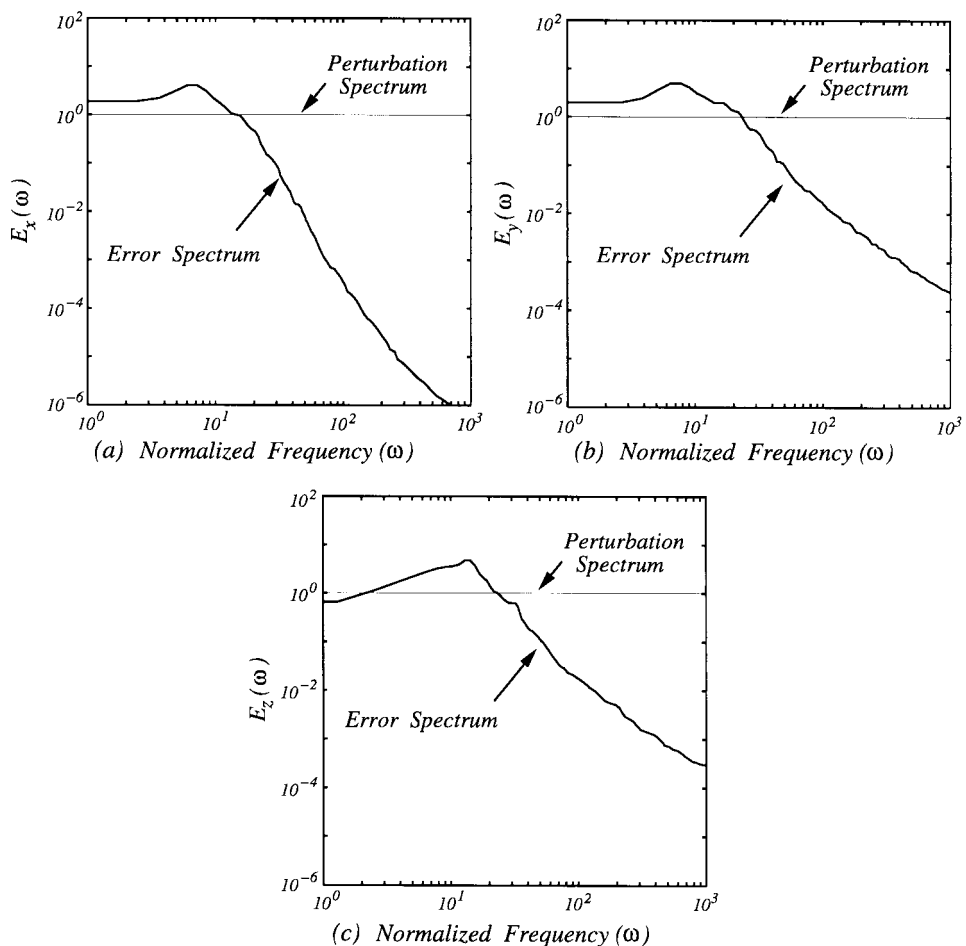

FIGURE 71.1: Power spectra of the error signals: (a) $E_x(\omega)$. (b) $E_y(\omega)$. (c) $E_z(\omega)$.

71.4.3 Circuit Implementation and Experiments

In Section 71.4.2, we showed that, theoretically, a low-level speech signal could be added to the synchronizing drive signal and approximately recovered at the receiver. These results were based on an analysis of the *exact* Lorenz transmitter and receiver equations. When implementing synchronized chaotic systems in hardware, the limitations of available circuit components result in approximations of the defining equations. The Lorenz transmitter and receiver equations can be implemented relatively easily with standard analog circuits [17, 20, 21]. The resulting system performance is in excellent agreement with numerical and theoretical predictions. Some potential implementation difficulties are avoided by scaling the Lorenz state variables according to $u = x/10$, $v = y/10$, and $w = z/20$. With this scaling, the Lorenz equations are transformed to

$$\begin{aligned}\dot{u} &= \sigma(v - u) \\ \dot{v} &= ru - v - 20uw \\ \dot{w} &= 5uv - bw.\end{aligned}\tag{71.5}$$

For this system, which we refer to as the circuit equations, the state variables all have similar dynamic range and circuit voltages remain well within the range of typical power supply limits. Below, we

FIGURE 71.2: Power spectra of $x(t)$ and $p(t)$ when the perturbation is a speech signal.

discuss and demonstrate some applied aspects of the Lorenz circuits.

In Fig. 71.3, we illustrate a communication scenario that is based on chaotic signal masking and recovery [18, 19, 20, 21]. In this figure, a chaotic masking signal $u(t)$ is added to the information-bearing signal $p(t)$ at the transmitter, and at the receiver the masking is removed. By subtracting the regenerated drive signal $u_r(t)$ from the received signal $s(t)$ at the receiver, the recovered message is

$$\hat{p}(t) = s(t) - u_r(t) = p(t) + [u(t) - u_r(t)].$$

In this context, $e_u(t)$, the error between $u(t)$ and $u_r(t)$, corresponds directly to the error in the recovered message.

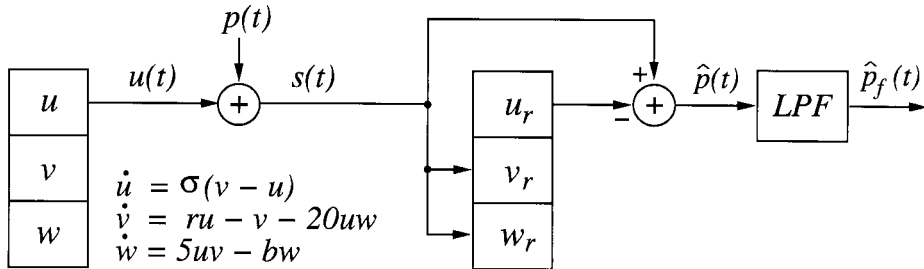

FIGURE 71.3: Chaotic signal masking and recovery system.

For this experiment, $p(t)$ is a low-level speech signal (the message to be transmitted and recovered). The normalizing time parameter is $400 \mu\text{sec}$ and the speech signal is bandlimited to 4 kHz or, equivalently, to a normalized frequency ω of 10. In Fig. 71.4, we show the power spectrum of $p(t)$ and $\hat{p}(t)$, where $\hat{p}(t)$ is obtained from both a simulation and from the circuit. The two spectra for $\hat{p}(t)$ are in excellent agreement, indicating that the circuit performs very well. Because $\hat{p}(t)$ includes considerable energy beyond the bandwidth of the speech, the speech recovery can be improved by lowpass filtering $\hat{p}(t)$. We denote the lowpass filtered version of $\hat{p}(t)$ by $\hat{p}_f(t)$. In Fig. 71.5(a) and (b), we show a comparison of $\hat{p}_f(t)$ from both a simulation and from the circuit, respectively. Clearly, the circuit performs well and, in informal listening tests, the recovered message is of reasonable quality.

Although $\hat{p}_f(t)$ is of reasonable quality in this experiment, the presence of additive channel noise will produce message recovery errors that cannot be completely removed by lowpass filtering; there

will always be some error in the recovered message. Because the message and noise are directly added to the synchronizing drive signal, the message-to-noise ratio should be large enough to allow a faithful recovery of the original message. This requires a communication channel that is nearly noise free.

FIGURE 71.4: Power spectra of $p(t)$ and $\hat{p}(t)$ when the perturbation is a speech signal.

An alternative approach to private communications allows the information-bearing waveform to be exactly recovered at the self-synchronizing receiver(s), even when moderate-level channel noise is present. This approach is referred to as chaotic binary communications [20, 21]. The basic idea behind this technique is to modulate a transmitter parameter with the information-bearing waveform and to transmit the chaotic drive signal. At the receiver, the parameter modulation will produce a synchronization error between the received drive signal and the receiver's regenerated drive signal with an error signal amplitude that depends on the modulation. Using the synchronization error, the modulation can be detected.

This modulation/detection process is illustrated in Fig. 71.6. To illustrate the approach, we use a periodic square-wave for $p(t)$ as shown in Fig. 71.7(a). The square-wave has a repetition frequency of approximately 110 Hz with zero volts representing the zero-bit and one volt representing the one-bit. The square-wave modulates the transmitter parameter b with the zero-bit and one-bit parameters given by $b(0) = 4$ and $b(1) = 4.4$, respectively. The resulting drive signal $u(t)$ is transmitted and the noisy received signal $s(t)$ is used as the driving input to the synchronizing receiver circuit. In Fig. 71.7(b), we show the synchronization error power $e^2(t)$. The parameter modulation produces significant synchronization error during a "1" transmission and very little error during a "0" transmission. It is plausible that a detector based on the average synchronization error power, followed by a threshold device, could yield reliable performance. We illustrate in Fig. 71.7(c) that the square-wave modulation can be reliably recovered by lowpass filtering the synchronization error power waveform and applying a threshold test. The threshold device used in this experiment consisted of a simple analog comparator circuit.

The allowable data rate of this communication technique is, of course, dependent on the synchronization response time of the receiver system. Although we have used a low bit rate to demonstrate the technique, the circuit time scale can be easily adjusted to allow much faster bit rates.

While the results presented above appear encouraging, there are many communication scenarios where it is undesirable to be restricted to the Lorenz system, or for that matter, any other low-dimensional chaotic system. In private communications, for example, the ability to choose from a wide variety of synchronized chaotic systems would be highly advantageous. In the next section, we briefly describe an approach for synthesizing an unlimited number of high-dimensional chaotic systems. The significance of this work lies in the fact that the ability to synthesize high-dimensional

FIGURE 71.5: (a) Recovered speech (simulation). (b) Recovered speech (circuit).

chaotic systems further enhances their applicability for practical applications.

71.5 Synthesizing Self-Synchronizing Chaotic Systems

An effective approach to synthesis is based on a systematic four step process. First, an algebraic model is specified for the transmitter and receiver systems. As shown in [22, 23], the chaotic system models can be very general; in [22] the model represents a large class of quadratically nonlinear systems, while in [23] the model allows for an unlimited number of Lorenz oscillators to be mutually coupled via an N -dimensional linear system.

The second step in the synthesis process involves subtracting the receiver equations from the transmitter equations and imposing a global asymptotic stability constraint on the resulting error equations. Using Lyapunov's direct method, sufficient conditions for the error system's global sta-

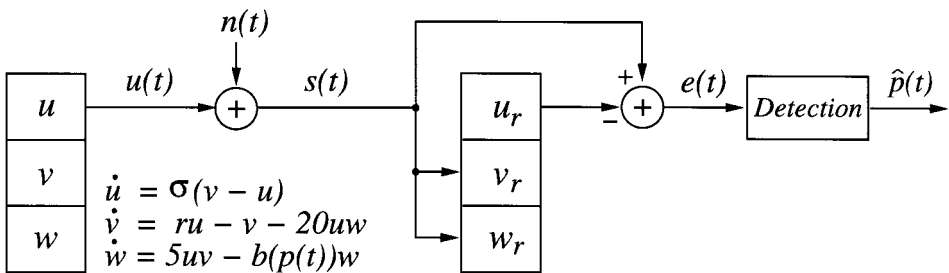

FIGURE 71.6: Communicating binary-valued bit streams with synchronized chaotic systems.

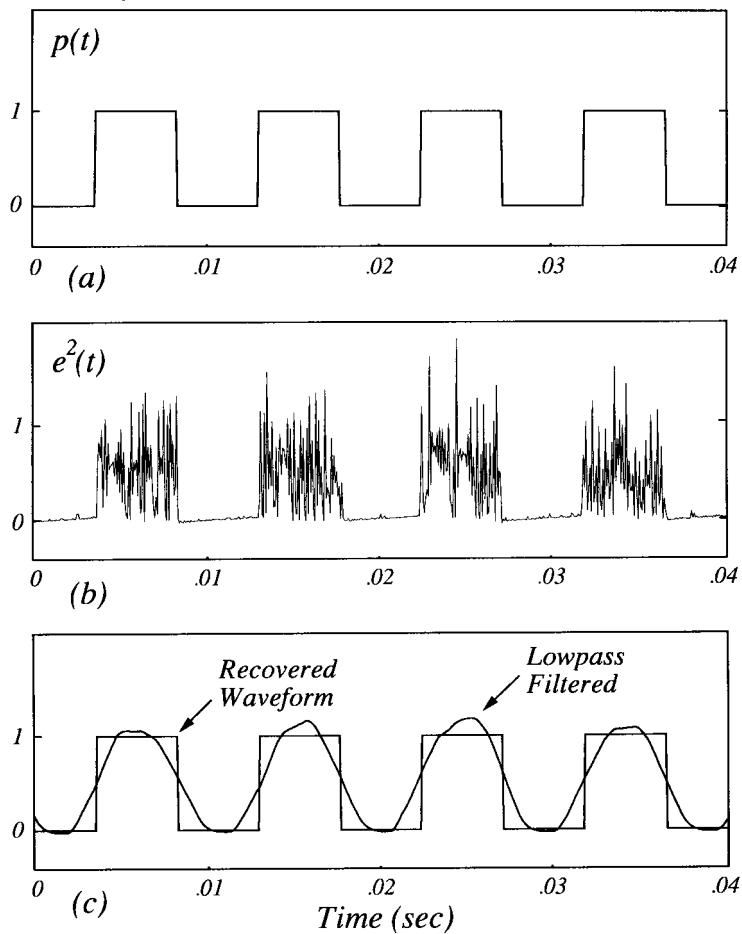

FIGURE 71.7: (a) Binary modulation waveform. (b) Synchronization error power. (c) Recovered binary waveform.

bility are usually straightforward to obtain. The sufficient conditions determine constraints on the free parameters of the transmitter and receiver which guarantee that they possess the global self-synchronization property.

The third step in the synthesis process focuses on the global stability of the transmitter equations. First, a family of ellipsoids in state space is defined and then sufficient conditions are determined which guarantee the existence of a *trapping region*. The trapping region imposes additional constraints on the free parameters of the transmitter and receiver equations.

The final step involves determining sufficient conditions that render all of the transmitter's fixed points unstable. In most cases, this involves numerically integrating the transmitter equations and computing the system's Lyapunov exponents and/or attractor dimension. If stable fixed points exist, the system's bifurcation parameter is adjusted until they all become unstable. Below, we demonstrate the synthesis approach for linear feedback chaotic systems.

Linear feedback chaotic systems (LFBCSs) are composed of a low-dimensional chaotic system and a linear feedback system as illustrated in Fig. 71.8. Because the linear system is N -dimensional,

considerable design flexibility is possible with LFBCSs. Another practical property of LFBCSs is that they synchronize via a single drive signal while exhibiting complex dynamics.

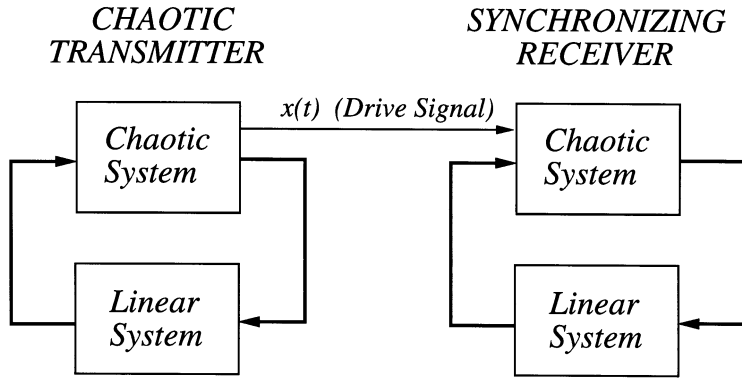

FIGURE 71.8: Linear feedback chaotic systems.

While many types of LFBCSs are possible, two specific cases have been considered in detail: (1) the chaotic Lorenz signal $x(t)$ drives an N -dimensional linear system and the output of the linear system is added to the equation for \dot{x} in the Lorenz system; and (2) the Lorenz signal $z(t)$ drives an N -dimensional linear system and the output of the linear system is added to the equation for \dot{z} in the Lorenz system. In both cases, a complete synthesis procedure was developed.

Below, we summarize the procedure; a complete development is given elsewhere [24].

Synthesis Procedure

1. Choose any stable A matrix and any $N \times N$ symmetric positive definite matrix Q .
2. Solve $PA + A^T P + Q = 0$ for the positive definite solution P .
3. Choose any vector B and set $C = -B^T P/r$.
4. Choose any D such that $\sigma - D > 0$.

The first step of the procedure is simply the self-synchronization condition; it requires the linear system to be stable. Clearly, many choices for A are possible. The second and third steps are akin to a negative feedback constraint, i.e., the linear feedback tends to stabilize the chaotic system. The last step in the procedure restricts $\sigma - D > 0$ so that the \dot{x} equation of the Lorenz system remains dissipative after feedback is applied.

For the purpose of demonstration, consider the following five-dimensional x -input/ x -output LFBCS.

$$\begin{aligned}
 \dot{x} &= \sigma(y - x) + v \\
 \dot{y} &= rx - y - xz \\
 \dot{z} &= xy - bz
 \end{aligned}$$

$$\begin{bmatrix} \dot{l}_1 \\ \dot{l}_2 \end{bmatrix} = \begin{bmatrix} -\frac{1}{2} & 10 \\ -10 & -\frac{1}{2} \end{bmatrix} \begin{bmatrix} l_1 \\ l_2 \end{bmatrix} + \begin{bmatrix} 1 \\ 1 \end{bmatrix} x$$

$$v = - \begin{bmatrix} 1 & 1 \end{bmatrix} \begin{bmatrix} l_1 \\ l_2 \end{bmatrix}$$
(71.6)

FIGURE 71.9: Lyapunov dimension of a 5-D LFBCS.

FIGURE 71.10: Self-synchronization in a 5-D LFBCS.

It can be shown in a straightforward way that the linear system satisfies the synthesis procedure for suitable choices of P , Q , and R . For the numerical demonstrations presented below, the Lorenz parameters chosen are $\sigma = 16$ and $b = 4$; the bifurcation parameter r will be varied.

In Fig. 71.9, we show the computed Lyapunov dimension as r is varied over the range, $20 < r < 100$. This figure demonstrates that the LFBCS achieves a greater Lyapunov dimension than the Lorenz system without feedback. The Lyapunov dimension could be increased by using more states in the linear system. However, numerical experiments suggest that stable linear feedback creates only negative Lyapunov exponents, limiting the dynamical complexity of LFBCSs. Nevertheless, their relative ease of implementation is an attractive practical feature.

In Fig. 71.10, we demonstrate the rapid synchronization between the transmitter and receiver systems. The curve measures the distance in state space between the transmitter and receiver trajectories when the receiver is initialized from the zero state. Synchronization is maintained indefinitely.

72.1 Introduction

One-dimensional nonlinear systems, although simple in form, are applicable in a surprisingly wide variety of engineering contexts. As models for engineering systems, their richly complex behavior has provided insight into the operation of, for example, analog-to-digital converters [1], nonlinear oscillators [2], and power converters [3]. As realizable systems, they have been proposed as random number generators [4] and as signal generators for communication systems [5, 6]. As analytic tools, they have served as mirrors for the behavior of more complex, higher dimensional systems [7, 8, 9].

Although one-dimensional nonlinear systems are, in general, hard to analyze, certain useful classes of them are relatively well understood. These systems are described by the recursion

$$x[n] = f(x[n-1]) \quad (72.1a)$$

$$y[n] = g(x[n]), \quad (72.1b)$$

initialized by a scalar initial condition $x[0]$, where $f(\cdot)$ and $g(\cdot)$ are real-valued functions that describe the evolution of a nonlinear system and the observation of its state, respectively. The dependence of the sequence $x[n]$ on its initial condition is emphasized by writing $x[n] = f^n(x[0])$ where $f^n(\cdot)$ represents the n -fold composition of $f(\cdot)$ with itself.

Without further restrictions of the form of $f(\cdot)$ and $g(\cdot)$, this class of systems is too large to easily explore. However, systems and signals corresponding to certain “well-behaved” maps $f(\cdot)$ and observation functions $g(\cdot)$ can be rigorously analyzed. Maps of this type often generate chaotic signals—loosely speaking, bounded signals that are neither periodic nor transient—under easily verifiable conditions. These chaotic signals, although completely deterministic, are in many ways analogous to stochastic processes. In fact, one-dimensional chaotic maps illustrate in a relatively simple setting that the distinction between deterministic and stochastic signals is sometimes artificial

and can be profitably emphasized or deemphasized according to the needs of an application. For instance, problems of signal recovery from noisy observations are often best approached with a deterministic emphasis, while certain signal generation problems [10] benefit most from a stochastic treatment.

72.2 Eventually Expanding Maps and Markov Maps

Although signal models of the form [1] have simple, one-dimensional state spaces, they can behave in a variety of complex ways that model a wide range of phenomena. This flexibility comes at a cost, however; without some restrictions on its form, this class of models is too large to be analytically tractable. Two tractable classes of models that appear quite often in applications are eventually expanding maps and Markov maps.

72.2.1 Eventually Expanding Maps

Eventually expanding maps—which have been used to model sigma-delta modulators [11], switching power converters [3], other switched flow systems [12], and signal generators [6, 13]—have three defining features: they are piecewise smooth, they map the unit interval to itself, and they have some iterate with slope that is everywhere greater than unity. Maps with these features generate time series that are chaotic, but on average well behaved. For reference, the formal definition is as follows, where the restriction to the unit interval is convenient but not necessary:

DEFINITION 72.1 A nonsingular map $f : [0, 1] \rightarrow [0, 1]$ is called *eventually expanding* if

1. There is a set of partition points $0 = a_0 < a_1 < \cdots < a_N = 1$ such that restricted to each of the intervals $\mathcal{V}_i = [a_{i-1}, a_i)$, called partition elements, the map $f(\cdot)$ is monotonic, continuous and differentiable.
2. The function $1/|f'(x)|$ is of bounded variation [14]. (In some definitions, this smoothness condition on the reciprocal of the derivative is replaced with a more restrictive bounded slope condition, i.e., there exists a constant B such that $|f'(x)| < B$ for all x .)
3. There exists a real $\lambda > 1$ and a integer m such that

$$\left| \frac{d}{dx} f^m(x) \right| \geq \lambda$$

wherever the derivative exists. This is the eventually expanding condition.

Every eventually expanding map can be expressed in the form

$$f(x) = \sum_{i=1}^N f_i(x) \chi_i(x) \quad (72.2)$$

where each $f_i(\cdot)$ is continuous, monotonic, and differentiable on the interior of the i th partition element and the indicator function $\chi_i(x)$ is defined by

$$\chi_i(x) = \begin{cases} 1 & x \in \mathcal{V}_i, \\ 0 & x \notin \mathcal{V}_i. \end{cases} \quad (72.3)$$

This class is broad enough to include for example, discontinuous maps and maps with discontinuous or unbounded slope. Eventually expanding maps also include a class that is particularly amenable to analysis—the Markov maps.

Markov maps are analytically tractable and broadly applicable to problems of signal estimation, signal generation, and signal approximation. They are defined as eventually expanding maps that are piecewise-linear and have some extra structure.

DEFINITION 72.2 A map $f : [0, 1] \rightarrow [0, 1]$ is an *eventually expanding, piecewise-linear, Markov map* if f is an eventually expanding map with the following additional properties:

1. The map is piecewise-linear, i.e., there is a set of partition points $0 = a_0 < a_1 < \dots < a_N = 1$ such that restricted to each of the intervals $\mathcal{V}_i = [a_{i-1}, a_i)$, called partition elements, the map $f(\cdot)$ is affine, i.e., the functions $f_i(\cdot)$ on the right side of (72.2) are of the form

$$f_i(x) = s_i x + b_i .$$

2. The map has the Markov property that partition points map to partition points, i.e., for each i , $f(a_i) = a_j$ for some j .

Every Markov map can be expressed in the form

$$f(x) = \sum_{i=1}^N (s_i x + b_i) \chi_i(x) , \quad (72.4)$$

where $s_i \neq 0$ for all i . Fig. 72.1 shows the Markov map

$$f(x) = \begin{cases} (1-a)x/a + a & 0 \leq x \leq a \\ (1-x)/(1-a) & a < x \leq 1 \end{cases} , \quad (72.5)$$

which has partition points $\{0, a, 1\}$, and partition elements $\mathcal{V}_1 = [0, a)$ and $\mathcal{V}_2 = [a, 1)$.

FIGURE 72.1: An example of a piecewise-linear Markov map with two partition elements.

Markov maps generate signals with two useful properties: they are, when suitably quantized, indistinguishable from signals generated by Markov chains; they are close, in a sense, to signals generated by more general eventually expanding maps [15]. These two properties lead to applications of Markov maps for generating random numbers and approximating other signals. The analysis underlying these types of applications depends on signal representations that provide insight into the structure of chaotic signals.

72.3 Signals From Eventually Expanding Maps

There are several general representations for signals generated by eventually expanding maps. Each provides different insights into the structure of these signals and proves useful in different applications. First, and most obviously, a sequence generated by a particular map is completely determined by (and is thus represented by) its initial condition $x[0]$. This representation allows certain signal estimation problems to be recast as problems of estimating the scalar initial condition. Second, and less obviously, the quantized signal $y[n] = g(x[n])$, for $n \geq 0$ generated by (72.1) with $g(\cdot)$ defined by

$$g(x) = i \quad x \in \mathcal{V}_i, \quad (72.6)$$

uniquely specifies the initial condition $x[0]$ and hence the entire state sequence $x[n]$. Such quantized sequences $y[n]$ are called the symbolic dynamics associated with $f(\cdot)$ [7]. Certain properties of a map, such as the collection of initial conditions leading to periodic points, are most easily described in terms of its symbolic dynamics. Finally, a hybrid representation of $x[n]$ combining the initial condition and symbolic representations

$$\mathbf{H}[N] = \{g(x[0]), \dots, g(x[N]), x[N]\}$$

is often useful.

72.4 Estimating Chaotic Signals in Noise

The hybrid signal representation described in the previous section can be applied to a classical signal processing problem—estimating a signal in white Gaussian noise. For example, suppose the problem is to estimate a chaotic sequence $x[n]$, $n = 0, \dots, N - 1$ from the noisy observations

$$r[n] = x[n] + w[n], \quad n = 0, \dots, N - 1 \quad (72.7)$$

where $w[n]$ is a stationary, zero-mean white Gaussian noise sequence with variance σ_w^2 , and $x[n]$ is generated by iterating (72.1) from an unknown initial condition. Because $w[n]$ is white and Gaussian, the maximum likelihood estimation problem is equivalent to the constrained minimum distance problem

$$\underset{x[n] : x[i] = f(x[i-1])}{\text{minimize}} \quad \varepsilon[N] = \sum_{k=0}^N (r[k] - x[k])^2 \quad (72.8)$$

and to the scalar problem

$$\underset{x[0] \in [0, 1]}{\text{minimize}} \quad \varepsilon[N] = \sum_{k=0}^N \left(r[k] - f^k(x[0]) \right)^2 \quad (72.9)$$

Thus, the maximum-likelihood problem can, in principle, be solved by first estimating the initial condition, then iterating (72.1) to generate the remaining estimates. However, the initial condition is often difficult to estimate directly because the likelihood function (72.9), which is highly irregular with fractal characteristics, is unsuitable for gradient-descent type optimization [16]. Another solution divides the domain of $f(\cdot)$ into subintervals and then solves a dynamic programming problem [17]; however, this solution is, in general, suboptimal and computationally expensive.

Although the maximum likelihood problem described above need not, in general, have a computationally efficient recursive solution, it does have one when, for example, the map $f(\cdot)$ is a symmetric tent map of the form

$$f(x) = \beta - 1 - \beta|x|, \quad x \in [-1, 1] \quad (72.10)$$

with parameter $1 < \beta \leq 2$ [5]. This algorithm solves for the hybrid representation of the initial condition from which an estimate of the entire signal can be determined. The hybrid representation is of the form

$$\mathbf{H}[N] = \{y[0], \dots, y[N], x[N]\} ,$$

where each $y[i]$ takes one of two values which, for convenience, we define as $y[i] = \text{sgn}(x[i])$. Since each $y[n]$ can independently takes one of two values, there are 2^N feasible solutions to this problem and a direct search for the optimal solution is thus impractical even for moderate values of N .

The resulting algorithm has computational complexity that is linear in the length of the observation, N . This efficiency is the result of a special *separation property*, possessed by the map [10]: given $y[0], \dots, y[i-1]$ and $y[i+1], \dots, y[N]$ the estimate of the parameter $y[i]$ is independent of $y[i+1], \dots, y[N]$. The algorithm is as follows. Denoting by $\hat{\phi}[n|m]$ the ML estimates of any sequence $\phi[n]$ given $r[k]$ for $0 \leq k \leq m$, the ML solution is of the form,

$$\hat{x}[n|n] = \frac{(\beta^2 - 1)\beta^{2n}r[n] + (\beta^{2n} - 1)\hat{x}[n|n-1]}{\beta^{2(n+1)} - 1} \quad (72.11)$$

$$\hat{y}[n|N] = \text{sgn} \hat{x}[n|n] \quad (72.12)$$

$$\hat{x}_{ML}[n|n] = \mathcal{L}_\beta(\hat{x}[n|n]) , \quad (72.13)$$

where $\hat{x}[n|n-1] = f(\hat{x}[n-1|n-1])$, the initialization is $\hat{x}[0|0] = r[0]$, and the function $\mathcal{L}_\beta(\hat{x}[n|n])$, defined by

$$\mathcal{L}_\beta(x) = \begin{cases} x & x \in (-1, \beta - 1) \\ -1 & x \leq -1 \\ \beta - 1 & x \geq \beta - 1 \end{cases} , \quad (72.14)$$

serves to restrict the ML estimates to the interval $x \in (-1, \beta - 1)$. The smoothed estimates $\hat{x}_{ML}[n|N]$ are obtained by converting the hybrid representation to the initial condition and then iterating the estimated initial condition forward.

72.5 Probabilistic Properties of Chaotic Maps

Almost all waveforms generated by a particular eventually expanding map have the same average behavior [18], in the sense that the time average

$$\bar{h}(x[0]) = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} h(x[k]) = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} h(f^k(x[0])) \quad (72.15)$$

exists and is essentially independent of the initial condition $x[0]$ for sufficiently well-behaved functions $h(\cdot)$. This result, which is reminiscent of results from the theory of stationary stochastic processes [19], forms the basis for a probabilistic interpretation of chaotic signals, which in turn leads to analytic methods for characterizing their time-average behavior.

To explore the link between chaotic and stochastic signals, first consider the stochastic process generated by iterating (72.1) from a random initial condition $x[0]$, with probability density function $p_0(\cdot)$. Denote by $p_n(\cdot)$ the density of the n th iterate $x[n]$. Although, in general, the members of the sequence $p_n(\cdot)$ will differ, there can exist densities, called *invariant densities*, that are time-invariant, i.e.,

$$p_0(\cdot) = p_1(\cdot) = \dots = p_n(\cdot) \stackrel{\Delta}{=} p(\cdot) . \quad (72.16)$$

When the initial condition $x[0]$ is chosen randomly according to an invariant density, the resulting stochastic process is stationary [19] and its ensemble averages depend on the invariant density. Even

when the initial condition is not random, invariant densities play an important role in describing the time-average behavior of chaotic signals. This role depends on, among other things, the number of invariant densities that a map possesses.

A general one-dimensional nonlinear map may possess many invariant densities. For example, eventually expanding maps with N partition elements have at least one and at most N invariant densities [20]. However, maps can often be decomposed into collections of maps, each with only one invariant density [19], and little generality is lost by concentrating on maps with only one invariant density. In this special case, the results that relate the invariant density to the average behavior of chaotic signals are more intuitive.

The invariant density, although introduced through the device of a random initial condition, can also be used to study the behavior of individual signals. Individual signals are connected to ensembles of signals, which correspond to random initial conditions, through a classical result due to Birkhoff, which asserts that the time average $\bar{h}(x[0])$ defined by Eq. (72.15) exists whenever $f(\cdot)$ has an invariant density. When the $f(\cdot)$ has only one invariant density, the time average is independent of the initial condition for almost all (with respect to the invariant density $p(\cdot)$) initial conditions and equals

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} h(x[k]) = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} h(f^k(x[0])) = \int h(x) p(x) dx . \quad (72.17)$$

where the integral is performed over the domain of $f(\cdot)$ and where $h(\cdot)$ is measurable.

Birkhoff's theorem leads to a relative frequency interpretation of time-averages of chaotic signals. To see this, consider the time-average of the indicator function $\tilde{\chi}_{[s-\epsilon, s+\epsilon]}(x)$, which is zero everywhere but in the interval $[s - \epsilon, s + \epsilon]$ where it is equal to unity. Using Birkhoff's theorem with Eq. (72.17) yields

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} \tilde{\chi}_{[s-\epsilon, s+\epsilon]}(x[k]) = \int \tilde{\chi}_{[s-\epsilon, s+\epsilon]}(x) p(x) dx \quad (72.18)$$

$$= \int_{[s-\epsilon, s+\epsilon]} p(x) dx \quad (72.19)$$

$$\approx 2\epsilon p(s) , \quad (72.20)$$

where Eq. (72.20) follows from Eq. (72.19) when ϵ is small and $p(\cdot)$ is sufficiently smooth. The time-average (72.18) is exactly the fraction of time that the sequence $x[n]$ takes values in the interval $[s - \epsilon, s + \epsilon]$. Thus, from (72.20), the value of the invariant density at any point s is approximately proportional to the relative frequency with which $x[n]$ takes values in a small neighborhood of the point. Motivated by this relative frequency interpretation, the probability that an arbitrary function $h(x[n])$ falls into an arbitrary set A can be defined by

$$Pr \{h(x) \in A\} = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} \tilde{\chi}_A(h(x[k])) . \quad (72.21)$$

Using this definition of probability, it can be shown that for any Markov map, the symbol sequence $y[n]$ defined in Section 72.3 is indistinguishable from a Markov chain in the sense that

$$Pr \{y[n]|y[n-1], \dots, y[0]\} = Pr \{y[n]|y[n-1]\} , \quad (72.22)$$

holds for all n [21]. The first order transition probabilities can be shown to be of the form

$$Pr(y[n]|y[n-1]) = \frac{|\mathcal{V}_{y[n]}|}{|s_{y[n]}| |\mathcal{V}_{y[n-1]}|} ,$$

where the s_i are the slopes of the map $f(\cdot)$ as in Eq. (72.4) and $|\mathcal{V}_{y[n]}|$ denotes the length of the interval $\mathcal{V}_{y[n]}$. As an example, consider the asymmetric tent map

$$f(x) = \begin{cases} x/a & 0 \leq x \leq a \\ (1-x)/(1-a) & a < x \leq 1 \end{cases},$$

with parameter in the range $0 < a < 1$ and a quantizer $g(\cdot)$ of the form (72.6). The previous results establish that $y[n] = g(x[n])$ is equivalent to a sample sequence from the Markov chain with transition probability matrix

$$[P]_{ij} = \begin{bmatrix} a & 1-a \\ a & 1-a \end{bmatrix},$$

where $[P]_{ij} = \Pr\{y[n] = i | y[n-1] = j\}$. Thus, the symbolic sequence appears to have been generated by independent flips of a biased coin with the probability of heads, say, equal to a . When the parameter takes the value $a = 1/2$, this corresponds to a sequence of independent equally likely bits. Thus, a sequence of Bernoulli random variables can be constructed from a deterministic sequence $x[n]$. Based on this remarkable result, a circuit that generates statistically independent bits for cryptographic applications has been designed [4].

Some of the deeper probabilistic properties of chaotic signals depend on the integral (72.17), which in turn depends on the invariant density. For some maps, invariant densities can be determined explicitly. For example, the tent map (72.10) with $\beta = 2$ has invariant density

$$p(x) = \begin{cases} 1/2 & -1 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

as can be readily verified using elementary results from the theory of derived distributions of functions of random variables [22]. More generally, all Markov maps have invariant densities that are piecewise-constant function of the form

$$\sum_{i=1}^n c_i \chi_i(x) \quad (72.23)$$

where c_i are real constants that can be determined from the map's parameters [23]. This makes Markov maps especially amenable to analysis.

72.6 Statistics of Markov Maps

The transition probabilities computed above may be viewed as statistics of the sequence $x[n]$. These statistics, which are important in a variety of applications, have the attractive property that they are defined by integrals having, for Markov maps, readily computable, closed-form solutions. This property holds more generally—Markov maps generate sequences for which a large class of statistics can be determined in closed form. These analytic solutions have two primary advantages over empirical solutions computed by time averaging: they circumvent some of the numerical problems that arise when simulating the long sequences of chaotic data that are necessary to generate reliable averages; and they often provide insight into aspects of chaotic signals, such as dependence on a parameter, that could not be easily determined by empirical averaging.

Statistics that can be readily computed include correlations of the form

$$R_{f;h_0,h_1,\dots,h_r}[k_1,\dots,k_r] = \lim_{L \rightarrow \infty} \frac{1}{L} \sum_{n=0}^{L-1} h_0(x[n])h_1(x[n+k_1]) \cdots h_r(x[n+k_r]) \quad (72.24)$$

$$= \int h_0(x[n])h_1(x[n+k_1]) \cdots h_r(x[n+k_r]) p(x) dx \quad (72.25)$$

where the $h_i(\cdot)$'s are suitably well-behaved but otherwise arbitrary functions, the k_i 's are nonnegative integers, the sequence $x[n]$ is generated by Eq. (72.1), and $p(\cdot)$ is the invariant density. This class of statistics includes as important special cases the autocorrelation function and all higher-order moments of the time-series. Of primary importance in determining these statistics is a linear transformation called the Frobenius-Perron (FP) operator, which enters into the computation of these correlations in two ways. First, it suggests a method for determining an invariant density. Second, it provides a “change of variables” within the integral that leads to simple expressions for correlation statistics.

The definition of the FP operator can be motivated by using the device of a random initial condition $x[0]$ with density $p_0(x)$ as in Section 72.5. The FP operator describes the time evolution of this initial probability density. More precisely, it relates the initial density to the densities $p_n(\cdot)$ of the random variables $x[n] = f^n(x[0])$ through the equation

$$p_n(x) = P_f^n p_0(x) \quad (72.26)$$

where P_f^n denotes the n -fold self-composition of P_f . This definition of the FP operator, although phrased in terms of its action on probability densities, can be extended to all integrable functions. This extended operator, which is also called the FP operator, is linear and continuous. Its properties are closely related to the statistical structure of signals generated by chaotic maps (see [9] for a thorough discussion of these issues). For example, the evolution equation (72.26) implies that an invariant density of a map is a fixed point of its FP operator, that is, it satisfies

$$p(x) = P_f p(x) . \quad (72.27)$$

This relation can be used to determine explicitly the invariant densities of Markov maps [23], which may in turn be used to compute more general statistics.

Using the change of variables property of the FP operator, the correlation statistic (72.25) can be expressed as the ensemble average

$$R_{f; h_0, h_1, \dots, h_r} [k_1, \dots, k_r] = \quad (72.28)$$

$$\int h_r(x) P_f^{k_r - k_{r-1}} \left\{ h_{r-1}(x) \dots P_f^{k_2 - k_1} \left\{ h_1(x) P_f^{k_1} \{ h_0(x) p(x) \} \right\} \dots \right\} dx . \quad (72.29)$$

Although such integrals are, for general one-dimensional nonlinear maps, difficult to evaluate, closed-form solutions exist when $f(\cdot)$ is a Markov map—a development that depends on an explicit expression for FP operator.

The FP operator of a Markov map has a simple, finite-dimensional matrix representation when it operates on certain piecewise polynomial functions. Any function of the form

$$h(\cdot) = \sum_{i=0}^K \sum_{j=1}^N a_{ij} x^i \chi_j(x)$$

can be represented by an $N(K + 1)$ dimensional coordinate vector with respect to the basis

$$\begin{aligned} & \{ \theta_1(x), \theta_2(x), \dots, \theta_{N(K+1)} \} \triangleq \\ & \left\{ \chi_1(x), \dots, \chi_N(x), x\chi_1(x), \dots, x\chi_N(x), \dots, x^K\chi_1(x), \dots, x^K\chi_N(x) \right\} . \end{aligned} \quad (72.30)$$

The action of the FP operator on any such function can be expressed as a matrix-vector product: when the coordinate vector of $h(x)$ is \mathbf{h} , the coordinate vector of $q(x) = P_f h(x)$ is

$$\mathbf{q} = \mathbf{P}_K \mathbf{h} ,$$

where \mathbf{P}_k is the square $N(K + 1)$ dimensional, block upper-triangular matrix

$$\mathbf{P}_K = \begin{bmatrix} \mathbf{P}_{00} & \mathbf{P}_{01} & \cdots & \cdots & \mathbf{P}_{0K} \\ 0 & \mathbf{P}_{11} & \mathbf{P}_{12} & \cdots & \mathbf{P}_{1K} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & \cdots & \mathbf{P}_{KK} \end{bmatrix}, \quad (72.31)$$

and where each nonzero $N \times N$ block is of the form

$$\mathbf{P}_{ij} = \binom{j}{i} \mathbf{P}_0 \mathbf{B}^{j-i} \mathbf{S}^j \quad \text{for } j \geq i. \quad (72.32)$$

The $N \times N$ matrices \mathbf{B} and \mathbf{S} are diagonal with elements $B_{ii} = -b_i$ and $S_{ii} = 1/s_i$, respectively, while $\mathbf{P}_0 = \mathbf{P}_{00}$ is the $N \times N$ matrix with elements

$$[\mathbf{P}_0]_{ij} = \begin{cases} 1/|s_j| & i \in \mathcal{I}_j, \\ 0 & \text{otherwise.} \end{cases} \quad (72.33)$$

The invariant density of a Markov map, which is needed to compute the correlation statistic (72.25), can be determined as the solution of an eigenvector problem. It can be shown that such invariant densities are piecewise constant functions so that the fixed point equation (72.27) reduces to the matrix expression

$$\mathbf{P}_0 \mathbf{p} = \mathbf{p}.$$

Due to the properties of the matrix \mathbf{P}_0 , this equation always has a solution that can be chosen to have nonnegative components. It follows that the correlation statistic (72.29) can always be expressed as

$$R_{f;h_0,h_1,\dots,h_r}[k_1, \dots, k_r] = \mathbf{g}_1^T \mathbf{M} \mathbf{g}_2 \quad (72.34)$$

where \mathbf{M} is a basis correlation matrix with elements

$$[\mathbf{M}]_{ij} = \int \theta_i(x) \theta_j(x) dx. \quad (72.35)$$

and \mathbf{g}_i are the coordinate vectors of the functions

$$g_1(x) = h_r(x) \quad (72.36)$$

$$g_2(x) = P_f^{k_r-k_{r-1}} \left\{ h_{r-1}(x) \cdots P_f^{k_2-k_1} \left\{ h_1(x) P_f^{k_1} \{ h_0(x) p(x) \} \right\} \cdots \right\}. \quad (72.37)$$

By the previous discussion, the coordinate vectors \mathbf{g}_1 and \mathbf{g}_2 can be determined using straightforward matrix-vector operations. Thus, expression (72.34) provides a practical way of exactly computing the integral (72.29), and reveals some important statistical structure of signals generated by Markov maps.

72.7 Power Spectra of Markov Maps

An important statistic in the context of many engineering applications is the power spectrum. The power spectrum associated with a Markov map is defined as the Fourier transform of its autocorrelation sequence

$$R_{xx}[k] = \int x[n] x[n+k] p(x) dx \quad (72.38)$$

which, using Eq. (72.34) can be rewritten in the form

$$R_{xx}[k] = \mathbf{g}_1^T \mathbf{M}_1 \mathbf{P}_1^k \tilde{\mathbf{g}}_2, \quad (72.39)$$

where \mathbf{P}_1 is the matrix representation of the FP operator restricted to the space of piecewise linear functions, and where \mathbf{g}_1 is the coordinate vector associated with the function x , and where $\tilde{\mathbf{g}}_2$ is the coordinate vector associated with $\tilde{g}_2(x) = xp(x)$.

The power spectrum is obtained from the Fourier transform of Eq. (72.39), yielding,

$$S_{xx}(e^{j\omega}) = \mathbf{g}_1^T \mathbf{M}_1 \left(\sum_{k=-\infty}^{+\infty} \mathbf{P}_1^{|k|} e^{-j\omega k} \right) \tilde{\mathbf{g}}_2. \quad (72.40)$$

This sum can be simplified by examining the eigenvalues of the FP matrix \mathbf{P}_1 . In general, \mathbf{P}_1 has eigenvalues whose magnitude is strictly less than unity, and others with unit-magnitude [9]. Using this fact, Eq. (72.40) can be expressed in the form

$$S_{xx}(e^{j\omega}) = \mathbf{h}_1^T \mathbf{M} (\mathbf{I} - \Gamma_2 e^{-j\omega})^{-1} (\mathbf{I} - \Gamma_2^2) (\mathbf{I} - \Gamma_2 e^{j\omega})^{-1} \tilde{\mathbf{g}}_2 + \sum_{i=1}^m C_i \delta(\omega - \omega_i), \quad (72.41)$$

where Γ_2 has eigenvalues that are strictly less than one in magnitude, and C_i and ω_i depend on the unit magnitude eigenvalues of \mathbf{P}_1 .

As Eq. (72.41) reflects, the spectrum of a Markov map is a linear combination of an impulsive component and a rational function. This implies that there are classes of rational spectra that can be generated not only by the usual method of driving white noise through a linear time-invariant filter with a rational system function, but also by iterating deterministic nonlinear dynamics. For this reason it is natural to view chaotic signals corresponding to Markov maps as “chaotic ARMA (autoregressive moving-average) processes”. Special cases correspond to the “chaotic white noise” described in [5] and the first order autoregressive processes described in [24].

Consider now a simple example involving the Markov map defined in Eq. (72.5) and shown in Figure 72.1. Using the techniques described above, the invariant density is determined to be the piecewise-constant function

$$p(x) = \begin{cases} 1/(1+a) & 0 \leq x \leq a \\ 1/(1-a^2) & a \leq x \leq 1. \end{cases}$$

Using Eq. (72.41) and a parameter value $a = 8/9$, the rational part of the autocorrelation sequence associated with $f(\cdot)$ is determined to be

$$S_{xx}(z) = -\frac{42632}{459} \frac{36z^{-1} - 145 + 36z}{(9 + 8z)(9 + 8z^{-1})(64z^2 + z + 81)(64z^{-2} + z^{-1} + 81)}. \quad (72.42)$$

The power spectrum corresponding to evaluating Eq. (72.42) on the unit circle $z = e^{j\omega}$ is plotted in Figure 72.2, along with an empirical spectrum computed by periodogram averaging with a window length of 128 on a time series of length 50,000. The solid line corresponds to the analytically obtained expression (72.42), while the circles represent the spectral samples estimated by periodogram averaging.

72.8 Modeling Eventually Expanding Maps with Markov Maps

One approach to studying the statistics of more general eventually expanding maps involves approximation by Markov maps—the statistics of any eventually expanding map can be approximated to

FIGURE 72.2: Comparison of analytically computed power spectrum to empirical power spectrum for the map of Figure 72.1. The solid line indicates the analytically computed spectrum, while the circles indicate the samples of the spectrum estimated by applying periodogram averaging to a time series of length 50,000.

arbitrary accuracy by those of some Markov map. This approximation strategy provides a powerful method for analyzing chaotic time series from eventually expanding maps: first approximate the map by a Markov map, then use the previously described techniques to determine its statistics. In order for this approach to be useful, an appropriate notion, the approximation quality, and a constructive procedure for generating an approximate map are required.

A sequence of piecewise-linear Markov maps $\hat{f}_i(\cdot)$ with statistics that converge to those of a given eventually expanding map $f(\cdot)$ is said to *statistically converge* to $f(\cdot)$. More formally:

DEFINITION 72.3 Let $f(\cdot)$ be an eventually expanding map with a unique invariant density $p(\cdot)$. A sequence of maps $\{\hat{f}_i(\cdot)\}$ statistically converges to $f(\cdot)$ if each $\hat{f}_i(\cdot)$ has a unique invariant density $p_i(\cdot)$ and

$$R_{\hat{f}_i, h_0, h_1, \dots, h_r} [k_1, \dots, k_r] \rightarrow R_{f, h_0, h_1, \dots, h_r} [k_1, \dots, k_r] \text{ as } i \rightarrow \infty$$

for any continuous $h_j(\cdot)$ and all finite k_j and finite r .

Any eventually expanding map $f(\cdot)$ is the limit of a sequence of Markov maps that statistically converges and can be constructed in a straightforward manner. The idea is to define a Markov map on an increasingly fine set of partition points that includes the original partition points of $f(\cdot)$. Denote by \mathcal{Q} the set of partition points of $f(\cdot)$, and by \mathcal{Q}_i the set of partition points of the i th map in the sequence of Markov map approximations. The sets of partition points for the increasingly fine approximations are defined recursively via

$$\mathcal{Q}_i = \mathcal{Q}_{i-1} \cup f^{-1}(\mathcal{Q}_{i-1}) . \quad (72.43)$$

In turn, each approximating map $\hat{f}_i(\cdot)$ is defined by specifying its value at the partition points \mathcal{Q}_i by a procedure that ensures that the Markov property holds [15]. At all other points, the map $\hat{f}_i(\cdot)$ is defined by linear interpolation.

Conveniently, if $f(\cdot)$ is an eventually expanding map in the sense of Definition 72.1, then the sequence of piecewise-linear Markov approximations $\hat{f}_i(\cdot)$ obtained by the above procedure statistically converges to $f(\cdot)$, i.e., converges in the sense of Definition 72.3. This means that, for sufficiently large i , the statistics of $\hat{f}_i(\cdot)$ are close to those of $f(\cdot)$. As a practical consequence, the correlation statistics of the eventually expanding map $f(\cdot)$ can be approximated by first determining a Markov map $\hat{f}_k(\cdot)$ that is a good approximation to $f(\cdot)$, and then finding the statistics of Markov map using the techniques described in Section 72.6.

73.1 Introduction

Fractal signal models are important in a wide range of signal processing applications. For example, they are often well-suited to analyzing and processing various forms of natural and man-made phenomena. Likewise, the synthesis of such signals plays an important role in a variety of electronic systems for simulating physical environments. In addition, the generation, detection, and manipulation of signals with fractal characteristics has become of increasing interest in communication and remote-sensing applications.

A defining characteristic of a fractal signal is its invariance to time- or space-dilation. In general, such signals may be one-dimensional (e.g., fractal time series) or multidimensional (e.g., fractal natural terrain models). Moreover, they may be continuous-time or discrete-time in nature, and may be continuous or discrete in amplitude.

73.2 Fractal Random Processes

Most generally, fractal signals are signals having detail or structure on all temporal or spatial scales. The fractal signals of most interest in applications are those in which the structure at different scales is similar. Formally, a zero-mean random process $x(t)$ defined on $-\infty < t < \infty$ is *statistically self-similar* if its statistics are invariant to dilations and compressions of the waveform in time. More specifically, a random process $x(t)$ is statistically self-similar with parameter H if for any real $a > 0$ it obeys the scaling relation $x(t) \stackrel{\mathcal{P}}{=} a^{-H} x(at)$, where $\stackrel{\mathcal{P}}{=}$ denotes equality in a statistical sense. For *strict-sense* self-similar processes, this equality is in the sense of all finite-dimensional joint probability distributions. For *wide-sense* self-similar processes, the equality is interpreted in the sense of second-order statistics, i.e., the

$$R_x(t, s) \triangleq E[x(t)x(s)] = a^{-2H} R_x(at, as)$$

A sample path of a self-similar process is depicted in Fig. 73.1.

FIGURE 73.1: A sample waveform from a statistically scale-invariant random process, depicted on three different scales.

While regular self-similar random processes cannot be stationary, many physical processes exhibiting self-similarity possess some stationary attributes. An important class of models for such phenomena are referred to as “ $1/f$ processes”. The $1/f$ family of statistically self-similar random processes are empirically defined as processes having measured power spectra obeying a power law relationship of the form

$$S_x(\omega) \sim \frac{\sigma_x^2}{|\omega|^\gamma} \quad (73.1)$$

for some spectral parameter γ related to H according to $\gamma = 2H + 1$.

Generally, the power law relationship (73.1) extends over several decades of frequency. While data length typically limits access to spectral information at lower frequencies, and data resolution typically limits access to spectral content at higher frequencies, there are many examples of phenomena for which arbitrarily large data records justify a $1/f$ spectrum of the form (73.1) over all accessible frequencies. However, (73.1) is not integrable and hence, strictly speaking, does not constitute a valid power spectrum in the theory of stationary random processes. Nevertheless, a variety of interpretations of such spectra have been developed based on notions of generalized spectra [1, 2, 3].

As a consequence of their inherent self-similarity, the sample paths of $1/f$ processes are typically fractals [4]. The graphs of sample paths of random processes are one-dimensional curves in the plane; this is their “topological dimension”. However, fractal random processes have sample paths that are so irregular that their graphs have an “effective” fractional dimension that exceeds their topological dimension of unity. It is this effective dimension that is usually referred to as the “fractal” dimension of the graph. However, it is important to note that the notion of fractal dimension is not uniquely defined. There are several different definitions of fractal dimension from which to choose for a given application—each with subtle but significant differences [5]. Nevertheless, regardless of the particular definition, the fractal dimension D of the graph of a fractal function typically ranges between $D = 1$ and $D = 2$. Larger values of D correspond to functions whose graphs are increasingly rough in appearance and,

in an appropriate sense, fill the plane in which the graph resides to a greater extent. For $1/f$ processes, there is an inverse relationship between the fractal dimension D and the self-similarity parameter H of the process: an increase in the parameter H yields a decrease in the dimension D , and vice-versa. This is intuitively reasonable, since an increase in H corresponds to an increase in γ , which, in turn, reflects a redistribution of power from high to low frequencies and leads to sample functions that are increasingly smooth in appearance.

A truly enormous and tremendously varied collection of natural phenomena exhibit $1/f$ -type spectral behavior over many decades of frequency. A partial list includes (see, e.g., [4, 6, 7, 8, 9] and the references therein): geophysical, economic, physiological, and biological time series; electromagnetic and resistance fluctuations in media; electronic device noises; frequency variation in clocks and oscillators; variations in music and vehicular traffic; spatial variation in terrestrial features and clouds; and error behavior and traffic patterns in communication networks.

While $\gamma \approx 1$ in many of these examples, more generally $0 \leq \gamma \leq 2$. However, there are many examples of phenomena in which γ lies well outside this range. For $\gamma \geq 1$, the lack of integrability of (73.1) in a neighborhood of the spectral origin reflects the preponderance of low-frequency energy in the corresponding processes. This phenomenon is termed the *infrared catastrophe*. For many physical phenomena, measurements corresponding to very small frequencies show no low-frequency roll off, which is usually understood to reveal an inherent nonstationarity in the underlying process. Such is the case for the Wiener process (regular Brownian motion), for which $\gamma = 2$. For $\gamma \leq 1$, the lack of integrability in the tails of the spectrum reflects a preponderance of high-frequency energy and is termed the *ultraviolet catastrophe*. Such behavior is familiar for generalized Gaussian processes such as stationary white Gaussian noise ($\gamma = 0$) and its usual derivatives. When $\gamma = 1$, both catastrophes are experienced. This process is referred to as “pink” noise, particularly in the audio applications where such noises are often synthesized for use in room equalization.

An important property of $1/f$ processes is their persistent statistical dependence. Indeed, the generalized Fourier pair [10]

$$\frac{|\tau|^{\gamma-1}}{2\Gamma(\gamma) \cos(\gamma\pi/2)} \xleftrightarrow{\mathcal{F}} \frac{1}{|\omega|^\gamma} \quad (73.2)$$

valid for $\gamma > 0$ but $\gamma \neq 1, 2, 3, \dots$, reflects that the autocorrelation $R_x(\tau)$ associated with the spectrum (73.1) for $0 < \gamma < 1$ is characterized by slow decay of the form $R_x(\tau) \sim |\tau|^{\gamma-1}$.

This power law decay in correlation structure distinguishes $1/f$ processes from many traditional models for time series analysis. For example, the well-studied family of autoregressive moving-average (ARMA) models have a correlation structure invariably characterized by *exponential* decay. As a consequence, ARMA models are generally inadequate for capturing long-term dependence in data.

One conceptually important characterization for $1/f$ processes is that based on the effects of bandpass filtering on such processes [11]. This characterization is strongly tied to empirical characterizations of $1/f$ processes, and is particularly useful for engineering applications. With this characterization, a $1/f$ process is formally *defined* as a wide-sense statistically self-similar random process having the property that when filtered by some arbitrary ideal bandpass filter (where $\omega = 0$ and $\omega = \pm\infty$ are strictly not in the passband), the resulting process is wide-sense stationary and has finite variance.

Among a variety of implications of this definition, it follows that such a process also has the property that when filtered by *any* ideal bandpass filter (again such that $\omega = 0$ and $\omega = \pm\infty$ are strictly not in the passband), the result is a wide-sense stationary process with a spectrum that is $\sigma_x^2/|\omega|^\gamma$ within the passband of the filter.

73.2.1 Models and Representations for $1/f$ Processes

A variety of exact and approximate mathematical models for $1/f$ processes are useful in signal processing applications. These include fractional Brownian motion, generalized autoregressive-moving-average, and wavelet-based models.

Fractional Brownian Motion and Fractional Gaussian Noise

Fractional Brownian motion and fractional Gaussian noise have proven to be useful mathematical models for Gaussian $1/f$ behavior. In particular, the fractional Brownian motion framework provides a useful construction for models of $1/f$ -type spectral behavior corresponding to spectral exponents in the range $-1 < \gamma < 1$ and $1 < \gamma < 3$; see, e.g., [4, 7]. In addition, it has proven useful for addressing certain classes of signal processing problems; see, e.g., [12, 13, 14, 15].

Fractional Brownian motion is a nonstationary Gaussian self-similar process $x(t)$ with the property that its corresponding self-similar increment process

$$\Delta x(t; \varepsilon) \triangleq \frac{x(t + \varepsilon) - x(t)}{\varepsilon}$$

is stationary for every $\varepsilon > 0$.

A convenient though specialized definition of fractional Brownian motion is given by Barton and Poor [12]:

$$\begin{aligned} x(t) \triangleq & \frac{1}{\Gamma(H + 1/2)} \left[\int_{-\infty}^0 \left(|t - \tau|^{H-1/2} - |\tau|^{H-1/2} \right) w(\tau) d\tau \right. \\ & \left. + \int_0^t |t - \tau|^{H-1/2} w(\tau) d\tau \right] \end{aligned} \quad (73.3)$$

where $0 < H < 1$ is the self-similarity parameter, and where $w(t)$ is a zero-mean, stationary white Gaussian noise process with unit spectral density. When $H = 1/2$, (73.3) specializes to the Wiener process, i.e., classical Brownian motion. Sample functions of fractional Brownian motion have a fractal dimension (in the Hausdorff-Besicovitch sense) given by [4, 5]

$$D = 2 - H.$$

Moreover, the correlation function for fractional Brownian motion is given by

$$R_x(t, s) = E[x(t)x(s)] = \frac{\sigma_H^2}{2} \left(|s|^{2H} + |t|^{2H} - |t - s|^{2H} \right),$$

where

$$\sigma_H^2 = \text{var } x(1) = \Gamma(1 - 2H) \frac{\cos(\pi H)}{\pi H}.$$

The increment process leads to a conceptually useful interpretation of the derivative of fractional Brownian motion: as $\varepsilon \rightarrow 0$, fractional Brownian motion has, with $H' = H - 1$, the generalized derivative [12]

$$x'(t) = \frac{d}{dt}x(t) = \lim_{\varepsilon \rightarrow 0} \Delta x(t; \varepsilon) = \frac{1}{\Gamma(H' + 1/2)} \int_{-\infty}^t |t - \tau|^{H'-1/2} w(\tau) d\tau, \quad (73.4)$$

which is termed *fractional Gaussian noise*. This process is stationary and statistically self-similar with parameter H' . Moreover, since (73.4) is equivalent to a convolution, $x'(t)$ can be interpreted as the output of an unstable linear time-invariant system with impulse response

$$v(t) = \frac{1}{\Gamma(H - 1/2)} t^{H-3/2} u(t)$$

driven by $w(t)$. Fractional Brownian motion $x(t)$ is recovered via

$$x(t) = \int_0^t x'(t) dt.$$

The character of the fractional Gaussian noise $x'(t)$ depends strongly on the value of H . This follows from the autocorrelation function for the increments of fractional Brownian motion, viz.,

$$\begin{aligned} R_{\Delta x}(\tau; \varepsilon) &\triangleq E [\Delta x(t; \varepsilon) \Delta x(t - \tau; \varepsilon)] \\ &= \frac{\sigma_H^2 \varepsilon^{2H-2}}{2} \left[\left(\frac{|\tau|}{\varepsilon} + 1 \right)^{2H} - 2 \left(\frac{|\tau|}{\varepsilon} \right)^{2H} + \left(\frac{|\tau|}{\varepsilon} - 1 \right)^{2H} \right], \end{aligned}$$

which at large lags ($|\tau| \gg \varepsilon$) takes the form

$$R_{\Delta x}(\tau) \approx \sigma_H^2 H(2H - 1) |\tau|^{2H-2}. \quad (73.5)$$

Since the right side of Eq. (73.5) has the same algebraic sign as $H - 1/2$, for $1/2 < H < 1$ the process $x'(t)$ exhibits long-term dependence, i.e., persistent correlation structure; in this regime, fractional Gaussian noise is stationary with autocorrelation

$$R_{x'}(\tau) = E [x'(t)x'(t - \tau)] = \sigma_H^2 (H' + 1)(2H' + 1) |\tau|^{2H'},$$

and the generalized Fourier pair (73.2) suggests that the corresponding power spectral density can be expressed as $S_{x'}(\omega) = 1/|\omega|^{\gamma'}$, where $\gamma' = 2H' + 1$. In other regimes, for $H = 1/2$ the derivative $x'(t)$ is the usual stationary white Gaussian noise, which has no correlation, while for $0 < H < 1/2$, fractional Gaussian noise exhibits persistent anti-correlation.

A closely related discrete-time fractional Brownian motion framework for modeling $1/f$ behavior has also been extensively developed based on the notion of fractional differencing [16, 17].

ARMA Models for $1/f$ Behavior

Another class of models that has been used for addressing signal processing problems involving $1/f$ processes is based on a generalized autoregressive moving-average framework. These models have been used both in signal modeling and processing applications, as well as in synthesis applications as $1/f$ noise generators and simulators [18, 19, 20].

One such framework is based on a “distribution of time constants” formulation [21, 22]. With this approach, a $1/f$ process is modeled as the weighted superposition of an infinite number of independent random processes, each governed by a distinct characteristic time-constant $1/\alpha > 0$. Each of these random processes has correlation function $R_\alpha(\tau) = e^{-\alpha|\tau|}$ corresponding to a Lorentzian spectra of the form $S_\alpha(\omega) = 2\alpha/(\alpha^2 + \omega^2)$, and can be modeled as the output of a causal LTI filter with system function $\Upsilon_\alpha(s) = \sqrt{2\alpha}/(s + \alpha)$ driven by an independent stationary white noise source. The weighted superposition of a continuum of such processes has an effective spectrum

$$S_x(\omega) = \int_0^\infty S_\alpha(\omega) f(\alpha) d\alpha, \quad (73.6)$$

where the weights $f(\alpha)$ correspond to the density of poles or, equivalently, relaxation times. If an unnormalizable, scale-invariant density of the form $f(\alpha) = \alpha^{-\gamma}$ is chosen for $0 < \gamma < 2$, the resulting spectrum (73.6) is $1/f$, i.e., of the form (73.1).

More practically, useful approximate $1/f$ models result from using a countable collection of single time-constant processes in the superposition. With this strategy, poles are uniformly distributed along a logarithmic scale along the negative part of the real axis in the s -plane. The process $x(t)$

synthesized in this manner has a nearly- $1/f$ spectrum in the sense that it has a $1/f$ characteristic with superimposed ripple that is uniform-spaced and of uniform amplitude on a log-log frequency plot. More specifically, when the poles are exponentially spaced according to

$$\alpha_m = \Delta^m, \quad -\infty < m < \infty, \quad (73.7)$$

for some $1 < \Delta < \infty$, the limiting spectrum

$$S_x(\omega) = \sum_m \frac{\Delta^{(2-\gamma)m}}{\omega^2 + \Delta^{2m}} \quad (73.8)$$

satisfies

$$\frac{\sigma_L^2}{|\omega|^\gamma} \leq S_x(\omega) \leq \frac{\sigma_U^2}{|\omega|^\gamma} \quad (73.9)$$

for some $0 < \sigma_L^2 \leq \sigma_U^2 < \infty$, and has exponentially spaced ripple such that for all integers k

$$|\omega|^\gamma S_x(\omega) = |\Delta^k \omega|^\gamma S_x(\Delta^k \omega). \quad (73.10)$$

As Δ is chosen closer to unity, the pole spacing decreases, which results in a decrease in both the amplitude and spacing of the spectral ripple on a log-log plot.

The $1/f$ model that results from this discretization may be interpreted as an infinite-order ARMA process, i.e., $x(t)$ may be viewed as the output of a rational LTI system with a countably infinite number of both poles and zeros driven by a stationary white noise source. This implies, among other properties, that the corresponding space descriptions of these models for long-term dependence require infinite numbers of state variables. These processes have been useful in modeling physical $1/f$ phenomena; see, e.g., [23, 24, 25]. And practical signal processing algorithms for them can often be obtained by extending classical tools for processing regular ARMA processes.

The above method focuses on selecting appropriate pole locations for the extended ARMA model. The zero locations, by contrast, are controlled indirectly, and bear a rather complicated relationship to the pole locations. With other extended ARMA models for $1/f$ behavior, both pole and zero locations are explicitly controlled, often with improved approximation characteristics [20]. As an example, [6, 26] describe a construction as filtered white noise where the filter structure consists of a cascade of first-order sections each with a single pole and zero. With a continuum of such sections, exact $1/f$ behavior is obtained. When a countable collection of such sections is used, nearly- $1/f$ behavior is obtained as before. In particular, when stationary white noise is driven through an LTI system with a rational system function

$$\Upsilon(s) = \prod_{m=-\infty}^{\infty} \left[\frac{s + \Delta^{m+\gamma/2}}{s + \Delta^m} \right], \quad (73.11)$$

the output has power spectrum

$$S_x(\omega) \propto \prod_{m=-\infty}^{\infty} \left[\frac{\omega^2 + \Delta^{2m+\gamma}}{\omega^2 + \Delta^{2m}} \right]. \quad (73.12)$$

This nearly- $1/f$ spectrum also satisfies both (73.9) and (73.10). Comparing the spectra (73.12) and (73.8) reveals that the pole placement strategy for both is identical, while the zero placement strategy is distinctly different.

The system function (73.11) associated with this alternative extended ARMA model lends useful insight into the relationship between $1/f$ behavior and the limiting processes corresponding to $\gamma \rightarrow 0$

and $\gamma \rightarrow 2$. On a logarithmic scale, the poles and zeros of (73.11) are each spaced uniformly along the negative real axis in the s -plane, and to the left of each pole lies a matching zero, so that poles and zeros are alternating along the half-line. However, for certain values of γ , pole-zero cancellation takes place. In particular, as $\gamma \rightarrow 2$, the zero pattern shifts left canceling all poles except the limiting pole at $s = 0$. The resulting system is therefore an integrator, characterized by a single state variable, and generates a Wiener process as anticipated. By contrast, as $\gamma \rightarrow 0$, the zero pattern shifts right canceling all poles. The resulting system is therefore a multiple of the identity system, requires no state variables, and generates stationary white noise as anticipated.

An additional interpretation is possible in terms of a Bode plot. Stable, rational system functions composed of real poles and zeros are generally only capable of generating transfer functions whose Bode plots have slopes that are integer multiples of $20 \log_{10} 2 \approx 6$ dB/octave. However, a $1/f$ synthesis filter must fall off at $10\gamma \log_{10} 2 \approx 3\gamma$ dB/octave, where $0 < \gamma < 2$ is generally not an integer. With the extended ARMA models, a rational system function with an alternating sequence of poles and zeros is used to generate a stepped approximation to a -3γ dB/octave slope from segments that alternate between slopes of -6 dB/octave and 0 dB/octave.

Wavelet-Based Models for $1/f$ Behavior

Another approach to $1/f$ process modeling is based on the use of wavelet basis expansions. These lead to representations for processes exhibiting $1/f$ -type behavior that are useful in a wide range of signal processing applications.

Orthonormal wavelet basis expansions play the role of Karhunen-Loève-type expansions for $1/f$ -type processes [11, 27]. More specifically, wavelet basis expansions in terms of uncorrelated random variables constitute very good models for $1/f$ -type behavior. For example, when a sufficiently regular orthonormal wavelet basis $\{\psi_n^m(t) = 2^{m/2} \psi(2^m t - n)\}$ is used, expansions of the form

$$x(t) = \sum_m \sum_n x_n^m \psi_n^m(t),$$

where the x_n^m are a collection of mutually uncorrelated, zero-mean random variables with the geometric scale-to-scale variance progression

$$\text{var } x_n^m = \sigma^2 2^{-\gamma m}, \quad (73.13)$$

lead to a nearly- $1/f$ power spectrum of the type obtained via the extended ARMA models. This behavior holds regardless of the choice of wavelet within this class, although the detailed structure of the ripple in the nearly- $1/f$ spectrum can be controlled by judicious choice of the particular wavelet.

More generally, wavelet decompositions of $1/f$ -type processes have a decorrelating property. For example, if $x(t)$ is a $1/f$ process, then the coefficients of the expansion of the process in terms of a sufficiently regular wavelet basis, i.e., the

$$x_n^m = \int_{-\infty}^{+\infty} x(t) \psi_n^m(t) dt$$

are very weakly correlated and obey the scale-to-scale variance progression (73.13). Again, the detailed correlation structure depends on the particular choice of wavelet [3, 11, 28, 29].

This decorrelating property is exploited in many wavelet-based algorithms for processing $1/f$ signals, where the residual correlation among the wavelet coefficients can usually be ignored. In addition, the resulting algorithms typically have very efficient implementations based on the discrete wavelet transform. Examples of robust wavelet-based detection and estimation algorithms for use with $1/f$ -type signals are described in [11, 27, 30].

73.3 Deterministic Fractal Signals

While stochastic signals with fractal characteristics are important models in a wide range of engineering applications, deterministic signals with such characteristics have also emerged as potentially important in engineering applications involving signal generation ranging from communications to remote sensing.

Signals $x(t)$ of this type satisfying the deterministic scale-invariance property

$$x(t) = a^{-H} x(at) \quad (73.14)$$

for all $a > 0$, are generally referred to in mathematics as *homogeneous* functions of degree H . Strictly homogeneous functions can be parameterized with only a few constants [31], and constitute a rather limited class of models for signal generation applications. A richer class of homogeneous signal models is obtained by considering waveforms that are required to satisfy (73.14) only for values of a that are integer powers of two, i.e., signals that satisfy the dyadic self-similarity property $x(t) = 2^{-kH} x(2^k t)$ for all integers k .

Homogeneous signals have spectral characteristics analogous to those of $1/f$ processes, and have fractal properties as well. Specifically, although all non-trivial homogeneous signals have infinite energy and many have infinite power, there are classes of such signals with which one can associate a generalized $1/f$ -like Fourier transform, and others with which one can associate a generalized $1/f$ -like power spectrum. These two classes of homogeneous signals are referred to as energy-dominated and power-dominated, respectively [11, 32]. An example of such a signal is depicted in Fig. 73.2.

FIGURE 73.2: Dilated homogeneous signal.

Orthonormal wavelet basis expansions provide convenient and efficient representations for these classes of signals. In particular, the wavelet coefficients of such signals are related according to

$$x_n^m = \int_{-\infty}^{+\infty} x(t) \psi_n^m(t) dt = \beta^{-m/2} q[n],$$

where $q[n]$ is termed a generating sequence and $\beta = 2^{2H+1} = 2^\gamma$. This relationship is depicted in Fig. 73.3, where the self-similarity inherent in these signals is immediately captured in the time-frequency portrait of such signals as represented by their wavelet coefficients. More generally, wavelet expansion naturally lead to “orthonormal self-similar bases” for homogeneous signals [11, 32]. Fast synthesis and analysis algorithms for these signals are based on the discrete wavelet transform.

FIGURE 73.3: The time-frequency portrait of a homogeneous signal.

For some communications applications, the objective is to embed an information sequence into a fractal waveform for transmission over an unreliable communication channel. In this context, it is often natural for $q[n]$ to be the information bearing sequence such as a symbol stream to be transmitted, and the corresponding modulation

$$x(t) = \sum_m \sum_n x_n^m \psi_n^m(t)$$

to be the fractal waveform to be transmitted. This encoding, referred to as “fractal modulation” [32] corresponds to an efficient diversity transmission strategy for certain classes of communication channels. Moreover, it can be viewed as a multirate modulation strategy in which data is transmitted simultaneously at multiple rates, and is particularly well-suited to channels having the characteristic that they are “open” for some unknown time interval T , during which they have some unknown bandwidth W and a particular signal-to-noise ratio (SNR). Such a channel model can be used, for example, to capture both characteristics of the transmission medium, such as in the case of meteor-burst channels, the constraints inherent in disparate receivers in broadcast applications, and/or the effects of jamming in military applications.

73.4 Fractal Point Processes

Fractal point processes correspond to event distributions in one or more dimensions having self-similar statistics, and are well-suited to modeling, among other examples, the distribution of stars

and galaxies, demographic distributions, the sequence of spikes generated by auditory neural firing in animals, vehicular traffic, and data traffic on packet-switched data communication networks [4, 33, 34, 35, 36].

A point process is said to be self-similar if the associated counting process $N_X(t)$, whose value at time t is the total number of arrivals up to time t , is statistically invariant to temporal dilations and compressions, i.e., $N_X(t) \stackrel{\mathcal{P}}{=} N_X(at)$ for all $a > 0$, where the notation $\stackrel{\mathcal{P}}{=}$ again denotes statistical equality in the sense of all finite-dimensional distributions. An example of a sample path for such a counting process is depicted in Fig. 73.4.

FIGURE 73.4: Dilated fractal renewal process sample path.

Physical fractal point process phenomena generally also possess certain quasi-stationary attributes. For example, empirical measurements of the statistics of the interarrival times $X[n]$, i.e., the time interval between the $(n-1)$ st and n th arrivals, are consistent with a *renewal* process. Moreover, the

associated interarrival density is a power-law, i.e.,

$$f_X(x) \sim \frac{\sigma_x^2}{x^\gamma} u(x), \quad (73.15)$$

where $u(x)$ is the unit-step function. However, (73.15) is an unnormalizable density, which is a reflection of the fact that a point process cannot, in general, be both self-similar and renewing. This is analogous to the result that a continuous process cannot, in general, be simultaneously self-similar and stationary.

However, self-similar processes can possess a milder “conditionally renewing” property [37, 38]. Such processes are referred to as “fractal renewal processes” and have an effectively stationary character. The shape parameter γ in the unnormalizable interarrival density (73.15) is related to the fractal dimension D of the process via [4] $D = \gamma - 1$, and is a measure of the extent to which arrivals “cover” the line.

73.4.1 Multiscale Models

As in the case of continuous fractal processes, multiscale models are both conceptually and practically important representations for discrete fractal processes. As an example, one useful class of multiscale models corresponds to a mixture of simple Poisson processes on different time scales [37]. The construction of such processes involves a collection $\{N_{W_A}(t)\}$ of mutually independent Poisson counting processes such that $N_{W_A}(t) \stackrel{\mathcal{P}}{=} N_{W_0}(e^{-A}t)$. The process $N_{W_0}(t)$ is a prototype whose mean arrival rate we denote by λ , so that the mean arrival rates of the constituent processes are related according to $\lambda_A = e^{-A}\lambda$. A random mixture of this continuum of Poisson processes yields a fractal renewal process when the index choice $A[n]$ for the n th arrival is distributed according to the extended exponential density $f_A(a) \sim \sigma_A^2 e^{-(\gamma-1)a}$. In particular, the first interarrival of the composite process is chosen to be the first arrival of the Poisson process indexed by $A[1]$; the second arrival of the composite process is chosen to be the next arrival in the Poisson process indexed by $A[2]$; and so on.

Useful alternative but equivalent constructions result from exploiting the memoryless property of Poisson processes. For example, interarrival times can be generated according to $X[n] = W_{A[n]}[n]$ or

$$X[n] = e^{A[n]} W_0[n], \quad (73.16)$$

where $W_A[n]$ is the n th interarrival time for the Poisson process indexed by A . The synthesis (73.16) is particularly appealing in that it requires access to only exponential random variables that can be obtained in practice from a single prototype Poisson process. The construction (73.16) also leads to the interpretation of a fractal point process as a Poisson process in which the arrival rate is selected randomly and independently after each arrival (and held constant between consecutive arrivals). Related doubly stochastic process models are described by Johnson et al. [39].

In addition to their use in applications requiring the synthesis of fractal point processes, these multiscale models have also proven useful in signal estimation problems. For these kinds of signal analysis applications, it is frequently convenient to replace the continuum Poisson mixture with a discrete Poisson mixture. Typically, a collection of constituent Poisson counting processes $N_{W_M}(t)$ is used, where M is an integer-valued scale index, and where the mean arrival rates are related according to $\lambda_M = \rho^{-M}\lambda$ for some λ . In this case, the scale selection is governed by an extended geometric probability mass function of the form $p_M(m) \sim \sigma_M^2 \rho^{-(\gamma-1)m}$. This discrete synthesis leads to processes that are approximate fractal renewal processes, in the sense that the interarrival densities follow a power law with a typically small amount of superimposed ripple. A number of efficient algorithms for exploiting such models in the development of robust signal estimation algorithms for use with fractal renewal processes are described in, e.g., [37].

From a broader perspective, the Poisson mixtures can be viewed as a nonlinear multiresolution signal analysis framework that can be generalized to accommodate a broad class of point process phenomena. As such, this framework is the point process counterpart to the linear multiresolution signal analysis framework based on wavelets that is used for a broad class of continuous-valued signals.

73.4.2 Extended Markov Models

An equivalent description of the discrete Poisson mixture model is in terms of an extended Markov model. The associated multiscale pure-birth process, depicted in Fig. 73.5, involves a state space consisting of a set of “superstates”, each of which corresponds to fixed number of arrivals (births). Included in a superstate is a set of states corresponding to the scales in the Poisson mixture. Hence, each state is indexed by an ordered pair (i, j) , where i is the superstate index and j is the scale index within each superstate.

FIGURE 73.5: Multiscale pure-birth process corresponding to Poisson mixture.

The extended Markov model description has proven useful in analyzing the properties of fractal point processes under some fundamental transformations, including superposition and random erasure. These properties, in turn, provide key insight into the behavior of merging and branching traffic at nodes in data communication, vehicular, and other networks. See, e.g., [40].

Other important classes of fractal point process transformations that arise in applications involving queuing. And the extended Markov model also plays an important role in analyzing fractal queues. To address these problems, a multiscale birth-death process model is generally used [40].

74.1 Introduction

This chapter provides a brief introduction to the theory of morphological signal processing and its applications to image analysis and nonlinear filtering. By “morphological signal processing” we mean a broad and coherent collection of theoretical concepts, mathematical tools for signal analysis, nonlinear signal operators, design methodologies, and applications systems that are based on or related to *mathematical morphology* (MM), a set- and lattice-theoretic methodology for image analysis. MM aims at quantitatively describing the geometrical structure of image objects. Its mathematical origins stem from set theory, lattice algebra, convex analysis, and integral and stochastic geometry. It was initiated mainly by Matheron [42] and Serra [58] in the 1960s. Some of its early signal operations are also found in the work of other researchers who used cellular automata and Boolean/threshold logic to analyze binary image data in the 1950s and 1960s, as surveyed in [49, 54]. MM has formalized these earlier operations and has also added numerous new concepts and image operations. In the 1970s it was extended to gray-level images [22, 45, 58, 62]. Originally MM was applied to analyzing

images from geological or biological specimens. However, its rich theoretical framework, algorithmic efficiency, easy implementability on special hardware, and suitability for many shape-oriented problems have propelled its widespread diffusion and adoption by many academic and industry groups in many countries as one among the dominant image analysis methodologies. Many of these research groups have also extended the theory and applications of MM. As a result, MM nowadays offers many theoretical and algorithmic tools to and inspires new directions in many research areas from the fields of signal processing, image processing and machine vision, and pattern recognition.

As the name ‘morphology’ implies (study/analysis of shape/form), morphological signal processing can quantify the shape, size, and other aspects of the geometrical structure of signals viewed as image objects, in a rigorous way that also agrees with human intuition and perception. In contrast, the traditional tools of linear systems and Fourier analysis are of limited or no use for solving geometry-based problems in image processing because they do not directly address the fundamental issues of how to quantify shape, size, or other geometrical structures in signals and may distort important geometrical features in images. Thus, morphological systems are more suitable than linear systems for shape analysis. Further, they offer simple and efficient solutions to other nonlinear problems, such as non-Gaussian noise suppression or envelope estimation. They are also closely related to another class of nonlinear systems, the median, rank, and stack operators, which also outperform linear systems in non-Gaussian noise suppression and in signal enhancement with geometric constraints. Actually, rank and stack operators can be represented in terms of elementary morphological operators. All of the above, coupled with the rich mathematical background of mathematical morphology, make morphological signal processing a rigorous and efficient framework to study and solve many problems in image analysis and nonlinear filtering.

74.2 Morphological Operators for Sets and Signals

74.2.1 Boolean Operators and Threshold Logic

Early works in the fields of visual pattern recognition and cellular automata dealt with analysis of binary digital images using local neighborhood operations of the Boolean type. For example, given a sampled¹ binary image signal $f[x]$ with values 1 for the image foreground and 0 for the background, typical signal transformations involving a neighborhood of n samples whose indices are arranged in a window set $W = \{y_1, y_2, \dots, y_n\}$ would be

$$\psi_b(f)[x] = b(f[x - y_1], \dots, f[x - y_n])$$

where $b(v_1, \dots, v_n)$ is a Boolean function of n variables. The mapping $f \mapsto \psi_b(f)$ is a nonlinear system, called a *Boolean operator*. By varying the Boolean function b , a large variety of Boolean operators can be obtained; see Table 74.1 where $W = \{-1, 0, 1\}$. For example, choosing a Boolean AND for b would *shrink* the input image foreground, whereas a Boolean OR would *expand* it.

Two alternative implementations and views of these Boolean operations are (1) *thresholded convolutions*, where a binary input is linearly convolved with an n -point mask of ones and then the output is thresholded at 1 or n to produce the Boolean OR or AND, respectively, and (2) *min / max operations*, where the moving local minima and maxima of the binary input signal produce the same output as Boolean AND/OR, respectively. In the thresholded convolution interpretation, thresholding at an intermediate level r between 1 and n produces a binary rank operation of the binary input data (inside the moving window). For example, if $r = (n + 1)/2$, we obtain the binary median filter whose

¹Signals of a continuous variable $x \in \mathbb{R}^d$ are usually denoted by $f(x)$, whereas for signals with discrete variable $x \in \mathbb{Z}^d$ we write $f[x]$.

TABLE 74.1 Discrete Set Operators and Their
Generating Boolean Function

Set Operator $\Psi(X)$, $X \subseteq \mathbb{Z}$	Boolean function $b(v_1, v_2, v_3)$
Erosion: $X \ominus \{-1, 0, 1\}$	$v_1 v_2 v_3$
Dilation: $X \oplus \{-1, 0, 1\}$	$v_1 + v_2 + v_3$
Median: $X \square_2 \{-1, 0, 1\}$	$v_1 v_2 + v_1 v_3 + v_2 v_3$
Hit-Miss: $X \otimes (\{-1, 1\}, \{0\})$	$v_1 v_2 v_3$
Opening: $X \circ \{0, 1\}$	$v_1 v_2 + v_2 v_3$
Closing: $X \bullet \{0, 1\}$	$v_2 + v_1 v_3$

Boolean function expresses the majority voting logic; see the third example of Table 74.1. Of course, numerous other Boolean operators are possible, since there are 2^{2^n} possible Boolean functions of n variables. The main applications of such Boolean signal operations have been in biomedical image processing, character recognition, object detection, and general 2D shape analysis. Detailed accounts and more references of these approaches and applications can be found in [49, 54].

74.2.2 Morphological Set Operators

Among the new important conceptual leaps offered by mathematical morphology was to use *sets* to represent binary image signals and set operations to represent binary image transformations. Specifically, given a binary image, let its foreground be represented by the set X and its background by the set complement X^c . The Boolean OR transformation of X by a (window) set B (local neighborhood of pixels) is mathematically equivalent to the Minkowski set addition \oplus , also called **dilation**, of X by B :

$$X \oplus B \equiv \{x + y : x \in X, y \in B\} = \bigcup_{y \in B} X_{+y} \quad (74.1)$$

where $X_{+y} \equiv \{x + y : x \in X\}$ is the *translation* of X along the vector y . Likewise, if $B^r \equiv \{x : -x \in B\}$ denotes the *reflection* of B with respect to the axes' origin, the Boolean AND transformation of X by the reflected B is equivalent to the Minkowski set subtraction [24] \ominus , also called **erosion**, of X or B :

$$X \ominus B \equiv \{x : B_{+x} \subseteq X\} = \bigcap_{y \in B} X_{-y} \quad (74.2)$$

In applications, B is usually called a *structuring element* and has a simple geometrical shape and a size smaller than the image set X . As shown in Fig. 74.1, erosion shrinks the original set, whereas dilation expands it.

The erosion (74.2) can also be viewed as Boolean template matching since it gives the center points at which the shifted structuring elements fits inside the image foreground. If we now consider a set A probing the image foreground set X and another set B probing the background X^c , the set of points at which the shifted pair (A, B) fits inside the images is the **hit-miss** transformation of X by (A, B) :

$$X \otimes (A, B) \equiv \{x : A_{+x} \subseteq X, B_{+x} \subseteq X^c\} \quad (74.3)$$

In the discrete case, this can be represented by a Boolean product function whose uncomplemented (complemented) variables correspond to points of $A(B)$; see Table 74.1. It has been used extensively for binary feature detection [58] and especially in document image processing [8, 9].

Dilating an eroded set by the same structuring element in general does not recover the original set but only a part of it, its opening. Performing the same series of operations to the set complement yields a set containing the original, its closing. Thus, cascading erosion and dilation gives rise to two new operations, the **opening** $X \circ B \equiv (X \ominus B) \oplus B$ and the **closing** $X \bullet B \equiv (X \oplus B) \ominus B$ of X by B . As shown in Fig. 74.1, the opening suppresses the sharp capes and cuts the narrow isthmuses of X , whereas the closing fills in the thin gulfs and small holes. Thus, if the structuring element B

FIGURE 74.1: Erosion, dilation, opening, and closing of X (binary image of an island) by a disk B centered at the origin. The shaded areas correspond to the interior of the sets, the dark solid curve to the boundary of the transformed sets, and the dashed curve to the boundary of the original set X .

has a regular shape, both opening and closing can be thought of as nonlinear filters which smooth the contours of the input signal.

These set operations make mathematical morphology more general than previous approaches because it unifies and systematizes all previous digital and analog binary image operations, mathematically rigorous and notationally elegant since it is based on set theory, and intuitive since the set formalism is easily connected to mathematical logic. Further, the basic morphological set operators directly relate to the shape and size of binary images in a way that has many common points with human perception about geometry and spatial reasoning.

74.2.3 Morphological Signal Operators and Nonlinear Convolutions

In the 1970s, morphological operators were extended from binary to gray-level images and real-valued signals. Going from sets to functions was made possible by using *set representations of signals* and transforming these input sets via morphological set operations. Thus, consider a signal $f(x)$

defined on the d -dimensional continuous or discrete domain $\mathbb{D} = \mathbb{R}^d$ or \mathbb{Z}^d and assuming values in $\bar{\mathbb{R}} = \mathbb{R} \cup \{-\infty, \infty\}$. Thresholding the signal at all amplitude values v produces an ensemble of **threshold binary signals**

$$\theta_v(f)(x) \equiv 1 \text{ if } f(x) \geq v, \text{ and } 0 \text{ else,} \quad (74.4)$$

represented by the **threshold sets** [58]

$$\Theta_v(f) \equiv \{x \in \mathbb{D} : f(x) \geq v\}, \quad -\infty < v < +\infty \quad (74.5)$$

The signal can be exactly reconstructed from all its thresholded versions since

$$f(x) = \sup\{v \in \mathbb{R} : x \in \Theta_v(f)\} = \sup\{v \in \mathbb{R} : \theta_v(f)(x) = 1\} \quad (74.6)$$

Transforming each threshold set by a set operator Ψ and viewing the transformed sets as threshold sets of a new signal creates a **flat** signal operator ψ whose output is

$$\psi(f)(x) = \sup\{v \in \mathbb{R} : x \in \Psi[\Theta_v(f)]\} \quad (74.7)$$

Using set dilation and erosion in place of Ψ , the above procedure creates the two most elementary morphological signal operators: the dilation and erosion of a signal $f(x)$ by a set B :

$$(f \oplus B)(x) \equiv \bigvee_{y \in B} f(x - y) \quad (74.8)$$

$$(f \ominus B)(x) \equiv \bigwedge_{y \in B} f(x + y) \quad (74.9)$$

where \bigvee denotes supremum (or maximum for finite B) and \bigwedge denotes infimum (or minimum for finite B). These gray-level morphological operations can also be created from their binary counterparts using concepts from fuzzy sets where set union and intersection becomes maximum and minimum on gray-level images [22, 45]. As Fig. 74.2 shows, flat erosion (dilation) of a function f by a small convex set B reduces (increases) the peaks (valleys) and enlarges the minima (maxima) of the function. The flat opening $f \circ B = (f \ominus B) \oplus B$ of f by B smooths the graph of f from below by cutting down its peaks, whereas the closing $f \bullet B = (f \oplus B) \ominus B$ smooths it from above by filling up its valleys.

More general morphological operators for gray-level 2D image signals $f(x)$ can be created [62] by representing the surface of f and all the points underneath by a 3D set $U(f) = \{(x, v) : v \leq f(x)\}$, called its *umbra*; then dilating or eroding $U(f)$ by the umbra of another signal g yields the umbras of two new signals, the dilation or erosion of f by g , which can be computed directly by the formulae:

$$(f \oplus g)(x) \equiv \bigvee_{y \in \mathbb{D}} f(x - y) + g(y) \quad (74.10)$$

$$(f \ominus g)(x) \equiv \bigwedge_{y \in \mathbb{D}} f(x + y) - g(y) \quad (74.11)$$

and two supplemental rules for adding and subtracting with infinities: $r \pm s = -\infty$ if $r = -\infty$ or $s = -\infty$, and $+\infty - r = +\infty$ if $r \in \mathbb{R} \cup \{+\infty\}$. These two signal transformations are nonlinear and translation-invariant. Their computational structure closely resembles that of a linear convolution $(f * g)[x] = \sum_y f[x - y]g[y]$ if we correspond the sum of products to the supremum of sums in the dilation. Actually, in the areas of convex analysis [50] and optimization [6], the operation (74.10) has been known as the **supremal convolution**. Similarly, replacing $-g(-x)$ with $g(x)$ in the erosion (74.11) yields the **infimal convolution**

$$(f \square g)(x) \equiv \bigwedge_{y \in \mathbb{D}} f(x - y) + g(y) \quad (74.12)$$

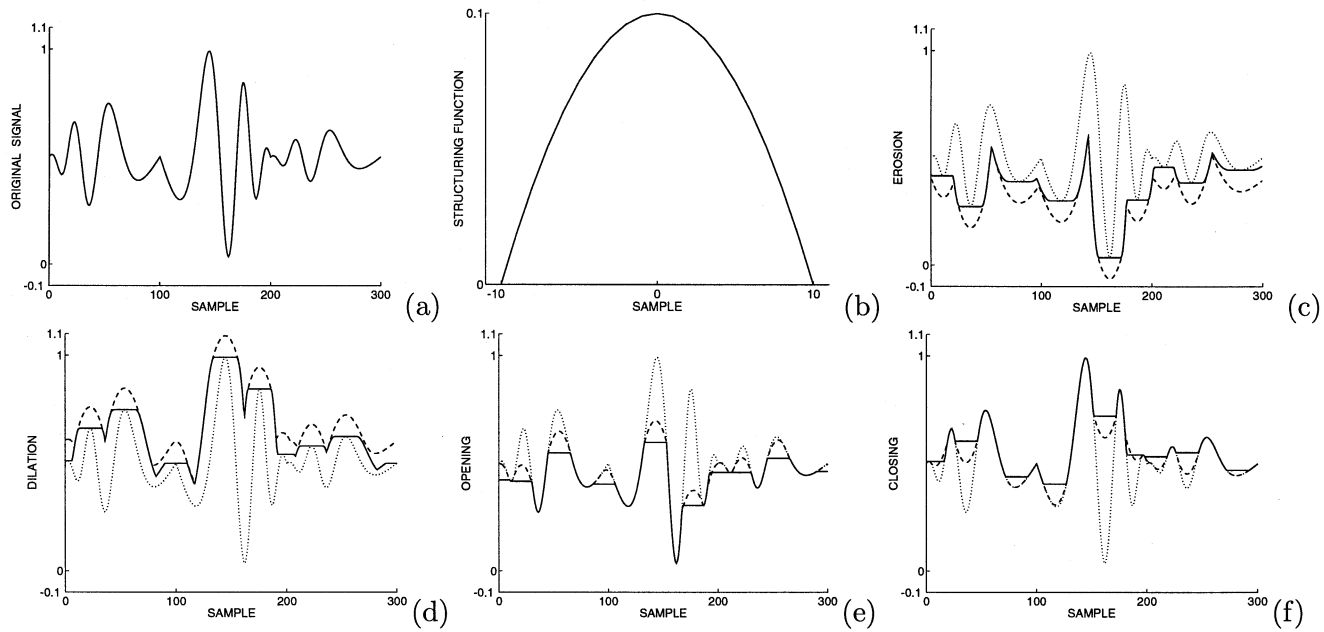

FIGURE 74.2: (a) Original signal f . (b) Structuring function g (a parabolic pulse). (c) Erosion $f \ominus g$ with dashed line and flat erosion $f \ominus B$ with solid line, where the set $B = \{x \in \mathbb{Z} : |x| \leq 10\}$ is the support of g . Dotted line shows original signal f . (d) Dilation $f \oplus g$ (dashed line) and flat dilation $f \oplus B$ (solid line). (e) Opening $f \circ g$ (dashed line) and flat opening $f \circ B$ (solid line). (f) Closing $f \bullet g$ (dashed line) and flat closing $f \bullet B$ (solid line).

The nonlinearity of \oplus and \ominus causes some differences between these signal operations and the linear convolutions. A major difference is that serial or parallel interconnections of systems represented by linear convolutions are equivalent to an overall linear convolution, whereas interconnections of dilations and erosions lead to entirely different nonlinear systems. Thus, there is an infinite variety of nonlinear operators created by cascading dilations and erosions or by interconnecting them in parallel via max / min or addition. Two such useful examples are the opening \circ and closing \bullet :

$$f \circ g \equiv (f \ominus g) \oplus g \quad (74.13)$$

$$f \bullet g \equiv (f \oplus g) \ominus g \quad (74.14)$$

which act as nonlinear smoothers.

Figure 74.2 shows that the four basic morphological transformations of a 1D signal f by a concave even function g with a compact support B have similar effects as the corresponding flat transformations by the set B . Among the few differences, the erosion (dilation) of f by g subtracts from (adds to) f the values of the moving template g during the decrease (increase) of signal peaks (valleys) and the broadening of the local signal minima (maxima) that would incur during erosion (dilation) by B . Similarly, the opening (closing) of f by g cuts the peaks (fills up the valleys) inside which no translated version of $g(-g)$ can fit and replaces these eliminated peaks (valleys) by replicas of $g(-g)$. In contrast, the flat opening or closing by B only cuts the peaks or fills valleys and creates flat plateaus in the output.

The four above morphological operators of dilation, erosion, opening, and closing have a rich collection of algebraic properties, some of which are listed in Tables 74.2 and 74.3, which endow them with a broad range of applications, make them rigorous, and lead to a variety of efficient serial or parallel implementations.

TABLE 74.2 Definitions of Operator Properties

Property	Set operator Ψ	Signal operator ψ
Translation-Invar.	$\Psi(X+y) = \Psi(X)+y$	$\psi[f(x-y) + c] = c + \psi(f)(x-y)$
Shift-Invariant	$\Psi(X+y) = \Psi(X)+y$	$\psi[f(x-y)] = \psi(f)(x-y)$
Increasing	$X \subseteq Y \implies \Psi(X) \subseteq \Psi(Y)$	$f \leq g \implies \psi(f) \leq \psi(g)$
Extensive	$X \subseteq \Psi(X)$	$f \leq \psi(f)$
Anti-extensive	$\Psi(X) \subseteq X$	$\psi(f) \leq f$
Idempotent	$\Psi(\Psi(X)) = \Psi(X)$	$\psi(\psi(f)) = \psi(f)$

TABLE 74.3 Properties of Basic Morphological Signal Operators

Property	Dilation	Erosion	Opening	Closing
Duality	$f \oplus g = -[(-f) \ominus g^r]$		$f \circ g = -[(-f) \bullet g^r]$	
Distributivity	$(\vee_i f_i) \oplus g = \vee_i f_i \oplus g$	$(\wedge_i f_i) \ominus g = \wedge_i f_i \ominus g$	No	No
Composition	$(f \oplus g) \oplus h = f \oplus (g \oplus h)$	$(f \ominus g) \ominus h = f \ominus (g \oplus h)$		
Extensive	Yes if $g(0) \geq 0$	No	No	Yes
Anti-Extensive	No	Yes if $g(0) \geq 0$	Yes	No
Commutative	$f \oplus g = g \oplus f$	No	No	No
Increasing	Yes	Yes	Yes	Yes
Translation-Invar.	Yes	Yes	Yes	Yes
Idempotent	No	No	Yes	Yes

74.3 Median, Rank, and Stack Operators

Flat erosion and dilation of a discrete-domain signal $f[x]$ by a finite window $W = \{y_1, \dots, y_n\} \subseteq \mathbb{Z}^d$ is a moving local minimum or maximum. Replacing \min / \max with a more general rank leads to rank operators. At each location $x \in \mathbb{Z}^d$, sorting the signal values within the reflected and shifted n -point window $(W^r)_{+x}$ in decreasing order and picking the p th largest value, $p = 1, 2, \dots, n = \text{card}(W)$, yields the output signal from the p th **rank operator**:

$$(f \square_p W)[x] \equiv p\text{th rank of } (f[x - y_1], \dots, f[x - y_n]) \quad (74.15)$$

For odd n and $p = (n + 1)/2$ we obtain the **median** operator. If the input signal is binary, the output is also binary since sorting preserves a signal's range. Representing the input binary signal with a set $S \subseteq \mathbb{Z}^d$, the output set produced by the p th **rank set operators** is

$$S \square_p W \equiv \{x : \text{card}((W^r)_{+x} \cap S) \geq p\} \quad (74.16)$$

Thus, computing the output from a set rank operator involves only counting of points and no sorting. All rank operators *commute with thresholding* [21, 27, 41, 45, 58, 65]; i.e.,

$$\Theta_v[f \square_p W] = [\Theta_v(f)] \square_p W, \quad \forall v, \forall p. \quad (74.17)$$

This property is also shared by all morphological operators that are finite compositions or maxima/minima of flat dilations and erosions, e.g., openings and closings, by finite structuring elements. All such signal operators ψ that have a corresponding set operator Ψ and commute with thresholding can be alternatively implemented via *threshold superposition* [41, 58] as in (74.7). Namely, to transform a multilevel signal f by ψ is equivalent to decomposing f into all its threshold sets, transforming each set by the corresponding set operator Ψ , and reconstructing the output signal $\psi(f)$ via its thresholded versions. This allows us to study all rank operators and their cascade or parallel (using \vee, \wedge) combinations by focusing on their corresponding binary operators. Such representations are much simpler to analyze and they suggest alternative implementations that do not involve numeric comparisons or sorting.

Binary rank operators and all other binary discrete translation-invariant finite-window operators can be described by their generating Boolean function; see Table 74.1. Thus, in synthesizing discrete multilevel signal operators from their binary counterparts via threshold superposition all that is needed is knowledge of this Boolean function. Specifically, transforming all the threshold binary signals $\theta_v(f)[x]$ of an input signal $f[x]$ with an increasing Boolean function $b(u_1, \dots, u_n)$ (i.e., containing no complemented variables) in place of the set operator Ψ in (74.7) creates a large variety of nonlinear signal operators via threshold superposition, called **stack filters** [41, 70]

$$\phi_b(f)[x] \equiv \sup\{v : b(\theta_v(f)[x - y_1], \dots, \theta_v(f)[x - y_n]) = 1\} \quad (74.18)$$

For example, ϕ_b becomes the p th rank operator if b is equal to the sum $\left(\sum_p^n\right)$ product terms where each contains one distinct p -point subset from the n variables. In general, the use of Boolean functions facilitates the design of such discrete flat operators with determinable structural properties. Since each increasing Boolean function can be uniquely represented by an irreducible sum (product) of product (sum) terms, and each product (sum) term corresponds to an erosion (dilation), each stack filter can be represented as a finite maximum (minimum) of flat erosions (dilations) [41].

74.4 Universality of Morphological Operators

Dilations or erosions, the basic nonlinear convolutions of morphological signal processing, can be combined in many ways to create more complex morphological operators that can solve a broad

variety of problems in image analysis and nonlinear filtering. In addition, they can be implemented using simple and fast software or hardware; examples include various digital [58, 61] and analog, i.e., optical or hybrid optical-electronic implementations [46, 63]. Their wide applicability and ease of implementation poses the question which signal processing systems can be represented by using dilations and erosions as the basic building blocks. Toward this goal, a theory was introduced in [33, 34] that represents a broad class of nonlinear and linear operators as a minimal combination of erosions or dilations. Here we summarize the main results of this theory, in a simplified way, restricting our discussion only to signals with discrete domain $\mathbb{D} = \mathbb{Z}^d$.

Consider a translation-invariant set operator Ψ on the class $\mathcal{P}(\mathbb{D})$ of all subsets of \mathbb{D} . Any such Ψ is uniquely characterized by its **kernel** that is defined [42] as the subclass $\text{Ker}(\Psi) \equiv \{X \in \mathcal{P}(\mathbb{D}) : 0 \in \Psi(X)\}$ of input sets, where 0 is the origin of \mathbb{D} . If Ψ is also increasing, then it can be represented [42] as the union of erosions by its kernel sets and as the intersection of dilations by the reflected kernel sets of its *dual operator* $\Psi^d(X) \equiv [\Psi(X^c)]^c$. This kernel representation can be extended to signal operators ψ on the class $\text{Fun}(\mathbb{D}, \bar{\mathbb{R}})$ of signals with domain \mathbb{D} and range $\bar{\mathbb{R}}$. The kernel of ψ is defined as the subclass $\text{Ker}(\psi) = \{f \in \text{Fun}(\mathbb{D}, \bar{\mathbb{R}}) : [\psi(f)](0) \geq 0\}$ of input signals. If ψ is translation-invariant and increasing, then it can be represented [33, 34] as the pointwise supremum of erosions by its kernel functions, and as the infimum of dilations by the reflected kernel functions of its dual operator $\psi^d(f) \equiv -\psi(-f)$.

The two previous kernel representations require an infinite number of erosions or dilations to represent a given operator because the kernel contains an infinite number of elements. However, we can find more efficient (requiring less erosions) representations by using only a substructure of the kernel, its basis. The **basis** $\text{Bas}(\cdot)$ of a set (signal) operator is defined [33, 34] as the collection of kernel elements that are *minimal* with respect to the ordering \subseteq (\leq).

If a *translation-invariant increasing* set operator Ψ is also *upper semicontinuous*, i.e., obeys a monotonic continuity where $\Psi(\bigcap_n X_n) = \bigcap_n \Psi(X_n)$ for any decreasing set sequence X_n , then Ψ has a nonempty basis and can be represented via erosions only by its basis sets. If the dual Ψ^d is also upper semicontinuous, then its basis sets provide an alternative representation of Ψ via dilations:

$$\Psi(X) = \bigcup_{A \in \text{Bas}(\Psi)} X \ominus A = \bigcap_{B \in \text{Bas}(\Psi^d)} X \oplus B^r \quad (74.19)$$

Similarly, any signal operator ψ that is translation-invariant, increasing, and upper semicontinuous (i.e., $\psi(\wedge_n f_n) = \wedge_n \psi(f_n)$ for any decreasing function sequence f_n) can be represented as the supremum of erosions by its basis functions, and (if ψ^d is upper semicontinuous) as the infimum of dilations by the reflected basis functions of its dual operators:

$$\psi(f) = \bigvee_{g \in \text{Bas}(\psi)} f \ominus g = \bigwedge_{h \in \text{Bas}(\psi^d)} f \oplus h^r \quad (74.20)$$

where $h^r(x) \equiv h(-x)$. Finally, if ϕ is a flat signal operator as in (74.7) that is translation-invariant and commutes with thresholding, then ϕ can be represented as a supremum of erosions by the basis sets of its corresponding set operator Φ :

$$\phi(f) = \bigvee_{A \in \text{Bas}(\Phi)} f \ominus A = \bigwedge_{B \in \text{Bas}(\Phi^d)} f \oplus B^r \quad (74.21)$$

While all the above representations express translation-invariant increasing operators via erosions or dilations, operators that are not necessarily increasing can be represented [4] via operations closely related to hit-miss transformations.

Representing operators that satisfy a few general properties in terms of elementary morphological operations can be applied to more complex morphological systems and various other filters such as linear rank, hybrid linear/rank, and stack filters, as the following examples illustrate.

EXAMPLE 74.1: Morphological Filters

All systems made up of serial or sup/inf combinations of erosions, dilations, opening, and closings admit a basis, which is finite if the system's local definition depends on a finite window. For example, the set opening $\Phi(X) = X \circ A$ has as a basis the set collection $\text{Bas}(\Phi) = \{A_{-a} : a \in A\}$. Consider now 1D discrete-domain signals and let $A = \{-1, 0, 1\}$. Then, the basis of Φ has 3 sets: $G_1 = A_{-1}$, $G_2 = A$, $G_3 = A_{+1}$. The basis of the dual operator $\Phi^d(X) = X \bullet A$ has 4 sets: $H_1 = \{0\}$, $H_2 = \{-2, 1\}$, $H_3 = \{-1, 2\}$, $H_4 = \{-1, 1\}$. The flat signal operator corresponding to Φ is the opening $\phi(f) = f \circ A$. Thus, from (74.21), the signal opening can also be realized as a max (min) of local minima (maxima):

$$(f \circ A)[x] = \bigvee_{i=1}^3 \left\{ \bigwedge_{y \in G_i} f[x+y] \right\} = \bigwedge_{k=1}^4 \left\{ \bigvee_{y \in H_k} f[x+y] \right\}. \quad (74.22)$$

EXAMPLE 74.2: Linear Filters

A linear shift-invariant filter is translation-invariant and increasing (see Table 74.2 for definitions) if its impulse response is everywhere nonnegative and has area equal to one. Consider the 2-point FIR filter $\psi(f)[x] = af[x] + (1-a)f[x-1]$, where $0 < a < 1$. The basis of ψ consists of all functions $g[x]$ with $g[0] = r \in \mathbb{R}$, $g[-1] = -ar/(1-a)$, and $g[x] = -\infty$ for $x \neq 0, -1$. Then (74.20) yields

$$af[x] + (1-a)f[x-1] = \bigvee_{r \in \mathbb{R}} \left[\min \left\{ f[x] - r, f[x-1] + \frac{ar}{1-a} \right\} \right], \quad (74.23)$$

which expresses a linear convolution as a supremum of erosions. FIR linear filters have an infinite basis, which is a finite-dimensional vector space.

EXAMPLE 74.3: Median Filters

All rank operators have a finite basis; hence, they can be expressed as a finite max-of-erosions or min-of-dilations. Further, they commute with thresholding, which allows us to focus only on their binary versions. For example, the set median by the window $W = \{-1, 0, 1\}$ has 3 basis sets: $\{-1, 0\}$, $\{-1, 1\}$, and $\{0, 1\}$. Hence, (74.21) yields

$$\text{median}(f[x-1], f[x], f[x+1]) = \max \left\{ \begin{array}{l} \min(f[x-1], f[x]), \\ \min[f(x-1), f(x+1)], \\ \min[f(x), f(x+1)] \end{array} \right\}. \quad (74.24)$$

EXAMPLE 74.4: Stack Filters

Stack filters (74.18) are discrete translation-invariant flat operators ϕ_b , locally defined on a finite window W , and are generated by a increasing Boolean function $b(v_1, \dots, v_n)$, where $n = \text{card}(W)$. This function corresponds to a translation-invariant increasing set operator Φ . For example, consider 1D signals, let $W = \{-2, -1, 0, 1, 2\}$ and

$$b(v_1, \dots, v_5) = v_1 v_2 v_3 + v_2 v_3 v_4 + v_3 v_4 v_5 = v_3(v_1 + v_4)(v_2 + v_4)(v_2 + v_5). \quad (74.25)$$

This function generates via threshold superposition the flat opening $\phi_b(f) = f \circ A$, $A = \{-1, 0, 1\}$, of (74.22). There is one-to-one correspondence between the three prime implicants of b and the erosions (local min) by the three basis sets of Φ , as well as between the four prime implicates of β and the dilations (local max) by the four basis sets of the dual Φ^d . In general, given b , Φ or ϕ_b is found by replacing Boolean AND/OR with set \cap/\cup or with min / max, respectively. Conversely, given ϕ_b , we can find its generating Boolean function from the basis of its set operator (or directly from its max / min representation if available) [41].

The above examples show the power of the general representation theorems. An interesting applications of these results is the design of morphological systems via their basis [5, 20, 31]. Given the wide applicability of erosions/dilations, their parallelism, and their simple implementations, the previous theorems theoretically support a general purpose vision (software or hardware) module that can perform erosions/dilations, based on which numerous other complex image operations can be built.

74.5 Morphological Operators and Lattice Theory

In the late 1980s and 1990s a new and more general formalization of morphological operators was introduced [59, chaps.1,5-8], [26, 51, 52], which views them as operators on complete lattices. A *complete lattice* is a set \mathcal{L} equipped with a partial ordering \leq such that (\mathcal{L}, \leq) has the algebraic structure of a *partially ordered set (poset)* where the supremum and infimum of any of its subsets exist in \mathcal{L} . For any subset $\mathcal{K} \subseteq \mathcal{L}$, its *supremum* $\vee \mathcal{K}$ and *infimum* $\wedge \mathcal{K}$ are defined as the lowest (with respect to \leq) upper bound and greatest lower bound of \mathcal{K} , respectively. The two main examples of complete lattices used in morphological processing are: (1) the set space $\mathcal{P}(\mathbb{D})$ where the \vee/\wedge lattice operations are the set union/intersection, and (2) the signal space $\text{Fun}(\mathbb{D}, \mathbb{R})$ where the \vee/\wedge lattice operations are the supremum/infimum of sets of real numbers. Increasing operators on \mathcal{L} are of great importance because they preserve the partial ordering, and among them four fundamental examples are:

$$\delta \text{ is dilation} \iff \delta\left(\bigvee_{i \in I} f_i\right) = \bigvee_{i \in I} \delta(f_i) \quad (74.26)$$

$$\varepsilon \text{ is erosion} \iff \varepsilon\left(\bigwedge_{i \in I} f_i\right) = \bigwedge_{i \in I} \varepsilon(f_i) \quad (74.27)$$

$$\alpha \text{ is opening} \iff \alpha \text{ is increasing, idempotent, and anti-extensive} \quad (74.28)$$

$$\beta \text{ is closing} \iff \beta \text{ is increasing, idempotent, and extensive} \quad (74.29)$$

where I is an arbitrary index set.

The above definitions allow broad classes of signal operators to be grouped as lattice dilations, erosions, openings, or closing and their common properties to be studied under the unifying lattice framework. Thus, the translation-invariant morphological dilations, erosions, openings, and closings we saw before are simply special cases of their lattice counterparts. Next, we see some examples and applications of the above general definitions.

EXAMPLE 74.5: Dilation and Translation-Invariant (DTI) Systems

Consider a signal operator that is shift-invariant and obeys a supremum-of-sums superposition:

$$\mathcal{D}\left[\bigvee_i c_i + f_i(x)\right] = \bigvee_i c_i + \mathcal{D}[f_i(x)] \quad (74.30)$$

Then \mathcal{D} is both a lattice dilation and translation-invariant. We call it a DTI system in analogy to linear time-invariant (LTI) systems that are shift-invariant and obey a linear (sum-of-products) superposition. As an LTI system corresponds in the time-domain to a linear convolution with its impulse response, a DTI system can be represented as a supremal convolution with its upper ‘impulse response’ $g_{\vee}(x)$ defined as its output when the input is the upper *zero impulse* $\iota(x)$, defined in Table 74.4. Specifically,

$$\mathcal{D} \text{ is DTI} \iff \mathcal{D}(f) = f \oplus g_{\vee}, \quad g_{\vee} \equiv \mathcal{D}(\iota) \quad (74.31)$$

A similar class is the **erosion and translation-invariant (ETI)** systems ε which are shift-invariant and obey an infimum-of-sums superposition as in (74.30) but with \vee replaced by \wedge . Such systems are equivalent to infimal convolutions with their lower impulse response $g_{\wedge} = \varepsilon(-\iota)$, defined as the system’s output due to the lower impulse $-\iota(x)$. Thus, DTI and ETI systems are uniquely determined in the time/spatial domain by their impulse responses, which also control their causality and stability [37].

TABLE 74.4 Examples of Upper Slope Transform

Signal: $f(x)$	Transform: $F_{\vee}(a)$
$\iota(x - x_0) \equiv 0$ if $x = x_0$, and $-\infty$ else	$-ax_0$
a_0x	$-\iota(a - a_0)$
$\lambda(x) \equiv 0$ if $x \geq 0$, and $-\infty$ else	$-\lambda(a)$
$a_0x + \lambda(x)$	$-\lambda(a - a_0)$
$\begin{cases} 0, & x \leq r \\ -\infty, & x > r \end{cases}$	$r a $
$-a_0 x , \quad a_0 > 0$	$\begin{cases} 0, & a \leq a_0 \\ +\infty, & a > a_0 \end{cases}$
$\sqrt{1 - x^2}, \quad x \leq 1$	$\sqrt{1 + a^2}$
$-(x ^p)/p, \quad p > 1$	$(a ^q)/q, \quad 1/p + 1/q = 1$
$\exp(x)$	$a(1 - \log a)$

EXAMPLE 74.6: Shift-Varying Dilation

Let $\delta_B(f) = f \oplus B$ be the shift-invariant flat dilation of (74.8). In applying it to nonstationary signals, the need may arise to vary the moving window B by actually having a family of windows $B(x)$, possibly varying at each location x . This creates the new operator

$$\delta_B(f)(x) = \bigvee_{y \in B(x)} f(x - y) \quad (74.32)$$

which is still a lattice dilation, i.e., it distributes over suprema, but it is shift-varying.

EXAMPLE 74.7: Adjunctions

An operator pair (ε, δ) is called an **adjunction** if $\delta(f) \leq g \leq \varepsilon(g)$ for all $f, g \in \mathcal{L}$. Given a dilation δ , there is a unique erosion ε such that (ε, δ) is adjunction, and vice versa. Further, if (ε, δ) is an adjunction, then δ is a dilation, ε is an erosion, $\delta\varepsilon$ is an opening, and $\varepsilon\delta$ is a closing. Thus, from any adjunction we can generate an opening via the composition of its erosion and dilation. If ε and δ are the translation-invariant morphological erosion and dilation in (74.11) and (74.10), then $\delta\varepsilon$ coincides with the translation-invariant morphological opening of (74.13). But there are also numerous other possibilities.

EXAMPLE 74.8: Radial Opening

If a 2D image f contains 1D objects, e.g., lines, and B is a 2D convex structuring element, then the opening or closing of f by B will eliminate these 1D objects. Another problem arises when f contains large-scale objects with sharp corners that need to be preserved; in such cases opening or closing f by a disk B will round these corners. These two problems could be avoided in some cases if we replace the conventional opening with

$$\alpha(f) = \bigvee_{\theta} f \circ L_{\theta} \quad (74.33)$$

where the sets L_{θ} are rotated versions of a line segment L at various angles $\theta \in [0, 2\pi)$. The operator α , called **radial opening**, is a lattice opening in the sense of (74.28). It has the effect of preserving an object in f if this object is left unchanged after the opening by L_{θ} in at least one of the possible orientations θ .

EXAMPLE 74.9: Opening by Reconstruction

Consider a set $X = \bigcup_i X_i$ as a union of disjoint connected components X_i and let $M \subseteq X_j$ be a **marker** in the j th component; i.e., M could be a single point or some feature set in X that lies only in X_j . Then, define the **conditional dilation** of M by B within X as

$$\delta_{B|X}(M) \equiv (M \oplus B) \cap X \quad (74.34)$$

If B is a disk with a radius smaller than the distance between X_j and any of the other components, then by iterating this conditional dilation we can obtain in the limit

$$MR_{B|X}(M) = \lim_{n \rightarrow \infty} \underbrace{(\delta_{B|X} \cdots (\delta_{B|X}(\delta_{B|X}(M)))}_{n \text{ times}} \quad (74.35)$$

the whole component X_j . The operator MR is a lattice opening, called **opening by reconstruction**, and its output is called the *morphological reconstruction* of the component from the marker. An example is shown in Fig. 74.3. It can extract large-scale components of the image from knowledge only of a smaller marker inside them.

74.6 Slope Transforms

Fourier transforms are among the most useful linear signal transformations because they enable us to analyze the processing of signals by linear time-invariant (LTI) systems in the frequency domain, which could be more intuitive or easier to implement. Similarly, there exist some nonlinear signal transformations, called slope transforms, which allow the analysis of the dilation and erosion translation-invariant (DTI and ETI) systems in a transform domain, the slope domain. First, we note that the lines $f(x) = ax + b$ are *eigenfunctions* of any DTI system \mathcal{D} or ETI system \mathcal{E} because

$$\begin{aligned} \mathcal{D}[ax + b] &= ax + b + G_{\vee}(a), \quad G_{\vee}(a) \equiv \bigvee_x g_{\vee}(x) - ax \\ \mathcal{E}[ax + b] &= ax + b + G_{\wedge}(a), \quad G_{\wedge}(a) \equiv \bigwedge_x g_{\wedge}(x) - ax \end{aligned} \quad (74.36)$$

with corresponding eigenvalues $G_{\vee}(a)$ and $G_{\wedge}(a)$, which are called, respectively, the upper and lower **slope response** of the DTI and ETI system. They measure the amount of shift in the intercept of the input lines with slope a and are conceptually similar to the frequency response of LTI systems.

FIGURE 74.3: Let X be the union of the two region boundaries in the top left image, and let M be the single-point marker inside the left region. Top right shows the complement X^c . If $Y_0 = M$ and B is a disk-like set whose radius does not exceed the width of the region boundary, iterating the conditional dilation $Y_i = (Y_{i-1} \oplus B) \cap X^c$, for $i = 1, 2, 3, \dots$, yields in the limit (reached at $i = 18$ in this case) the interior Y_∞ of the left region via morphological reconstruction, shown in bottom right. (Bottom left shows an intermediate result for $i = 9$.)

Then, by viewing the slope response as a signal transform with variable the slope $a \in \mathbb{R}$, we define [37] for a 1D signal $f : \mathbb{D} \rightarrow \bar{\mathbb{R}}$ its **upper slope transform** F_\vee and its **lower slope transform**² F_\wedge as the functions

$$F_\vee(a) \equiv \bigvee_{x \in \mathbb{D}} f(x) - ax \quad (74.37)$$

$$F_\wedge(a) \equiv \bigwedge_{x \in \mathbb{D}} f(x) - ax \quad (74.38)$$

Since $f(x) - ax$ is the intercept of a line with slope a passing from the point $(x, f(x))$ on the signal's graph, for each a the upper (lower) slope transform of f is the maximum (minimum) value of this intercept, which occurs when the above line becomes a tangent. Examples of slope transforms are shown in Fig. 74.4. For *differentiable* signals, f , the maximization or minimization of the intercept $f(x) - ax$ can also be done by finding the stationary point(s) x^* such that $df(x^*)/dx = a$. This extreme value of the intercept is the **Legendre transform** of f :

$$F_L(a) \equiv f\left((df/dx)^{-1}(a)\right) - a[(df/dx)^{-1}(a)] \quad (74.39)$$

It is extensively used in mathematical physics. If the signal $f(x)$ is concave or convex and has an invertible derivative, its Legendre transform is single-valued and equal (over the slope regions it is

²In convex analysis [50], to a convex function h there uniquely corresponds its *Fenchel conjugate* $h^*(a) = \bigvee_x ax - h(x)$, which is the negative of the lower slope transform of h .

defined) to the upper or lower transform; e.g., see the last three examples in Table 74.4. If f is neither convex nor concave or if it does not have an invertible derivative, its Legendre transform becomes a set $F_L(a) = \{f(x^*) - ax^* : df(x^*)/dx = a\}$ of real numbers for each a . This multivalued Legendre transform, defined and studied in [19] as a ‘slope transform’, has properties similar to those of the upper/lower slope transform, but there are also some important differences [37].

FIGURE 74.4: (a) Original parabola signal $f(x) = -x^2/2$ (in dashed line) and its morphological opening (in solid line) by a flat structuring element $[-5, 5]$. (b) Upper slope transform $F_v(a)$ of the parabola (in dashed line) and of its opening (in solid line).

The upper and lower slope transform have a limitation in that they do not admit an inverse for arbitrary signals. The closest to an ‘inverse’ upper slope transform is

$$\hat{f}(x) \equiv \bigwedge_{a \in \mathbb{R}} F_v(a) + ax \quad (74.40)$$

which is equal to f only if f is concave; otherwise, \hat{f} covers f from above by being its smallest concave *upper envelope*. Similarly, the supremum over a of all lines $F_\wedge(a) + ax$ creates the greatest convex *lower envelope* $\check{f}(x)$ of f , which plays the role of an “inverse” lower slope transform and is equal to f only if f is convex. Thus, for arbitrary signals we have $\check{f} \leq f \leq \hat{f}$.

Tables 74.4 and 74.5 list several examples and properties of the upper slope transform. The most striking is that (dilation) supremal convolution in the time/space domain corresponds to addition in the slope domain. Note the analogy with LTI systems where linearly convolving two signals corresponds to multiplying their Fourier transforms. Very similar properties also hold for the lower slope transform, the only differences being the interchange of suprema with infima, concave with convex, and the supremal \oplus with the infimal convolution \square .

The upper/lower slope transforms for discrete-domain and/or multi-dimensional signals are defined as in the 1D continuous case by replacing the real variable x with an integer and/or multidimensional variable, and their properties are very similar or identical to the ones for signals defined on \mathbb{R} . See [37, 38] for details.

One of the most useful applications of LTI systems and Fourier transform is the design of frequency-selective filters. Similarly, it is also possible to design morphological systems that have a slope selectivity. Imagine a DTI system that rejects all line components with slopes in the band $[-a_0, a_0]$

TABLE 74.5 Properties of Upper Slope

Signal: $f(x)$	Transform: $F_{\vee}(a)$
$\vee_i c_i + f_i(x)$	$\vee_i c_i + F_i(a)$
$f(x - x_0)$	$F(a) - ax_0$
$f(x) + a_0x$	$F(a - a_0)$
$f(rx)$	$F(a/r)$
$f(x) \oplus g(x)$	$F(a) + G(a)$
$\vee_y f(x) + g(x + y)$	$F(-a) + G(a)$
$f(x) \leq g(x) \forall x$	$F(a) \leq G(a) \forall a$
$g(x) = \begin{cases} f(x), & x \leq r \\ -\infty, & x > r \end{cases}$	$G(a) = F(a) \square r a $

and passes all the rest unchanged. Then its slope response would be

$$G(a) = 0 \text{ if } |a| \leq a_0, \text{ and } +\infty \text{ else.} \quad (74.41)$$

This is an ideal-cutoff **slope bandpass** filter. In the time domain it acts as a supremal convolution with its impulse response

$$g(x) = -a_0|x| \quad (74.42)$$

However, $f \oplus g$ is a non-causal infinite-extent dilation, and hence not realizable. Instead, we could implement it as a cascade of a causal dilation by the half-line $g_1(x) = -a_0x + \lambda(x)$ followed by an anti-causal dilation by another half-line $g_2(x) = a_0x + \lambda(-x)$, where $\lambda(x)$ is the zero step defined in Table 74.4. This works because $g = g_1 \oplus g_2$. For a discrete-time signal $f[x]$, this slope-bandpass filtering could be implemented via the recursive max-sum difference equation $f_1[x] = \max(f_1[x] - a_0, f[x])$ run forward in time, followed by another difference equation $f_2[x] = \max(f_2[x + 1] + a_0, f_1[x])$ run backward in time. The final result would be $f_2 = f \oplus g$. Such slope filters are useful for envelope estimation [37].

74.7 Multiscale Morphological Image Analysis

Multiscale signal analysis has recently emerged as a useful framework for many computer vision and signal processing tasks. Examples include: (1) detecting geometrical features or other events at large scales and then refining their location or value at smaller scales, (2) video and audio data compression using multiband frequency analysis, and (3) measurements and modeling of fractal signals. Most of the work in this area has obtained multiscale signal versions via *linear* multiscale smoothing, i.e., convolutions with a Gaussian with a variance proportional to scale [15, 53, 72]. There is, however, a variety of *nonlinear* smoothing filters, including the morphological openings and closings [35, 42, 58] that can provide a multiscale image ensemble and have the advantage over the linear Gaussian smoothers that they do not blur or shift edges, as shown in Fig. 74.5. There we see that the gray-level close-openings by reconstruction are especially useful because they can extract the exact outline of a certain object by locking on it while smoothing out all its surroundings; these nonlinear smoothers have been applied extensively in multiscale image segmentation [56]. The use of morphological operators for multiscale signal analysis is not limited to operations of a smoothing type; e.g., in fractal image analysis, erosion and dilation can provide multiscale distributions of the shrink-expand type from which the fractal dimension can be computed [36].

Overall, many applications of morphological signal processing such as nonlinear smoothing, geometrical feature extraction, skeletonization, size distributions, and segmentation, inherently require or can benefit from performing morphological operations at multiples scales. The required building blocks for a morphological scale-space are the multiscale dilations and erosions. Consider a planar

FIGURE 74.5: (a) Original image and its multiscale smoothings via: (b,c,d) Gaussian convolution at scales 2, 4, 16; (e,f,g) close-opening by a square at scales 2, 4, 16; (h,i,j) close-opening by reconstruction at scales 2, 4, 16.

compact convex set $B = \{(x, y) : \|(x, y)\|_p \leq 1\}$ that is the unit ball generated by the L_p norm, $p = 1, 2, \dots, \infty$. Then the simplest multiscale dilation and erosion of a signal $f(x, y)$ at scales $t > 0$ are the multiscale flat sup/inf convolutions by $tB = \{tz : z \in B\}$

$$\delta(x, y, t) \equiv (f \oplus tB)(x, y) \quad (74.43)$$

$$\varepsilon(x, y, t) \equiv (f \ominus tB)(x, y) \quad (74.44)$$

which apply both to gray-level and binary images.

74.7.1 Binary Multiscale Morphology via Distance Transforms

Viewing the boundaries of multiscale erosions/dilations of a binary image by disks as wavefronts propagating from the original image boundary at uniform unit normal velocity and assigning to each pixel the time t of wavefront arrival creates a distance function, called the distance transform [10]. This transform is a compact way to represent their multiscale dilations and erosions by disks and other polygonal structuring elements whose shape depends on the norm $\|\cdot\|_p$ used to measure distances. Formally, the **distance transform** of the foreground set F of a binary image is defined as

$$D_p(F)(x, y) \equiv \bigwedge_{(v, u) \in F^c} \{\|(x - v, y - u)\|_p\} \quad (74.45)$$

Thresholding the distance transform at various levels $t > 0$ yields the erosions of the foreground F (or the dilation of the background F^c) by the norm-induced ball B at scale t :

$$F \ominus tB = \Theta_t[D_p(F)] \quad (74.46)$$

Another view of the distance transform results from seeing it as the infimal convolution of the $(0, +\infty)$ indicator function of F^c ,

$$I_{F^c}(x) \equiv 0 \text{ if } x \in F^c, \text{ and } +\infty \text{ else,} \quad (74.47)$$

with the norm-induced conical structuring function:

$$D_p(F)(x) = I_{F^c}(x) \square \|x\|_p \quad (74.48)$$

Recognizing $g_\wedge(x) = \|x\|_p$ as the lower impulse response of an ETI system with slope response

$$G_\wedge(a) = 0 \text{ if } \|a\|_q \leq 1, \text{ and } -\infty \text{ else,} \quad (74.49)$$

where $1/p + 1/q = 1$, leads to seeing the distance transform as the output of an ideal-cutoff slope-selective filter that rejects all input planes whose slope vector falls outside the unit ball with respect to the $\|\cdot\|_q$ norm, and passes all the rest unchanged.

To obtain isotropic distance propagation, the *Euclidean* distance transform is desirable because it gives multiscale morphology with the *disk* as the structuring element. However, since this has a significant computational complexity, various techniques are used to obtain approximations to the Euclidean distance transform of discrete images at a lower complexity. A general such approach is the use of discrete distances [54] and their generalization via *chamfer metrics* [11]. Given a discrete binary image $f[i, j] \in \{0, +\infty\}$ with 0 marking background/source pixels and $+\infty$ marking foreground/object pixels, its global chamfer distance transform is obtained by propagating local distances within a small neighborhood mask. An efficient method to implement it is a two-pass sequential algorithm [11, 54] where for a 3×3 neighborhood the min-sum difference equation

$$\begin{aligned} u_n[i, j] = \min(& u_{n-1}[i, j], u_n[i - 1, j] + a, u_n[i, j - 1] + a, \\ & u_n[i - 1, j - 1] + b, u_n[i + 1, j - 1] + b) \end{aligned} \quad (74.50)$$

is run recursively over the image domain: first ($n = 1$), in a forward scan starting from $u_0 = f$ to obtain u_1 , and second ($n = 2$) in a backward scan on u_1 using a reflected mask to obtain u_2 , which is the final distance transform. The coefficients a and b are the local distances within the neighborhood mask. The unit ball associated with chamfer metrics is a polygon whose approximation of the disk improves by increasing the size of the mask and optimizing the local distances so as to minimize the error in approximating the true Euclidean distances. In practice, integer-valued local distances are used for faster implementation of the distance transform. If (a, b) is $(1, 1)$ or $(1, \infty)$, the chamfer ball becomes a square or rhombus, respectively, and the chamfer distance transform gives poor approximations to multiscale morphology with disks. The commonly used $(a = 3, b = 4)$ chamfer metric gives a maximum absolute error of about 6%, but even better approximations can be found by optimizing a, b .

74.7.2 Multiresolution Morphology

In certain multiscale image analysis tasks, the need also arises to subsample the multiscale image versions and thus create a multiresolution *pyramid* [15, 53]. Such concepts are very similar to the ones encountered in classical signal decimation. Most research in image pyramids has been based on linear smoothers. However, since morphological filters preserve essential shape features, they may be superior in many applications. A theory of morphological decimation and interpolation has been developed in [25] to address these issues which also provides algorithms on reconstructing a signal after morphological smoothing and decimation with quantifiable error. For example, consider a binary discrete image represented by a set X that is smoothed first to $Y = X \circ B$ via opening and then down-sampled to $Y \cap S$ by intersecting it with a periodic sampling set S (satisfying certain conditions). Then the Hausdorff distance between the smoothed signal Y and the interpolation (via dilation) $(Y \cap S) \oplus B$ of its down-sampled version does not exceed the radius of B . These ideas also extend to multilevel signals.

74.8 Differential Equations for Continuous-Scale Morphology

Thus far, most of the multiscale image filtering implementations have been discrete. However, due to the current interest in analog VLSI and neural networks, there is renewed interest in analog computation. Thus, continuous models have been proposed for several computer vision tasks based on **partial differential equations (PDEs)**. In multiscale linear analysis [72] a continuous (in scale t and spatial argument x, y) multiscale signal ensemble

$$\gamma(x, y, t) = f(x, y) * G_t(x, y), \quad G_t(x, y) = \frac{\exp[-(x^2 + y^2)/4t]}{\sqrt{4\pi t}} \quad (74.51)$$

is created by linearly convolving an original signal f with a multiscale Gaussian function G_t whose variance ($2t$) is proportional to the scale parameter t . The Gaussian multiscale function γ can be generated [28] from the *linear diffusion* equation

$$\frac{\partial \gamma}{\partial t} = \frac{\partial^2 \gamma}{\partial x^2} + \frac{\partial^2 \gamma}{\partial y^2} \quad (74.52)$$

starting from the initial condition $\gamma(x, y, 0) = f(x, y)$.

Motivated by the limitations or inability of linear systems to successfully model several image processing problems, several nonlinear PDE-based approaches have been developed. Among them, some PDEs have been recently developed to model multiscale morphological operators as dynamical systems evolving in scale-space [1, 14, 66].

Consider the multiscale morphological flat dilation and erosion of a 2D image signal $f(x, y)$ by the unit-radius disk at scales $t \geq 0$ as the space-scale functions $\delta(x, y, t)$ and $\varepsilon(x, y, t)$ of (74.43) and (74.44). Then [14] the PDE generating these multiscale flat dilations is

$$\frac{\partial \delta}{\partial t} = \|\nabla \delta\| = \sqrt{\left(\frac{\partial \delta}{\partial x}\right)^2 + \left(\frac{\partial \delta}{\partial y}\right)^2} \quad (74.53)$$

and for the erosions is $\partial \varepsilon / \partial t = -\|\nabla \varepsilon\|$. These morphological PDEs directly apply to binary images because flat dilations/erosions commute with thresholding and hence, when the gray-level image is dilated/eroded, each one of its thresholded versions representing a binary image is simultaneously dilated/eroded by the same element and at the same scale.

In equivalent formulations [10, 57, 66], the boundary of the original binary image is considered as a closed curve and this curve is expanded perpendicularly at constant unit speed. The dilation of the original image with a disk of radius t is the expanded curve at time t . This propagation of the image boundary is a special case of more general curvature-dependent propagation schemes for **curve evolution** studied in [47]. This general curve evolution methodology was applied in [57] to obtain multiscale morphological dilations/erosions of binary images, using an algorithm [47] where the original curve is first embedded in the surface of a 2D continuous function $\Phi_0(x, y)$ as its zero level set and then the evolving 2D curve is obtained as the zero level set of a 2D function $\Phi(x, y, t)$ that evolves from the initial condition $\Phi(x, y, 0) = \Phi_0(x, y)$ according to the PDE $\partial \Phi / \partial t = \|\nabla \Phi\|$. This function evolution PDE makes zero level sets expand at unit normal speed and is identical to the PDE (74.53) for flat dilation by disk. The main steps in its numerical implementations [47] are:

$$\begin{aligned} \Phi_{i,j}^n &= \text{estimate of } \Phi(i \Delta x, j \Delta y, n \Delta t) \text{ on a grid} \\ D_x^+ &= (\Phi_{i+1,j}^n - \Phi_{i,j}^n) / \Delta x, \quad D_x^- = (\Phi_{i,j}^n - \Phi_{i-1,j}^n) / \Delta x \\ D_y^+ &= (\Phi_{i,j+1}^n - \Phi_{i,j}^n) / \Delta y, \quad D_y^- = (\Phi_{i,j}^n - \Phi_{i,j-1}^n) / \Delta y \\ G^2 &= \min^2(0, D_x^-) + \max^2(0, D_x^+) + \min^2(0, D_y^-) + \max^2(0, D_y^+) \\ \Phi_{i,j}^n &= \Phi_{i,j}^{n-1} + G \Delta t, \quad n = 1, 2, \dots, (R / \Delta t) \end{aligned}$$

where R is the maximum scale (radius) of interest, $\Delta x, \Delta y$ are the spatial grid spacings, and Δt is the time (scale) step.

Continuous multiscale morphology using the above curve evolution algorithm for numerically implementing the dilation PDE yields better approximations to disks and avoids the abrupt shape discretization inherent in modeling digital multiscale using discrete polygons [16, 57]. Comparing it to discrete multiscale morphology using chamfer distance transforms, we note that for binary images: (1) the chamfer distance transform is easier to implement and yields similar errors for small scale dilations/erosions; (2) implementing the distance transform via curve evolution is more complex, but at medium and large scales gives a better and very close approximation to Euclidean geometry, i.e., to morphological operations with the disk structuring element. See Fig. 74.6.

74.9 Applications to Image Processing and Vision

There are numerous applications of morphological image operators to image processing and computer vision. Examples of broad application areas include biomedical image processing, automated visual inspection, character and document image processing, remote sensing, nonlinear filtering, multiscale image analysis, feature extraction, motion analysis, segmentation, and shape recognition. Next we shall review a few of these applications to specific problems of image processing and low/mid-level vision.

FIGURE 74.6: Distance transforms of a binary image, shown as intensity images modulo 20, obtained using: (a) Metric $\| \cdot \|_\infty$ (chamfer metric with local distances (1,1)), (b) chamfer metric with 3×3 neighborhood and local distances (24,34)/25, and (c) curve evolution.

74.9.1 Noise Suppression

Rank filters and especially medians have been applied mainly to suppress impulse noise or noise whose probability density has heavier tails than the Gaussian for enhancement of image and other signals [2, 12, 27, 64, 65], since they can remove this type of noise without blurring edges, as would be the case for linear filtering. The rank filters have also been used for envelope detection. In their behavior as nonlinear smoothers, as shown in Fig. 74.7, the medians act similarly to an ‘open-closing’ $(f \circ B) \bullet B$ by a convex set B of diameter about half the diameter of the median window. The open-closing has the advantages over the median that it requires less computation and decomposes the noise suppression task into two independent steps, i.e., suppressing positive spikes via the opening and negative spikes via the closing. Further, cascading open-closings $\beta_t \alpha_t$ at multiple scales $t = 1, \dots, r$, where $\alpha_t(f) = f \circ tB$ and $\beta_t(f) = f \bullet tB$, generates a class of efficient nonlinear smoothing filters $\beta_r \alpha_r \dots \beta_2 \alpha_2 \beta_1 \alpha_1$, called **alternating sequential filters**, which smooth progressively from the smallest scale possible up to a maximum scale r and have a broad range of applications [59, 60, 62].

74.9.2 Feature Extraction

Residuals between a signal and some morphologically transformed versions of it can extract line- or blob-type features or enhance their contrast. An example is the difference between the flat dilation and erosion of an image f by a symmetric disk-like set B whose diameter, $\text{diam}(B)$, is very small;

$$\text{edge}(f) = \frac{(f \oplus B) - (f \ominus B)}{\text{diam}(B)} \quad (74.54)$$

If f is binary, $\text{edge}(f)$ extracts its boundary. If f is gray-level, the above residual enhances its edges [7, 58] by yielding an approximation to $\|\nabla f\|$, which is obtained in the limit of (74.54) as $\text{diam}(B) \rightarrow 0$. See Fig. 74.8. This morphological edge operator can be made more robust for edge detection by first smoothing the input image signal and compares favorably with other gradient approaches based on linear filtering.

Another example involves subtracting the opening of a signal f by a compact convex set B from the input signal yields an output consisting of the signal peaks whose support cannot contain B . This is the *top-hat transformation* [43, 58]

$$\text{peak}(f) = f - (f \circ B) \quad (74.55)$$

and can detect bright *blobs*, i.e., regions with significantly brighter intensities relative to the surroundings. Similarly, to detect dark blobs, modeled as intensity valleys, we can use the closing residual operator $f \mapsto (f \bullet B) - f$. See Fig. 74.8. The morphological peak/valley extractors, in addition to their being simple and efficient, have some advantages over curvature-based approaches.

FIGURE 74.7: (a) Noisy image f , corrupted with salt-and-pepper noise of probability 10%. (b) Opening $f \circ B$ of f by a 2×2 -pixel square B . (c) Open-closing $(f \circ B) \bullet B$. (d) Median of f by a 3×3 -pixel square window.

74.9.3 Shape Representation via Skeleton Transforms

There are applications in image processing and vision where a binary shape needs to be summarized down to its thin medial axis and then reconstructed exactly from this axial information. This process, known as *medial axis (or skeleton) transform* has been studied extensively for shape representation and description [10, 54]. Among many approaches, it can also be obtained via multiscale morphological operators, which offer as a by-product a multiscale representation of the original shape via its skeleton components [39, 58]. Let $X \subseteq \mathbb{Z}^2$ represent the foreground of a finite discrete binary image and let $B \subseteq \mathbb{Z}^2$ be a convex disk-like set at scale 1 and $B^{\oplus n}$ be its multiscale version at scale $n = 1, 2, \dots$. The n th **skeleton component** of X is the set

$$S_n = (X \ominus B^{\oplus n}) \setminus [(X \ominus B^{\oplus n}) \circ B] \quad , \quad n = 0, 1, \dots, N \quad , \quad (74.56)$$

where \setminus denotes the difference, n is a discrete scale parameter, and $N = \max\{n : X \ominus B^{\oplus n} \neq \emptyset\}$ is the maximum scale. The S_n are disjoint subsets of X , whose union is the **morphological skeleton** of X .

The **morphological skeleton transform** of X is the finite sequence (S_0, S_1, \dots, S_N) . The union of all the S_n s dilated by a n -scale disk reconstructs exactly the original shape; omitting the first k components leads to a smooth partial reconstruction, the opening of X at scale k :

$$X \circ B^{\oplus k} = \bigcup_{k \leq n \leq N} S_n \oplus B^{\oplus n} \quad , \quad 0 \leq k \leq N \quad . \quad (74.57)$$

Thus, we can view the S_n as ‘*shape components*’, where the small-scale components are associated with the lack of smoothness of the boundary of X , whereas skeleton components of large scale indices n

FIGURE 74.8: (a) Image f . (b) Edge enhancement: dilation-erosion residual $f \oplus B - f \ominus B$, where B is a 21-pixel octagon. (c) Peak detection: opening residual $f - f \circ B^{\oplus 3}$. (d) Valley detection: closing residual $f \bullet B^{\oplus 3} - f$.

are related to the bulky interior parts of X that are shaped similarly to $B^{\oplus n}$. Figure 74.9 shows a detailed description of the skeletal decomposition and reconstruction of an image.

Several generalizations or modifications of the morphological skeletonization include: using structuring elements different than disks that might result in fewer skeletal points, or removing redundant points from the skeleton [29, 33, 39]; using different structuring elements for each skeletonization step [23, 33]; using lattice generalizations of the erosions and openings involved in skeletonization [30]; image representation based on skeleton-like multiscale residuals [23]; and shape decomposition based on residuals between image parts and maximal openings [48]. In addition to its general use for shape analysis, a major application of skeletonization has been binary image coding [13, 30, 39].

74.9.4 Shape Thinning

The skeleton is not necessarily connected; for *connected* skeletons see [3]. Another approach for summarizing a binary shape down to a thin medial axis that is connected but does not necessarily guarantee reconstruction is via thinning. **Morphological thinning** is defined [58] as the difference between the original set X (representing the foreground of a binary image) and a set of feature locations extracted via hit-miss transformations by pairs of foreground-background probing sets

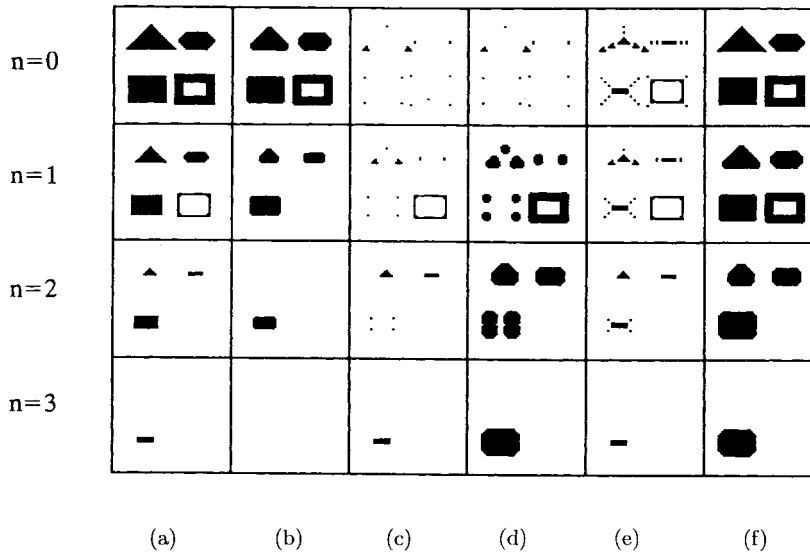

FIGURE 74.9: Morphological skeletonization of a binary image X (top left image) with respect to a 3×3 -pixel square structuring element B . (a) Erosions $X \ominus B^{\oplus n}$, $n = 0, 1, 2, 3$. (b) Openings of erosions $(X \ominus B^{\oplus n}) \circ B$. (c) Skeleton subsets S_n . (d) Dilated skeleton subsets $S_n \oplus B^{\oplus n}$. (e) Partial unions of skeleton subsets $\cup_{N \geq k \geq n} S_k$. (f) Partial unions of dilated skeleton subsets $\cup_{N \geq k \geq n} S_k \oplus B^{\oplus k}$.

(A_i, B_i) designed to detect features that thicken the shape's axis:

$$X \odot \{(A_i, B_i)\}_{i=1}^n \equiv X \setminus \bigcup_{i=1}^n X \otimes (A_i, B_i) \quad (74.58)$$

Usually each hit-miss by a pair (A_i, B_i) detects a feature at some orientation, and then the difference from the original peels off this feature from X . Since this feature might occur at several orientations, the above thinning operator is applied iteratively by rotating its set of probing elements until there is no further change in the image. Thinning has been applied extensively to character images. Examples are shown in Fig. 74.10, where each thinning iteration used $n = 3$ template pairs (A_i, B_i) for the hit-miss transformations of (74.58) designed in [8].

74.9.5 Size Distributions

Multiscale openings $X \mapsto X \circ rB$ and closings $X \mapsto X \bullet rB$ of compact sets X in \mathbb{R}^d by convex compact structuring elements rB , parameterized by a scale parameter $r \geq 0$, are called *granulometries* and can unify all sizing (sieving) operations [42]. Because they satisfy a monotonic ordering

$$\dots X \circ sB \subseteq X \circ rB \subseteq \dots \subseteq X \subseteq \dots X \bullet rB \subseteq X \bullet sB \subseteq \dots, \quad r < s, \quad (74.59)$$

if we measure the volume (or area) of these sets as a function of scale, this function will also satisfy the same ordering and hence create **size distributions**. Further, taking its derivative leads to a **size**

FIGURE 74.10: Left column shows binary images of handwritten characters. Right column shows their thinned version.

density function (or *size histogram* in the discrete case)

$$h(r) \equiv \begin{cases} -\frac{d\text{vol}(X \circ B)}{dr}, & r \geq 0 \\ \frac{d\text{vol}(X \bullet B)}{d|r|}, & r < 0 \end{cases} \quad (74.60)$$

This conveys several types of information useful for shape description and multiscale image analysis. For example, the *boundary roughness* of X relative to B manifests itself as contributions in the lower-size part of the size histogram. Long capes or bulky protruding parts in X that consist of patterns sB show up as isolated impulses in the histogram around positive $r = s$. Finally, the size density can be defined for ‘negative’ sizes by using closings instead of openings; in this case impulses at negative sizes indicate the existence of prominent intruding *gulfs* or *holes* in X .

If X is a random set [42], then probabilistic measures of its size distribution have been used extensively in image analysis applications to petrography and biology [58]. All of the above ideas can be extended to gray-level images [35]. One application of gray-level size distributions is texture classification [17].

74.9.6 Fractals

A large variety of natural image objects (e.g., clouds, coastlines, mountains, islands, trees, leaves, etc.) can be modeled with *fractals* [32]. Fractals are mathematical sets with a very high level of geometrical complexity; formally, their Hausdorff dimension is larger than their topological dimension. An important characteristic of fractals to measure for purposes of shape description or classification is their fractal dimension. Among the various methods [32] to estimate the *fractal dimension* D of the surface of a set $F \subseteq \mathbb{R}^3$, the *covering method* is based conceptually on Minkowski’s idea of finding the area of irregular sets; dilate them with spheres of radius r , find the volume $V(r)$ of the dilated set, and set its area equal to $\lim_{r \downarrow 0} A(r)$, where $A(r) = V(r)/2r$. Further, the fractal dimension of F can be found by

$$D = \lim_{r \downarrow 0} \frac{\log[V(r)/r^3]}{\log[(1/r)]} \quad (74.61)$$

The intuitive meaning of D is that $V(r) \approx (\text{constant}) \cdot r^{3-D}$ as $r \downarrow 0$, from which D can be estimated by least-squares fitting a straight line to a log-log plot of $V(r)$.

The theory of morphological operators allows us to find more efficient implementations of the above idea when F is the graph of a 2D function $f(x, y)$. Then, instead of multiscale 3D set dilations

of F by spheres, it is computationally more efficient to perform 2D multiscale signal dilations and erosions of f by disks rB and measure the multiscale volumes by

$$V(r) = \int \int [(f \oplus rB)(x, y) - (f \ominus rB)(x, y)] dx dy \quad (74.62)$$

Thus, morphological flat dilations and erosions are used to create a volume-blanket as a layer either covering or being peeled off from the surface of f at various scales. This morphological covering method can also be applied to 1D signals $f(x)$ by replacing volumes with areas and disks rB with horizontal linear segments $[-r, r]$; such a 1D application is shown in Fig. 74.11.

FIGURE 74.11: Speech waveform of the word ‘soothing’ sampled at 10 kHz and its short-time fractal dimension over 10-ms speech segments, computed every 1 ms and post-smoothed by a 3-point median filter. The short-time fractal dimension increases with the amount of turbulence existing during production of the corresponding sound, having a small value for vowels, medium for weak voiced fricatives, and high for unvoiced fricatives.

74.9.7 Image Segmentation

One of the most powerful and advanced tools of mathematical morphology is the watershed transformation [7] as applied to image segmentation. Let us regard the gray-level image to be segmented as a topographic relief and assume a drop of water falling at a point on it and flowing down along a steep slope path until it is trapped in a local minimum M of the relief. The set of points such that a drop falling on them eventually reaches M is the catchment basin associated with the minimum M . The union of the boundaries of the different catchment basins of the image constitute its **watershed**. Thus, the watershed consists of contours located on crest lines separating adjacent minima.

To ease the segmentation of the original image f , the watershed transformation is usually applied to its gradient magnitude $g = \|\nabla f\|$, which has higher contrast. However, direct computation of the watershed of g usually leads to poor results, i.e., oversegmentation of f , because, even after smoothing f or g , the latter often exhibits far too many minima. One of the best solutions to this

problem is to use markers for the regions to be extracted. A **marker** is a small connected component of pixels, a feature, located inside a region. Once the markers have been extracted, the gradient image g is modified via morphological reconstruction so that these markers are imposed as the only minima of the modified function while preserving the highest crest lines of g located between two markers. Then, computing the watershed of the modified g usually provides a good segmentation whose quality depends mainly on the markers and somewhat on g and the initial smoothing of f . An example is shown in Fig. 74.12. The power of this approach as well as its difficulty lies in the choice of the markers. Efficient ways to choose markers as well as fast algorithms for the watershed computation are detailed in [44, 69]. This watershed methodology has already proved to be very useful in various fields of image analysis, ranging from medical imaging to material sciences, remote sensing, and digital elevation models.

74.10 Conclusions

This chapter has provided a brief introduction of the theory of morphological signal processing and its applications to image analysis and nonlinear filtering. This methodology nowadays offers a large diversity of theoretical and algorithmic ideas that provide useful tools and inspire new directions in the following research areas from the fields of signal processing, image processing and machine vision, and pattern recognition: nonlinear filtering, nonlinear signal and system representation,

image feature extraction, multiscale analysis and geometry-driven diffusion, image segmentation, region-based image coding, motion analysis, automated visual inspection, and detection/estimation in random sets.

Some attractive aspects of morphological signal operators for efficiently solving problems in the above areas include: (1) suitability for geometry-related signal/image analysis problems; (2) unification power because they can be defined both for numerical signals as well as for more abstract data using their lattice generalizations; (3) simplicity of software or hardware implementations of the basic operators; and (4) existence of efficient algorithms for implementing complex morphological systems [68].

Three current research areas where successful future developments may significantly broaden and improve the applicability of morphological signal processing are: (A) *Optimal design of nonlinear systems based on morphological and related signal operators*, where, despite their numerous applications, very few ideas exist for their optimal design. (The current three main approaches are: (1) designing binary systems as a finite union of erosions [20, 31] or hit-miss operations [5] using the morphological representation theory of [33, 34] or [4]; (2) designing stack filters via threshold decomposition and linear programming [18]; (3) gradient-based optimization of morphological/rank filters either via simulated annealing [71] or via a least-mean-square algorithm and adaptive filtering [55].) (B) *The continuous (differential) approach to mathematical morphology via PDEs* and exploitation of its exciting relationships to the physics of wave propagation and eikonal optics [38, 57, 67]. (C) *Development of morphological systems for image pattern recognition* by exploiting the efficiency of morphological operators for shape analysis and their logic-related structure.

75.1 Introduction

As we increasingly turn to nonlinear models to capture some of the more salient behavior of physical or natural systems that cannot be expressed by linear means, systems that support solitons may be a natural class to explore because they share many of the properties that make LTI systems attractive from an engineering standpoint. Although nonlinear, these systems are solvable through inverse scattering, a technique analogous to the Fourier transform for linear systems [1]. Solitons are eigenfunctions of these systems which satisfy a nonlinear form of superposition. We can therefore decompose complex solutions in terms of a class of signals with simple dynamical structure. Solitons have been observed in a variety of natural phenomena from water and plasma waves [7, 12] to crystal lattice vibrations [2] and energy transport in proteins [7]. Solitons can also be found in a number of man-made media including super-conducting transmission lines [11] and nonlinear circuits [6, 13]. Recently, solitons have become of significant interest for optical telecommunications, where optical pulses have been shown to propagate as solitons for tremendous distances without significant dispersion [4].

We view solitons from a different perspective. Rather than focusing on the propagation of solitons over nonlinear channels, we consider using these nonlinear systems to both generate and process signals for transmission over traditional linear channels. By using solitons for signal synthesis, the

corresponding nonlinear systems become specialized signal processors which are naturally suited to a number of complex signal processing tasks. This section can be viewed as an exploration of the properties of solitons as signals. In the process, we explore the potential application of these signals in a multi-user wireless communication context. One possible benefit of such a strategy is that the soliton signal dynamics provide a mechanism for simultaneously decreasing transmitted signal energy and enhancing communication performance.

75.2 Soliton Systems: The Toda Lattice

The Toda lattice is a conceptually simple mechanical example of a nonlinear system with soliton solutions.¹ It consists of an infinite chain of masses connected with springs satisfying the nonlinear force law $f_n = a(e^{-b(y_n - y_{n-1})} - 1)$ where f_n is the force on the spring between masses with displacements y_n and y_{n-1} from their rest positions. The equations of motion for the lattice are given by

$$m\ddot{y}_n = a \left(e^{-b(y_n - y_{n-1})} - e^{-b(y_{n+1} - y_n)} \right), \quad (75.1)$$

where m is the mass, and a and b are constants. This equation admits pulse-like solutions of the form

$$f_n(t) = \left(\frac{m}{ab} \right) \beta^2 \text{sech}^2(\sinh^{-1}(\sqrt{m/ab} \beta)n - \beta t), \quad (75.2)$$

which propagate as compressional waves stored as forces in the nonlinear springs. A single right-traveling wave $f_n(t)$ is shown in Fig. 75.1(a).

FIGURE 75.1: Propagating wave solutions to the Toda lattice equations. Each trace corresponds to the force $f_n(t)$ stored in the spring between mass n and $n - 1$.

This compressional wave is localized in time, and propagates along the chain maintaining constant shape and velocity. The parameter β appears in both the amplitude and the temporal- and spatial-scales of this one parameter family of solutions giving rise to tall, narrow pulses which propagate faster than small, wide pulses. This type of localized pulse-like solution is what is often referred to as a *solitary wave*.

¹ A comprehensive treatment of the lattice and its associated soliton theory can be found in the monograph by Toda [18].

The study of solitary wave solutions to nonlinear equations dates back to the work of John Scott Russell in 1834 and perhaps the first recorded sighting of a solitary wave. Scott Russell's observations of an unusual water wave in the Union Canal near Edinburgh, Scotland, are interpreted as a solitary wave solution to the Korteweg de Vries (KdV) equation [12].² In a 1965 paper, Zabusky and Kruskal performed numerical experiments with the KdV equation and noticed that these solitary wave solutions retained their identity upon collision with other solitary waves, which prompted them to coin the term *soliton* implying a particle-like nature. The ability to form solutions to an equation from a superposition of simpler solutions is the type of behavior we would expect for linear wave equations. However, that nonlinear equations such as the KdV or Toda lattice equations permit such a form of superposition is an indication that they belong to a rather remarkable class of nonlinear systems.

An example of this form of soliton superposition is illustrated in Fig. 75.1(b) for two solutions of the form of Eq. (75.2). Note that as a function of time, a smaller, wider soliton appears before a taller, narrower one. However, as viewed by, e.g., the thirtieth mass in the lattice, the larger soliton appears first as a function of time. Since the larger soliton has arrived at this node before the smaller soliton, it has therefore traveled faster. Note that when the larger soliton catches up to the smaller soliton as viewed on the fifteenth node, the combined amplitude of the two solitons is actually less than would be expected for a linear system, which would display a linear superposition of the two amplitudes. Also, the signal shape changes significantly during this nonlinear interaction.

An analytic expression for the two soliton solution for $\beta_1 > \beta_2 > 0$ is given by [6]

$$f_n(t) = \frac{m}{ab} \frac{\beta_1^2 \text{sech}^2(\eta_1) + \beta_2^2 \text{sech}^2(\eta_2) + A \text{sech}^2(\eta_1) \text{sech}^2(\eta_2)}{(\cosh(\phi/2) + \sinh(\phi/2) \tanh(\eta_1) \tanh(\eta_2))^2}, \quad (75.3)$$

where

$$\begin{aligned} A &= \sinh(\phi/2) \left((\beta_1^2 + \beta_2^2) \sinh(\phi/2) + 2\beta_1\beta_2 \cosh(\phi/2) \right), \\ \phi &= \ln \left(\frac{\sinh((p_1 - p_2)/2)}{\sinh((p_1 + p_2)/2)} \right), \end{aligned} \quad (75.4)$$

and $\beta_i = \sqrt{ab/m} \sinh(p_i)$, and $\eta_i = p_i n - \beta_i(t - \delta_i)$. Although Eq. (75.3) appears rather complex, Fig. 75.1(b) illustrates that for large separations, $|\delta_1 - \delta_2|$, $f_n(t)$ essentially reduces to the linear superposition of two solitons with parameters β_1 and β_2 . As the relative separation decreases, the multiplicative cross term becomes significant, and the solitons interact nonlinearly. This asymptotic behavior can also be evidenced analytically

$$\begin{aligned} f_n(t) &= \frac{m}{ab} \beta_1^2 \text{sech}^2(p_1 n - \beta_1(t - \delta_1) \pm \phi/2) \\ &\quad + \frac{m}{ab} \beta_2^2 \text{sech}^2(p_2 n - \beta_2(t - \delta_2) \mp \phi/2), \quad t \rightarrow \pm\infty, \end{aligned} \quad (75.5)$$

where each component soliton experiences a net displacement ϕ from the nonlinear interaction. The Toda lattice also admits periodic solutions which can be written in terms of Jacobian elliptic functions [18].

An interesting observation can be made when the Toda lattice equations are written in terms of the forces,

$$\frac{d^2}{dt^2} \ln \left(1 + \frac{f_n}{a} \right) = \frac{b}{m} (f_{n+1} - 2f_n + f_{n-1}). \quad (75.6)$$

²A detailed discussion of linear and nonlinear wave theory including KdV can be found in [21].

If the substitution $f_n(t) = \frac{d^2}{dt^2} \ln \phi_n(t)$ is made into Eq. (75.6), then the lattice equations become

$$\frac{m}{ab} \left(\dot{\phi}_n^2 - \phi_n \ddot{\phi}_n \right) = \phi_n^2 - \phi_{n-1} \phi_{n+1} . \quad (75.7)$$

In view of the Teager energy operator introduced by Kaiser in [8], the left-hand side of Eq. (75.7) is the Teager instantaneous-time energy at the node n , and the right-hand side is the Teager instantaneous-space energy at time t . In this form, we may view solutions to Eq. (75.7) as propagating waveforms that have equal Teager energy as calculated in time and space, a relationship also observed by Kaiser [9].

75.2.1 The Inverse Scattering Transform

Perhaps the most significant discovery in soliton theory was that under a rather general set of conditions, certain nonlinear evolution equations such as KdV or the Toda lattice could be solved analytically. That is, given an initial condition of the system, the solution can be explicitly determined for all time using a technique called inverse scattering. Since much of inverse scattering theory is beyond the scope of this section, we will only present some of the basic elements of the theory and refer the interested reader to [1].

The nonlinear systems that have been solved by inverse scattering belong to a class of systems called conservative Hamiltonian systems. For the nonlinear systems that we discuss in this section, an integral component of their solution via inverse scattering lies in the ability to write the dynamics of the system implicitly in terms of an operator differential equation of the form

$$\frac{dL(t)}{dt} = B(t)L(t) - L(t)B(t), \quad (75.8)$$

where $L(t)$ is a symmetric linear operator, $B(t)$ is an anti-symmetric linear operator, and both $L(t)$ and $B(t)$ depend explicitly on the state of the system.

Using the Toda lattice as an example, the operators L and B would be the symmetric and anti-symmetric tridiagonal matrices

$$L = \begin{bmatrix} \ddots & & & \\ & \ddots & a_{n-1} & \\ a_{n-1} & b_n & & a_n \\ & & a_n & \ddots \end{bmatrix}, \quad B = \begin{bmatrix} \ddots & & & \\ & \ddots & -a_{n-1} & \\ a_{n-1} & 0 & & -a_n \\ & & a_n & \ddots \end{bmatrix}, \quad (75.9)$$

where $a_n = e^{(y_n - y_{n+1})/2}/2$, and $b_n = \dot{y}_n/2$, for mass positions y_n in a solution to Eq. (75.1). Written in this form, the entries of the matrices in Eq. (75.8) yield the following equations

$$\begin{aligned} \dot{a}_n &= a_n(b_n - b_{n+1}), \\ \dot{b}_n &= 2(a_{n-1}^2 - a_n^2). \end{aligned} \quad (75.10)$$

These are equivalent to the Toda lattice equations, Eq. (75.1), in the coordinates a_n and b_n . Lax has shown [10] that when the dynamics of such a system can be written in the form of Eq. (75.8), then the eigenvalues of the operator $L(t)$ are time-invariant, i.e., $\dot{\lambda} = 0$. Although each of the entries of $L(t)$, $a_n(t)$, and $b_n(t)$ evolve with the state of a solution to the Toda lattice, the eigenvalues of $L(t)$ remain constant.

If we assume that the motion on the lattice is confined to lie within a finite region of the lattice, i.e., the lattice is at rest for $|n| \rightarrow \infty$, then the spectrum of eigenvalues for the matrix $L(t)$ can be separated into two sets. There is a continuum of eigenvalues $\lambda \in [-1, 1]$ and a discrete set of eigenvalues for which $|\lambda_k| > 1$. When the lattice is at rest, the eigenvalues consist only of the continuum. When there are solitons in the lattice, one discrete eigenvalue will be present for each soliton excited. This

separation of eigenvalues of $L(t)$ into discrete and continuous components is common to all of the nonlinear systems solved with inverse scattering.

The inverse scattering method of solution for soliton systems is analogous to methods used to solve linear evolution equations. For example, consider a linear evolution equation for the state $y(x, t)$. Given an initial condition of the system, $y(x, 0)$, a standard technique for solving for $y(x, t)$ employs Fourier methods. By decomposing the initial condition into a superposition of simple harmonic waves, each of the component harmonic waves can be independently propagated. Given the Fourier decomposition of the state at time t , the harmonic waves can then be recombined to produce the state of the system $y(x, t)$. This process is depicted schematically in Fig. 75.2(a).

FIGURE 75.2: Schematic solution to evolution equations.

An outline of the inverse scattering method for soliton systems is similar. Given an initial condition for the nonlinear system, $y(x, 0)$, the eigenvalues λ and eigenfunctions $\psi(x, 0)$ of the linear operator $L(0)$ can be obtained. This step is often called *forward scattering* by analogy to quantum mechanical scattering, and the collection of eigenvalues and eigenfunctions is called the nonlinear spectrum of the system in analogy to the Fourier spectrum of linear systems. To obtain the nonlinear spectrum at a point in time t , all that is needed is the time evolution of the eigenfunctions, since the eigenvalues do not change with time. For these soliton systems, the eigenfunctions evolve simply in time, according to linear differential equations. Given the eigenvalue-eigenfunction decomposition of $L(t)$, through a process called *inverse scattering*, the state of the system $y(x, t)$ can be completely reconstructed. This process is depicted in Fig. 75.2(b) in a similar fashion to the linear solution process.

For a large class of soliton systems, the inverse scattering method generally involves solving either a linear integral equation or a linear discrete-integral equation. Although the equation is linear, finding its solution is often very difficult in practice. However, when the solution is made up of pure solitons, then the integral equation reduces a set of simultaneous linear equations.

Since the discovery of the inverse scattering method for the solution to KdV, there has been a large class of nonlinear wave equations, both continuous and discrete, for which similar solution methods have been obtained. In most cases, solutions to these equations can be constructed from a nonlinear superposition of soliton solutions. For a comprehensive study of inverse scattering and equations solvable by this method, the reader is referred to the text by Ablowitz and Clarkson [1].

75.3 New Electrical Analogs for Soliton Systems

Since soliton theory has its roots in mathematical physics, most of the systems studied in the literature have at least some foundation in physical systems in nature. For example, KdV has been attributed to studies ranging from ion-acoustic waves in plasma [22] to pressure waves in liquid gas bubble mixtures [12]. As a result, the predominant purpose of soliton research has been to explain physical properties of natural systems. In addition, there are several examples of man-made media that have

been designed to support soliton solutions and thus exploit their robust propagation. The use of optical fiber solitons for telecommunications and of Josephson junctions for volatile memory cells are two practical examples [11, 12].

Whether its goal has been to explain natural phenomena or to support propagating solitons, this research has largely focused on the properties of propagating solitons through these nonlinear systems. In this section, we will view solitons as signals and consider exploiting some of their rich signal properties in a signal processing or communication context. This perspective is illustrated graphically in Fig. 75.3, where a signal containing two solitons is shown as an input to a soliton system which can either combine or separate the component solitons according to the evolution equations. From the “solitons-as-signals” perspective, the corresponding nonlinear evolution equations can be

FIGURE 75.3: Two-soliton signal processing by a soliton system.

viewed as special-purpose signal processors that are naturally suited to such signal processing tasks as signal separation or sorting. As we shall see, these systems also form an effective means of generating soliton signals.

75.3.1 Toda Circuit Model of Hirota and Suzuki

FIGURE 75.4: Nonlinear LC ladder circuit of Hirota and Suzuki.

Motivated by the work of Toda on the exponential lattice, the nonlinear LC ladder network implementation shown in Fig. 75.4 was given by Hirota and Suzuki in [6]. Rather than a direct analogy to the Toda lattice, the authors derived the functional form of the capacitance required for the LC line to be equivalent. The resulting network equations are given by

$$\frac{d^2}{dt^2} \ln \left(1 + \frac{V_n(t)}{V_0} \right) = \frac{1}{LC_0 V_0} (V_{n-1}(t) - 2V_n(t) + V_{n+1}(t)) , \quad (75.11)$$

which is equivalent to the Toda lattice equation for the forces on the nonlinear springs given in Eq. (75.6). The capacitance required in the nonlinear LC ladder is of the form

$$C(V) = \frac{C_0 V_0}{V_0 + V} , \quad (75.12)$$

where V_0 and C_0 are constants representing the bias voltage and the nominal capacitance, respectively. Unfortunately, such a capacitance is rather difficult to construct from standard components.

75.3.2 Diode Ladder Circuit Model for Toda Lattice

In [14], the circuit model shown in Fig. 75.5(a) is presented which accurately matches the Toda lattice and is a direct electrical analog of the nonlinear spring mass system. When the shunt impedance Z_n

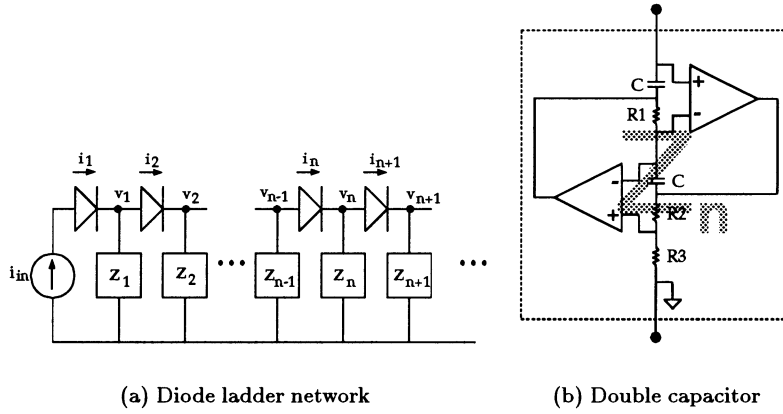

FIGURE 75.5: Diode ladder network in (a), with Z_n realized with a double capacitor as shown in (b).

has the voltage-current relation $\ddot{v}_n(t) = \alpha(i_n(t) - i_{n+1}(t))$, then the governing equations become

$$\frac{d^2 v_n(t)}{dt^2} = \alpha I_s \left(e^{(v_{n-1}(t) - v_n(t))/v_t} - e^{(v_n(t) - v_{n+1}(t))/v_t} \right), \quad (75.13)$$

or,

$$\frac{d^2}{dt^2} \ln \left(1 + \frac{i_n(t)}{I_s} \right) = \frac{\alpha}{v_t} (i_{n-1}(t) - 2i_n(t) + i_{n+1}(t)), \quad (75.14)$$

where $i_1(t) = i_{in}(t)$. These are equivalent to the Toda lattice equations with $a/m = \alpha I_s$ and $b = 1/v_t$. The required shunt impedance is often referred to as a double capacitor, which can be realized using ideal operational amplifiers in the gyrator circuit shown in Fig. 75.5(b), yielding the required impedance of $Z_n = \alpha/s^2 = R_3/R_1 R_2 C^2 s^2$ [13].

This circuit supports a single soliton solution of the form

$$i_n(t) = \beta^2 \text{sech}^2(pn - \beta\tau), \quad (75.15)$$

where $\beta = \sqrt{I_s} \sinh(p)$, and $\tau = t\sqrt{\alpha/v_t}$. The diode ladder circuit model is very accurate over a large range of soliton wavenumbers, and is significantly more accurate than the LC circuit of Hirota and Suzuki. Shown in Fig. 75.6(a) is an HSPICE simulation with two solitons propagating in the diode ladder circuit.

As illustrated in the bottom trace of Fig. 75.6(a), a soliton can be generated by driving the circuit with a square pulse of approximately the same area as the desired soliton. As seen on the third node in the lattice, once the soliton is excited, the non-soliton components rapidly become insignificant.

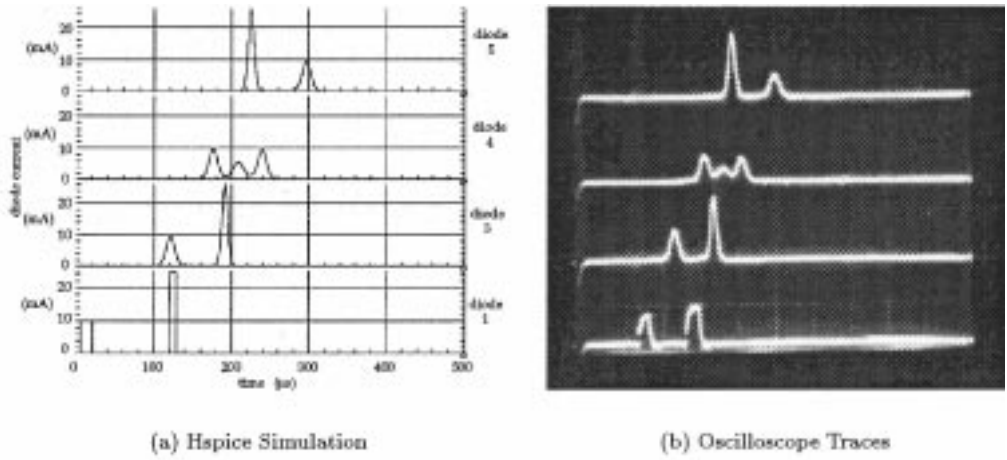

FIGURE 75.6: Evolution of a two-soliton signal through the diode lattice. Each horizontal trace shows the current through one of the diodes 1, 3, 4, and 5.

A two-soliton signal generated by a hardware implementation of this circuit is shown on the oscilloscope traces in Fig 75.6(b). The bottom trace in the figure corresponds to the input current to the circuit, and the remaining traces, from bottom to top, show the current through the third, fourth, and fifth diodes in the lattice.

75.3.3 Circuit Model for Discrete-KdV

The discrete-KdV equation (dKdV), sometimes referred to as the nonlinear ladder equations [1], or the KM system (Kac and vanMoerbeke) [17] is governed by the equation

$$\dot{u}_n(t) = e^{u_{n-1}(t)} - e^{u_{n+1}(t)}. \quad (75.16)$$

In [14], the circuit shown in Fig. 75.7, is shown to be governed by the discrete-KdV equation

$$\dot{v}_n(t) = \frac{I_s}{C} \left(e^{v_{n-1}(t)/v_t} - e^{v_{n+1}(t)/v_t} \right), \quad (75.17)$$

where I_s is the saturation current of the diode, C is the capacitance, and v_t is the thermal voltage. Since this circuit is first order, the state of the system is completely specified by the capacitor voltages.

Rather than processing continuous-time signals as with the Toda lattice system, we can use this system to process discrete-time solitons as specified by v_n . For the purposes of simulation, we consider the periodic dKdV equation by setting $v_{n+1}(t) = v_0(t)$ and initializing the system with the discrete-time signal corresponding to a listing of node capacitor voltages. We can place a multi-soliton solution in the circuit using inverse scattering techniques to construct the initial voltage profile. The single soliton solution to the dKdV system is given by

$$v_n(t) = \ln \left(\frac{\cosh(\gamma(n-2) - \beta t) \cosh(\gamma(n+1) - \beta t)}{\cosh(\gamma(n-1) - \beta t) \cosh(\gamma n - \beta t)} \right), \quad (75.18)$$

where $\beta = \sinh(2\gamma)$. Shown in Fig. 75.8, is the result of an HSPICE simulation of the circuit with 30 nodes in a loop configuration.

FIGURE 75.7: Circuit model for discrete-KdV.

FIGURE 75.8: To the left, the normalized node capacitor voltages, $v_n(t)/v_l$ for each node is shown as a function of time. To the right, the state of the circuit is shown as a function of node index for five different sample times. The bottom trace in the figure corresponds to the initial condition.

75.4 Communication with Soliton Signals

Many traditional communication systems use a form of sinusoidal carrier modulation, such as amplitude modulation (AM) or frequency/phase modulation (FM/PM) to transmit a message-bearing signal over a physical channel. The reliance upon sinusoidal signals is due in part to the simplicity with which such signals can be generated and processed using linear systems. More importantly, information contained in sinusoidal signals with different frequencies can easily be separated using linear systems or Fourier techniques. The complex dynamic structure of soliton signals and the ease with which these signals can be both generated and processed with analog circuitry renders them potentially applicable in the broad context of communication in an analogous manner to sinusoidal signals.

We define a soliton carrier as a signal that is composed of a periodically repeated single soliton solution to a particular nonlinear system. For example, a soliton carrier signal for the Toda lattice is shown in Fig. 75.9. As a Toda lattice soliton carrier is generated, a simple amplitude modulation scheme could be devised by slightly modulating the soliton parameter β , since the amplitude of these solitons is proportional to β^2 . Similarly, an analog of FM or pulse-position modulation could be achieved by modulating the relative position of each soliton in a given period, as shown in Fig. 75.9.

As a simple extension, these soliton modulation techniques can be generalized to include multiple solitons in each period and accommodate multiple information-bearing signals, as shown in Fig. 75.10 for a four soliton example using the Toda lattice circuits presented in [14]. In the figure, a signal is generated as a periodically repeated train of four solitons of increasing amplitude. The relative amplitudes or positions of each of the component solitons could be independently modulated about their nominal values to accommodate multiple information signals in a single soliton carrier.

The nominal soliton amplitudes can be appropriately chosen so that as this signal is processed

FIGURE 75.9: Modulating the relative amplitude or position of soliton carrier signal for the Toda lattice.

FIGURE 75.10: Multiplexing of a four soliton solution to the Toda lattice.

by the diode ladder circuit, the larger amplitude solitons propagate faster than the smaller solitons, and each of the solitons can become nonlinearly superimposed as viewed at a given node in the circuit. From an input-output perspective, the diode ladder circuit can be used to make each of the solitons coincidental in time. As indicated in the figure, this packetized soliton carrier could then be transmitted over a wireless communication channel. At the receiver, the multi-soliton signal can be processed with an identical diode ladder circuit which is naturally suited to perform the nonlinear signal separation required to demultiplex the multiple soliton carriers. As the larger amplitude solitons emerge before the smaller, after a given number of nodes, the original multi-soliton carrier re-emerges from the receiver in amplitude-reversed order. At this point, each of the component soliton carriers could be demodulated to recover the individual message signals it contains. Aside from a packetization of the component solitons, we will see that multiplexing the soliton carriers in this fashion can lead to an increased energy efficiency for such carrier modulation schemes, making such techniques particularly attractive for a broad range of portable wireless and power-limited communication applications.

Since the Toda lattice equations are symmetric with respect to time and node index, solitons can propagate in either direction. As a result, a single diode ladder implementation could be used as both a modulator and demodulator simultaneously. Since the forward propagating solitons correspond to positive eigenvalues in the inverse scattering transform and the reverse propagating solitons have negative eigenvalues, the dynamics of the two signals will be completely decoupled.

A technique for modulation of information on soliton carriers was also proposed by Hirota et al. in [15] and [16]. In their work, an amplitude and phase modulation of a two-soliton solution to the Toda lattice were presented as a technique for private communication. Although their signal generation and processing methods relied on an inexact phenomenon known as recurrence, the modulation paradigm they presented is essentially a two-soliton version of the carrier modulation paradigm presented in [14].

75.4.1 Low Energy Signaling

A consequence of some of the conservation laws satisfied by the Toda lattice is a reduction of energy in the transmitted signal for the modulation techniques of this section. In fact, as a function of the relative separation of two solitons, the minimum energy of the transmitted signal is obtained precisely at the point of overlap. This can be shown [14] for the two soliton case by analysis of the form of the equation for the energy in the waveform, $v(t) = f_n(t)$,

$$E = \int_{-\infty}^{\infty} v(t; \delta_1, \delta_2)^2 dt, \quad (75.19)$$

where $v(t; \delta_1, \delta_2)$ is given in Eq. (75.3). In [14] it is proven that E is exactly minimized when $\delta_1 = \delta_2$, i.e., the two solitons are mutually co-located. Significant energy reduction can be achieved for a fairly wide range of separations and amplitudes, indicating that the modulation techniques described here could take advantage of this reduction.

75.5 Noise Dynamics in Soliton Systems

In order to analyze the modulation techniques presented here, accurate models are needed for the effects of random fluctuations on the dynamics of soliton systems. Such disturbances could take the form of additive or convolutional corruption incurred during terrestrial or wired transmission, circuit thermal noise, or modeling errors due to system deviation from the idealized soliton dynamics. A fundamental property of solitons is that they are stable in the presence of a variety of disturbances.

With the development of the inverse scattering framework and the discovery that many soliton systems were conservative Hamiltonian systems, many of the questions regarding the stability of soliton solutions are readily answered. For example, since the eigenvalues of the associated linear operator remain unchanged under the evolution of the dynamics, then any solitons that are initially present in a system must remain present for all time, regardless of their interactions. Similarly, the dynamics of any non-soliton components that are present in the system are uncoupled from the dynamics of the solitons. However, in the communication scenario discussed in [14], soliton waveforms are generated and then propagated over a noisy channel. During transmission, these waveforms are susceptible to additive corruption from the channel. When the waveform is received and processed, the inverse scattering framework can provide useful information about the soliton and noise content of the received waveform.

In this section, we will assume that soliton signals generated in a communication context have been transmitted over an additive white Gaussian noise channel. We can then consider the effects of additive corruption on the processing of soliton signals with their nonlinear evolution equations. Two general approaches are taken to this problem. The first primarily deals with linearized models and investigates the dynamic behavior of the noise component of signals composed of an information bearing soliton signal and additive noise. The second approach is taken in the framework of inverse scattering and is based on some results from random matrix theory. Although the analysis techniques developed here are applicable to a large class of soliton systems, we focus our attention on the Toda lattice as an example.

75.5.1 Toda Lattice Small Signal Model

If a signal that is processed in a Toda lattice receiver contains only a small amplitude noise component, then the dynamics of the receiver can be approximated by a small signal model,

$$\frac{d^2 V_n(t)}{dt^2} = \frac{1}{LC} (V_{n-1}(t) - 2V_n(t) + V_{n+1}(t)), \quad (75.20)$$

when the amplitude of $V_n(t)$ is appropriately small.

If we consider processing signals with an infinite linear lattice and obtain an input-output relationship where a signal is input at the zeroth node and the output is taken as the voltage on the N th node, it can be shown that the input-output frequency response of the system can be given by

$$H_N(j\omega) = \begin{cases} e^{-2j \sin^{-1}(\omega\sqrt{LC}/2)N}, & |\omega| < 2/\sqrt{LC} \\ e^{[j\pi - 2 \cosh^{-1}(\omega\sqrt{LC}/2)]N}, & \text{else} \end{cases} \quad (75.21)$$

which behaves as a low pass filter, and for $N \gg 1$, approaches

$$|H_N(j\omega)|^2 = \begin{cases} 1, & |\omega| < \omega_c = 2/\sqrt{LC} \\ 0, & \text{else} \end{cases} \quad (75.22)$$

Our small signal model indicates that in the absence of solitons in the received signal, small amplitude noise will be processed by a low pass filter. If the received signal also contains solitons, then the small signal model of Eq. (75.20) will no longer hold. A linear small signal model can still be used if we linearize Eq. (75.11) about the known soliton signal. Assuming that the solution contains a single soliton in small amplitude noise, $V_n(t) = S_n(t) + v_n(t)$, we can write Eq. (75.11) as an exact equation that is satisfied by the non-soliton component

$$\frac{d^2}{dt^2} \ln \left(1 + \frac{v_n(t)}{1 + S_n(t)} \right) = \frac{1}{LC} (v_{n-1}(t) - 2v_n(t) + v_{n+1}(t)), \quad (75.23)$$

which can be viewed as the fully nonlinear model with a time-varying parameter, $(1 + S_n(t))$. As a result, over short time scales relative to $S_n(t)$, we would expect this model to behave in a similar manner to the small signal model of Eq. (75.20). With $v_n(t) \ll (1 + S_n(t))$, we obtain

$$\frac{d^2}{dt^2} \frac{v_n(t)}{1 + S_n(t)} \approx \frac{1}{LC} (v_{n-1}(t) - 2v_n(t) + v_{n+1}(t)). \quad (75.24)$$

When the contribution from the soliton is small, Eq. (75.24) reduces to the linear system of Eq. (75.20). We would therefore expect that both before and after a soliton has passed through the lattice, the system essentially low pass filters the noise. However, as the soliton is processed, there will be a time-varying component to the filter.

To confirm the intuition developed through small signal analyses, the fully nonlinear dynamics are shown in Fig. 75.11 in response to a single soliton at 20 dB signal-to-noise ratio. As expected, the response to the lattice is essentially the unperturbed soliton with an additional low pass perturbation. The spectrum of the noise remains essentially flat over the bandwidth of the soliton and is attenuated out of band.

75.5.2 Noise Correlation

The statistical correlation of the system response to the noise component can also be estimated from our linear analyses. Given that the lattice behaves as a lowpass filter, the small amplitude noise $v_n(t)$ is zero mean and has an auto-correlation function given by

$$R_{n,n}(\tau) = E\{v_n(t)v_n(t + \tau)\} \approx N_0 \frac{\sin(\omega_c \tau)}{\pi \tau}, \quad (75.25)$$

and a variance $\sigma_{v_n}^2 \approx N_0 \omega_c / \pi$, for $n \gg 1$.

FIGURE 75.11: Response to a single soliton with $\beta = \sinh(1)$ in 20 dB Gaussian noise.

Although the autocorrelation of the noise at each node is only affected by the magnitude response of Eq. (75.21), the cross-correlation between nodes is also affected by the phase response. The cross-correlation between nodes m and n is given by

$$R_{m,n}(\tau) = R_{m,m}(\tau) * h_{n-m}(-\tau), \quad (75.26)$$

where $h_m(\tau)$ is the inverse Fourier transform of $H_m(j\omega)$ in Eq. (75.21). Since $h_m(\tau) * h_m(-\tau)$ approaches the impulse response of an ideal low pass filter for $m \gg 1$, we have

$$R_{m,n}(\tau) \approx N_0 \frac{\sin(\omega_c \tau)}{\pi \tau} * h_{n-m}(\tau). \quad (75.27)$$

For small amplitude noise, the correlation structure can be examined through the linear lattice, which acts as a dispersive low pass filter. A corresponding analysis of the nonlinear system in the presence of solitons is prohibitively complex. However, we can explore the analyses numerically by linearizing the dynamics of the system about the known soliton trajectory.

From our earlier linearized analyses, the linear time-varying small signal model can be viewed over short time scales as a linear time-invariant chain, with a slowly varying parameter. The resulting input-output transfer function can be viewed as a low pass filter with time varying cutoff frequency equal to ω_c when a soliton is far from the node, and to $\omega_0 \sqrt{1 + V_n^0}$ as a soliton passes through. Thus, we would expect the variance of the node voltage to rise from a nominal value as a soliton passes through. This intuition can be verified experimentally by numerically integrating the corresponding Riccati equation for the node covariance and computing the resulting variance of the noise component on each node. Since the lattice was assumed initially at rest, there will be a startup transient, as well as an initial spatial transient at the beginning of the lattice, after which the variance of the noise is amplified from the nominal variance as each soliton passes through, confirming our earlier intuition.

75.5.3 Inverse Scattering-Based Noise Modeling

The inverse scattering transform provides a particularly useful mechanism for exploring the long term behavior of soliton systems. In a similar manner to the use of the Fourier transform for describing the ability of linear processors to extract a signal from a stationary random background, the nonlinear spectrum of a received soliton signal in noise can effectively characterize the ability of the nonlinear

system to extract or process the component solitons. In this section, we focus on the effects of random perturbations on the dynamics of solitons in the Toda lattice from the viewpoint of inverse scattering.

As seen in Section 75.2.1, the dynamics of the Toda lattice may be described by the evolution of the matrix

$$L(t) = \begin{bmatrix} & \ddots & & \\ & & a_{n-1}(t) & \\ a_{n-1}(t) & & b_n(t) & a_n(t) \\ & & a_n(t) & \ddots \end{bmatrix}, \quad (75.28)$$

whose eigenvalues outside the range $|\lambda| \leq 1$ give rise to soliton behavior. By considering the effects of small amplitude perturbations to the sequences $a_n(t)$ and $b_n(t)$ on the eigenvalues of $L(t)$, we can observe the effects on the soliton dynamics through the eigenvalues corresponding to solitons.

Following [20], we write the $N \times N$ matrix L as $L = L_0 + D$, where L_0 is the unperturbed symmetric matrix, and D is the symmetric random perturbation. To second order, the eigenvalues are given by

$$\lambda_g = \mu_g + \hat{d}_{gg} - \sum_{i=1, i \neq g}^N \frac{\hat{d}_{gi}\hat{d}_{ig}}{\mu_{ig}}, \quad (75.29)$$

where μ_g is the g th eigenvalue of L_0 , $\mu_{ig} = \mu_i - \mu_g$, and \hat{d}_{ij} are the elements of the matrix \hat{D} defined by $\hat{D} = C^\top DC$, and C is a matrix that diagonalizes L , $C^\top L_0 C = \text{diag}(\mu_1, \dots, \mu_N)$.

To second order, the means of the eigenvalues are given by

$$E\{\lambda_g\} = \mu_g - \sum_{i=1, i \neq g}^N \frac{\hat{d}_{gi}\hat{d}_{ig}}{\mu_{ig}}, \quad (75.30)$$

indicating that the eigenvalues of L are asymptotically ($\text{SNR} \rightarrow \infty$) unbiased estimates of the eigenvalues of L_0 . To first order, $\lambda_g \approx \mu_g - \hat{d}_{gg}$, and \hat{d}_{gg} is a linear combination of the elements of D ,

$$\hat{d}_{gg} = \sum_{r=1, s=1}^N c_{gr}c_{gs}d_{rs}. \quad (75.31)$$

Therefore, if the elements of D are jointly Gaussian, then to first order, the eigenvalues of L will be jointly Gaussian, distributed about the eigenvalues of L_0 .

The variance of the eigenvalues can be shown to be approximately given by

$$\text{Var}(\lambda_g) \approx \frac{\sigma_\beta^2 + 2\sigma_\alpha^2(1 + \cos(4\pi g/N))}{N}, \quad (75.32)$$

to second order, where σ_β^2 and σ_α^2 are the variances of the iid perturbations to b_n and a_n , respectively. This indicates that the eigenvalues of L are consistent estimates of the eigenvalues of L_0 .

To first order, when processing small amplitude noise alone, the noise only excites eigenvalues distributed about the continuum, corresponding to non-soliton components. When solitons are processed in small amplitude noise, to first order, there is a small Gaussian perturbation to the soliton eigenvalues as well.

75.6 Estimation of Soliton Signals

In the communication techniques suggested in Section 75.4, the parameters of a multi-soliton carrier are modulated with message-bearing signals and the carrier is then processed with the corresponding

nonlinear evolution equation. A potential advantage to transmission of this packetized soliton carrier is a net reduction in the transmitted signal energy. However, during transmission, the multi-soliton carrier signal can be subjected to distortions due to propagation, which we have assumed can be modeled as additive white Gaussian noise (AWGN). In this section, we investigate the ability of a receiver to estimate the parameters of a noisy multi-soliton carrier. In particular, we consider the problems of estimating the scaling parameters and the relative positions of component solitons of multi-soliton solutions, once again focusing on the Toda lattice as an example. For each of these problems, we derive Cramér-Rao lower bounds for the estimation error variance through which several properties of multi-soliton signals can be observed. Using these bounds, we will see that although the net transmitted energy in a multi-soliton signal can be reduced through nonlinear interaction, the estimation performance for the parameters of the component solitons can also be enhanced. However, at the receiver there are inherent difficulties in parameter estimation imposed by this nonlinear coupling. We will see that the Toda lattice can act as a tuned receiver for the component solitons, naturally decoupling them so that the parameters of each soliton can be independently estimated. Based on this strategy, we develop robust algorithms for maximum likelihood parameter estimation. We also extend the analogy of the inverse scattering transform as an analog of the Fourier transform for linear techniques, by developing a maximum likelihood estimation algorithm based on the nonlinear spectrum of the received signal.

75.6.1 Single Soliton Parameter Estimation: Bounds

In our simplified channel model, the received signal $r(t)$ contains a soliton signal $s(t)$ in an additive white Gaussian noise background $n(t)$ with noise power N_0 . A bound on the variance of an estimate of the parameter β may be useful in determining the demodulation performance of an AM-like modulation or PAM, where the component soliton wavenumbers are slightly amplitude modulated by a message-bearing waveform. When $s(t)$ contains a single soliton for the Toda lattice, $s(t) = \beta^2 \text{sech}^2(\beta t)$, the variance of any unbiased estimator $\hat{\beta}$ of β must satisfy the Cramér-Rao lower bound (CRB) [19],

$$\text{Var}(\hat{\beta}) \geq \frac{N_0}{\int_{t_i}^{t_f} \left(\frac{\partial s(t; \beta)}{\partial \beta} \right)^2 dt}, \quad (75.33)$$

where the observation interval is assumed to be $t_i < t < t_f$. For the infinite observation interval, $-\infty < t < \infty$, the CRB (75.33) is given by

$$\text{Var}(\hat{\beta}) \geq \frac{N_0}{\left(\frac{8}{3} + \frac{4\pi^2}{45} \right) \beta} \approx \frac{N_0}{3.544\beta}. \quad (75.34)$$

A slightly different bound may be useful in determining the demodulation performance of an FM-like modulation or PPM, where the soliton position, or time-delay, is slightly modulated by a message-bearing waveform. The fidelity of the recovered message waveform will be directly affected by the ability of a receiver to estimate the soliton position. When the signal $s(t)$ contains a single soliton $s(t) = \beta^2 \text{sech}^2(\beta(t - \delta))$, where δ is the relative position of the soliton in a period of the carrier, the CRB for $\hat{\delta}$ is given by

$$\text{Var}(\hat{\delta}) \geq \frac{N_0}{\int_{t_i}^{t_f} 4\beta^6 \text{sech}^4(\beta(t - \delta)) \tanh^2(\beta(t - \delta)) dt} = \frac{N_0}{\left(\frac{16}{15} \right) \beta^5}. \quad (75.35)$$

As a comparison, for estimating the time of arrival of the raised cosine pulse, $\beta^2 (1 + \cos(2\pi\beta(t - \delta)))$, the CRB for this more traditional pulse position modulation would be

$$\text{Var}(\hat{\delta}) \geq \frac{N_0}{\pi^2 \beta^5}, \quad (75.36)$$

which has the same dependence on signal amplitude as Eq. (75.35). These bounds can be used for multiple soliton signals if the component solitons are well separated in time.

75.6.2 Multi-Soliton Parameter Estimation: Bounds

When the received signal is a multi-soliton waveform where the component solitons overlap in time, the estimation problem becomes more difficult. It follows that the bounds for estimating the parameters of such signals must also be sensitive to the relative positions of the component solitons.

We will focus our attention on the two-soliton solution to the Toda lattice, given by Eq. (75.3). We are generally interested in estimating the parameters of the multi-soliton carrier for an unknown relative spacing among the solitons present in the carrier signal. Either the relative spacing of the solitons has been modulated and is therefore unknown, or the parameters β_1 and β_2 are slightly modulated and the induced phase shift in the received solitons, ϕ , is unknown. For large separations, $\delta = \delta_1 - \delta_2$, the CRB for estimating the parameters of either of the component solitons will be unaffected by the parameters of the other soliton. As shown in Fig. 75.12, when the component solitons are well separated, the CRB for either β_1 or β_2 approaches the CRB for estimation of a single soliton with that parameter value in the same level of noise. The bounds for estimating β_1 , and β_2 are shown in Fig. 75.12 as a function of the relative separation, δ .

FIGURE 75.12: The Cramér-Rao lower bound for estimating $\beta_1 = \sinh(2)$ and $\beta_2 = \sinh(1.75)$ with all parameters unknown in AWGN with $N_0 = 1$. The bounds are shown as a function of the relative separation, $\delta = \delta_1 - \delta_2$. The CRB for estimating β_1 and β_2 of a single soliton with the same parameter value is indicated with 'o' and 'x' marks, respectively.

Note that both of the bounds are reduced by the nonlinear superposition, indicating that the potential performance of the receiver is *enhanced* by the nonlinear superposition. However, if we let the parameter difference $\beta_2 - \beta_1$ increase, we notice a different character to the bounds. Specifically, we maintain $\beta_1 = \sinh(2)$, and let $\beta_1 = \sinh(1.25)$. The performance of the larger soliton is inhibited by the nonlinear superposition, while the smaller soliton is still enhanced. In fact, the CRB for the smaller soliton becomes lower than that for the larger soliton near the range $\delta = 0$. This phenomenon results from the relative sensitivity of the signal $s(t)$ to each of the parameters β_1 and β_2 . The ability to simultaneously enhance estimation performance while decreasing signal energy is an inherently nonlinear phenomena.

Combining these results with the results of Section 75.4.1, we see that the nonlinear interaction of the component solitons can simultaneously enhance the parameter estimation performance and reduce the net energy of the signal. This property may make superimposed solitons attractive for use in a variety of communication systems.

75.6.3 Estimation Algorithms

In this section we will present and analyze several parameter estimation algorithms for soliton signals. Again, we will focus on the diode ladder circuit implementation of the Toda lattice equations, Eq. (75.14). As motivation, consider the problem of estimating the position, δ , of a single soliton solution $s(t; \delta) = \beta^2 \text{sech}^2(\beta(t - \delta))$, with the parameter β known. This is a classical time-of-arrival estimation problem. For observations $r(t) = s(t) + n(t)$, where $n(t)$ is a stationary white Gaussian process, the maximum likelihood estimate is given by the value of the parameter δ which minimizes the expression

$$\hat{\delta} = \arg \min_{\tau} \int_{t_i}^{t_f} (r(t) - s(t - \tau))^2 dt . \quad (75.37)$$

Since the replica signals all have the same energy, we can represent the minimization in (75.37) as a maximization of the correlation

$$\hat{\delta} = \arg \min_{\tau} \int_{t_i}^{t_f} r(t)s(t - \tau) dt . \quad (75.38)$$

It is well known that an efficient way to perform the correlation (75.38) with all of the replica signals $s(t - \tau)$ over the range $\delta_{\min} < \tau < \delta_{\max}$, is through convolution with a matched filter followed by a peak-detector [19].

When the signal $r(t)$ contains a multi-soliton signal, $s(t; \underline{\beta}, \underline{\delta})$, where we wish to estimate the parameter vector $\underline{\delta}$, the estimation problem becomes more involved. If the component solitons are well separated in time, then the maximum likelihood estimator for the positions of each of the component solitons would again involve a matched filter processor followed by a peak-detector for each soliton. If the component solitons are not well separated and are therefore nonlinearly combined, the estimation problems are tightly coupled and should not be performed independently. The estimation problems can be decoupled by preprocessing the signal $r(t)$ with the Toda lattice. By setting $i_{\text{in}}(t) = r(t)$, that is the current through the first diode in the diode ladder circuit, then as the signal propagates through the lattice, the component solitons will naturally separate due to their different propagation speeds.

Defining the signal and noise components as viewed on the k th node in the lattice as $s_k(t)$ and $n_k(t)$, respectively, i.e., $i_k(t) = s_k(t) + n_k(t)$, where $n_0(t)$ is the stationary white Gaussian noise process $n(t)$, in Section 75.5, we saw that in the high SNR limit, $n_k(t)$ will be low pass and Gaussian. In this limit, the ML estimator for the positions, δ_i , can again be formulated using matched filters for each of the component solitons. Since the lattice equations are invertible, at least in principle through inverse scattering, then the ML estimate of the parameter $\underline{\delta}$ based on $r(t)$ must be the same as the estimate based on $i_n(t) = T(r(t))$, for any invertible transformation $T(\cdot)$. If the component solitons are well separated as viewed on the N th node of the lattice, $i_N(t)$, then an ML estimate based on observations of $i_N(t)$ will reduce to the aggregate of ML estimates for each of the separated component solitons on low pass Gaussian noise. For soliton position estimation, this amounts to a bank of matched filters. We can view this estimation procedure as a form of nonlinear matched filtering, whereby first, dynamics matched to the soliton signals are used to perform the necessary signal separation, and then filters matched to the separated signals are used to estimate their arrival time.

75.6.4 Position Estimation

We will focus our attention on the two-soliton signal (75.3). If the component solitons are well-separated as viewed on the N th node of the Toda lattice, the signal appears to be a linear superposition of two solitons,

$$i_N(t) \approx \beta_1^2 \text{sech}^2(\beta_1(t - \delta_1) - p_1 N - \phi/2) + \beta_2^2 \text{sech}^2(\beta_2(t - \delta_2) - p_2 N + \phi/2), \quad (75.39)$$

where $\phi/2$ is the time-shift incurred due to the nonlinear interaction. Matched filters can now be used to estimate the time of the arrival of each soliton at the N th node. We formulate the estimate

$$\hat{\delta}_1 = \left(t_{N,1}^a - \frac{p_1 N + \phi/2}{\beta_1} \right), \quad \hat{\delta}_2 = \left(t_{N,2}^a - \frac{p_2 N - \phi/2}{\beta_2} \right), \quad (75.40)$$

where $t_{N,i}^a$ is the time of arrival of the i th soliton on node N . The performance of this algorithm for a two-soliton signal with $\beta = [\sinh(2), \sinh(1.5)]$ is shown in Fig. 75.13. Note that although the error variance of each estimate appears to be a constant multiple of the CRB, the estimation error variance approaches the CRB in an absolute sense as $N_0 \rightarrow 0$.

FIGURE 75.13: The CRBs for δ_1 and δ_2 are shown with solid and dashed lines, while the estimation error results of 100 Monte-Carlo trials are indicated with 'o' and 'x' marks, respectively.

75.6.5 Estimation Based on Inverse Scattering

The transformation $L(t) = T\{r(t)\}$, where $L(t)$ is the symmetric matrix from the inverse scattering transform, is also invertible in principle. Therefore, an ML estimate based on the matrix $L(t)$ must be the same as an ML estimate based on $r(t)$. We therefore seek to form an estimate of the parameters of the signal $r(t)$ by performing the estimation in the nonlinear spectral domain. This can be accomplished by viewing the Toda lattice as a nonlinear filterbank which projects the signal $r(t)$ onto the spectral components of $L(t)$. This use of the inverse scattering transform is analogous to performing frequency estimation with the Fourier transform.

If $v_n(t)$ evolves according to the Toda lattice equations, then the eigenvalues of the matrix, $L(t)$ are time-invariant, where, $a_n(t) = \frac{1}{2}e^{(v_n(t) - v_{n+1}(t))/2}$, and $b_n = \dot{v}_n(t)/2$. Further, the eigenvalues of

$L(t)$ for which $|\lambda_i| > 1$ correspond to soliton solutions, with $\beta_i = \sinh(\cosh^{-1}(\lambda_i)) = \sqrt{\lambda_i^2 - 1}$. The eigenvalues of $L(t)$ are, to first order, jointly Gaussian and distributed about the true eigenvalues corresponding to the original multi-soliton signal, $s(t)$. Therefore, estimation of the parameters β_i from the eigenvalues of $L(t)$ as described above constitutes a maximum likelihood approach in the high SNR limit.

The parameter estimation algorithm now amounts to an estimation of the eigenvalues of $L(t)$. Note that since $L(t)$ is tridiagonal, very efficient techniques for eigenvalue estimation may be used [3]. The estimate of the parameter β is then found by the relation $\hat{\beta}_i = \sqrt{\lambda_i^2 - 1}$, where $|\lambda_i| > 1$, and the sign of β_i can be recovered from the sign of λ_i . Clearly if there is a pre-specified number of solitons, k , present in the signal, then the k largest eigenvalues would be used for the estimation. If the number k were unknown, then a simultaneous detection and estimation algorithm would be required.

An example of the joint estimation of the parameters of a two-soliton signal is shown in Fig. 75.14(a). The estimation error variance decreases with the noise power at the same exponential rate as the CRB.

To verify that the performance of the estimation algorithm has the same dependence on the relative separation of solitons as indicated in Section 75.6.2, the estimation error variance is also indicated in Fig. 75.14(b) vs. the relative separation, δ . In the figure, the mean-squared parameter estimation error for each of the parameters β_i are shown along with their corresponding CRB. At least empirically, we see that the fidelity of the parameter estimates are indeed enhanced by their nonlinear interaction, even though this corresponds to a signal with lower energy, and therefore lower observational SNR.

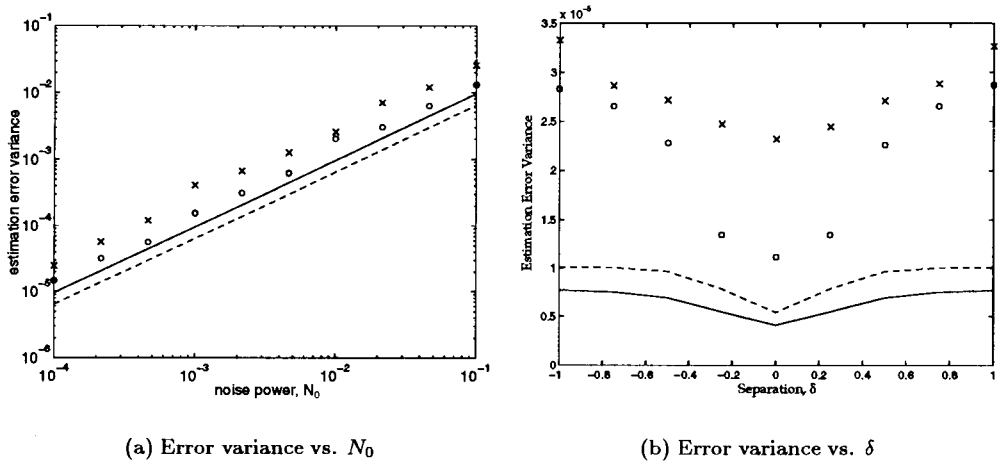

FIGURE 75.14: The estimation error variance for the inverse scattering-based estimates of $\beta_1 = \sinh(2)$, $\beta_2 = \sinh(1.5)$. The bounds for β_1 and β_2 are indicated with solid and dashed lines, respectively. The estimation results for 100 Monte Carlo trials with a diode lattice of $N = 10$ nodes for β_1 and β_2 are indicated by the points labeled 'o' and 'x', respectively.

75.7 Detection of Soliton Signals

The problem of detecting a single soliton or multiple non-overlapping solitons in AWGN falls within the theory of classical detection. The Bayes optimal detection of a known or multiple known signals in AWGN can be accomplished with matched filter processing. When the signal $r(t)$ contains a multi-soliton signal where the component solitons are not resolved, the detection problem becomes more involved. Specifically, consider a signal comprising a two-soliton solution to the Toda lattice, where we wish to decide which, if any, solitons are present. If the relative positions of the component solitons are known *a priori*, then the detection problem reduces to deciding which among four possible known signals is present,

$$\begin{aligned} H_0 &: r(t) = n(t) , \\ H_1 &: r(t) = s_1(t) + n(t) , \\ H_2 &: r(t) = s_2(t) + n(t) , \\ H_{12} &: r(t) = s_{12}(t) + n(t) , \end{aligned}$$

where $s_1(t)$, $s_2(t)$, and $s_{12}(t)$ are soliton one, soliton two, and the multi-soliton signals, respectively. Once again, this problem can be solved with standard Gaussian detection theory.

If the relative positions of the solitons are unknown, as would be the case for a modulated soliton carrier, then the signal $s_{12}(t)$ will vary significantly as a function of the relative separation. Similarly, if the signals are to be transmitted over a soliton channel where different users occupy adjacent soliton wavenumbers, any detection at the receiver would have to be performed with the possibility of another soliton component present at an unknown position. We therefore obtain a composite hypothesis testing problem, whereby under each hypothesis, we have

$$\begin{aligned} H_0 &: r(t) = n(t) , \\ H_1 &: r(t) = s_1(t; \delta_1) + n(t) , \\ H_2 &: r(t) = s_2(t; \delta_2) + n(t) , \\ H_{12} &: r(t) = s_{12}(t; \underline{\delta}) + n(t) , \end{aligned}$$

where $\underline{\delta} = [\delta_1, \delta_2]^\top$. The general problem of detection with an unknown parameter, $\underline{\delta}$, can be handled in a number of ways. For example, if the parameter can be modeled as random and the distribution for the parameter were known, $p_{\underline{\delta}}(\underline{\delta})$, along with the distributions $p_{r|\underline{\delta}, H}(R|\underline{\delta}, H_i)$ for each hypothesis, then the Bayes or Neyman-Pearson criteria can be used to formulate a likelihood ratio test. Unfortunately, even when the distribution for the parameter $\underline{\delta}$ is known, the likelihood ratios cannot be found in closed form for even the single soliton detection problem.

Another approach that is commonly used in radar processing [5, 19] applies when the distribution of δ does not vary rapidly over a range of possible values while the likelihood function has a sharp peak as a function of δ . In this case, the major contribution to the integral in the averaged likelihood function is due to the region around the value of δ for which the likelihood function is maximum, and therefore this value of the likelihood function is used as if the maximizing value, $\hat{\delta}_{\text{ML}}$, were the *actual* value. Since $\hat{\delta}_{\text{ML}}$ is the maximum likelihood estimate of δ based on the observation, $r(t)$, such techniques are called “maximum likelihood detection”. Also, the term “generalized likelihood ratio test” (GLRT) is used since the hypothesis test amounts to a generalization of the standard likelihood ratio test.

If we plan to employ a GLRT for the multi-soliton detection problem, we are again faced with the need for an ML estimate of the position, $\hat{\delta}_{\text{ML}}$. A standard approach to such problems would involve turning the current problem into one with hypotheses H_0 , H_1 , and H_2 as before, and an additional

M hypotheses—one for each value of the parameter δ sampled over a range of possible values. The complexity of this type of detection problem increases exponentially with the number of component solitons, N_s , resulting in a hypothesis testing problem with $O((M + 1)^{N_s})$ hypotheses.

However, as with the estimation problems in Section 75.6, the detection problems can be decoupled by preprocessing the signal $r(t)$ with the Toda lattice. If the component solitons separate as viewed on the N th node in the lattice, then the detection problem can be more simply formulated using $i_N(t)$. The invertibility of the lattice equations implies that a Bayes optimal decision based on $r(t)$ must be the same as that based on $i_N(t)$. Since the Bayes optimal decision can be performed based on the likelihood function $\Lambda(r(t))$, and $\Lambda(i_N(t)) = \Lambda(T\{r(t)\}) = \Lambda(r(t))$, the optimal decisions based on $r(t)$ and $i_N(t)$ must be the same for any invertible transformation $T\{\cdot\}$. Although we will be using a GLRT, where the value of $\hat{\delta}_{ML}$ is used for the unknown positions of the multi-soliton signal, since the ML estimates based on $r(t)$ and $i_N(t)$ must also be the same, the detection performance of a GLRT using those estimates must also be the same. Since at high SNR, the noise component of the signal $i_N(t)$ can be assumed low pass and Gaussian, the GLRT can be performed by pre-processing $r(t)$ with the Toda lattice equations followed by matched filter processing.

75.7.1 Simulations

To illustrate the algorithm, we consider the hypothesis test between H_0 and H_{12} , where the separation of the two solitons, $\delta_1 - \delta_2$, varies randomly in the interval $[-1/\beta_2, 1/\beta_2]$. The detection processor comprises a Toda lattice of $N = 20$ nodes, with the detection performed based on the signal $i_{10}(t)$. To implement the GLRT, we search over a fixed time interval about the expected arrival time for each soliton. In this manner we obtain a sequence of 1000 Monte Carlo values of the processor output for each hypothesis. A set of Monte Carlo runs has been completed for each of three different levels of the noise power, N_0 .

The receiver operating characteristic (ROC) for the soliton with $\beta_2 = \sinh(1.5)$ is shown in Fig. 75.15, where the probability of detection, P_D , for this hypothesis test is shown as a function of the false alarm probability, P_F . For comparison, we also show the ROC that would result from a detection of the soliton alone, at the same noise level and with the time-of-arrival known. The detection index, $d = \sqrt{E/N_0}$, is indicated for each case, where E is the energy in the component soliton. The corresponding results for the larger soliton are qualitatively similar, although the detection indices for that soliton alone, with $\beta_1 = \sinh(2)$, are 5.6, 4, and 3.3, respectively. Therefore, the detection probabilities are considerably higher for a fixed probability of false alarm. Note that the detection performance for the smaller soliton is well modeled by the theoretical performance for detection of the smaller soliton alone. This implies, at least empirically, that the ability to detect the component solitons in a multi-soliton signal appears to be unaffected by the nonlinear coupling with other solitons. Further, although the unknown relative separation results in significant waveform uncertainty and would require a prohibitively complex receiver for standard detection techniques, Bayes optimal performance can still be achieved with a minimal increase in complexity.

FIGURE 75.15: A set of empirically generated ROCs are shown for the detection of the smaller soliton from a two-soliton signal. For each of the three noise levels, the ROC for detection of the smaller soliton alone is also indicated along with the corresponding detection index, d .

76.1 Introduction

The past 20 years witnessed an expansion of power spectrum estimation techniques, which have proved essential in many applications, such as communications, sonar, radar, speech/image processing, geophysics, and biomedical signal processing [13, 11, 7]. In power spectrum estimation the process under consideration is treated as a superposition of statistically uncorrelated harmonic components. The distribution of power among these frequency components is the power spectrum. As such, phase relations between frequency components are suppressed. The information in the power spectrum is essentially present in the autocorrelation sequence, which would suffice for the complete statistical description of a Gaussian process of known mean. However, there are applications where one would need to obtain information regarding deviations from the Gaussianity assumption and presence of nonlinearities. In these cases power spectrum is of little help, and one would have to look beyond the power spectrum or autocorrelation domain. Higher-Order Spectra (HOS) (of order greater than 2), which are defined in terms of higher-order cumulants of the data, do contain such information [16]. The third-order spectrum is commonly referred to as bispectrum, the fourth-order one as trispectrum, and in fact, the power spectrum is also a member of the higher-order spectral class; it is the second-order spectrum.

HOS consist of higher-order moment spectra, which are defined for deterministic signals, and cumulant spectra, which are defined for random processes. In general, there are three motivations behind the use of HOS in signal processing: (1) to suppress Gaussian noise of unknown mean and variance; (2) to reconstruct the phase as well as the magnitude response of signals or systems; and (3) to detect and characterize nonlinearities in the data.

The first motivation stems from the property of Gaussian processes to have zero higher-order spectra. Due to this property, HOS are high signal-to-noise ratio domains, in which one can perform detection, parameter estimation, or even signal reconstruction even if the time domain noise is spatially correlated. The same property of cumulant spectra can provide means of detecting and characterizing deviations of the data from the Gaussian model.

The second motivation is based on the ability of cumulant spectra to preserve the Fourier-phase of signals. In the modeling of time series, second-order statistics (autocorrelation) have been heavily used because they are the result of least-squares optimization criteria. However, an accurate phase reconstruction in the autocorrelation domain can be achieved only if the signal is minimum phase. Nonminimum phase signal reconstruction can be achieved only in the HOS domain, due to the HOS ability to preserve phase. Figure 76.1 shows two signals, a nonminimum phase and a minimum phase, with identical magnitude spectra but different phase spectra. Although power spectrum cannot distinguish between the two signals, the bispectrum that uses phase information can.

Being nonlinear functions of the data, HOS are quite natural tools in the analysis of nonlinear systems operating under a random input. General relations for arbitrary stationary random data passing through an arbitrary linear system exist and have been studied extensively. Such expression, however, are not available for nonlinear systems, where each type of nonlinearity must be studied separately. Higher-order correlations between input and output can detect and characterize certain nonlinearities [34], and for this purpose several higher-order spectra-based methods have been developed.

The organization of this chapter is as follows. First the definitions and properties of cumulants and higher-order spectra are introduced. Then two methods for the estimation of HOS from finite length data are outlined and the asymptotic statistics of the obtained estimates are presented. Following that, parametric and nonparametric methods for HOS-based identification of linear systems are described, and the use of HOS in the identification of some particular nonlinear systems is briefly discussed. The chapter concludes with a section on applications of HOS and available software.

76.2 Definitions and Properties of HOS

In this chapter we will consider random one-dimensional processes only. The definitions can be easily extended to the two-dimensional case [15].

The joint moments of order r of the random variables x_1, \dots, x_n are given by [22]

$$\begin{aligned} Mom \left[x_1^{k_1}, \dots, x_n^{k_n} \right] &= E \{ x_1^{k_1}, \dots, x_n^{k_n} \} \\ &= (-j)^r \frac{\partial^r \Phi(\omega_1, \dots, \omega_n)}{\partial \omega_1^{k_1} \dots \partial \omega_n^{k_n}} \Big|_{\omega_1=\dots=\omega_n=0}, \end{aligned} \quad (76.1)$$

where $k_1 + \dots + k_n = r$, and $\Phi()$ is their joint characteristic function. The joint cumulants are defined as

$$Cum \left[x_1^{k_1}, \dots, x_n^{k_n} \right] = (-j)^r \frac{\partial^r \ln \Phi(\omega_1, \dots, \omega_n)}{\partial \omega_1^{k_1} \dots \partial \omega_n^{k_n}} \Big|_{\omega_1=\dots=\omega_n=0}. \quad (76.2)$$

For a stationary discrete time random process $X(k)$, (k denotes discrete time), the *moments* of order n are given by

$$m_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = E \{ X(k) X(k + \tau_1) \dots X(k + \tau_{n-1}) \}, \quad (76.3)$$

where $E\{\cdot\}$ denotes expectation. The n th order *cumulants* are functions of the moments of order up to n , i.e.,

1st order cumulants:

$$c_1^x = m_1^x = E \{ X(k) \} \quad (\text{mean}) \quad (76.4)$$

2nd order cumulants:

$$c_2^x(\tau_1) = m_2^x(\tau_1) - (m_1^x)^2 \quad (\text{covariance}) \quad (76.5)$$

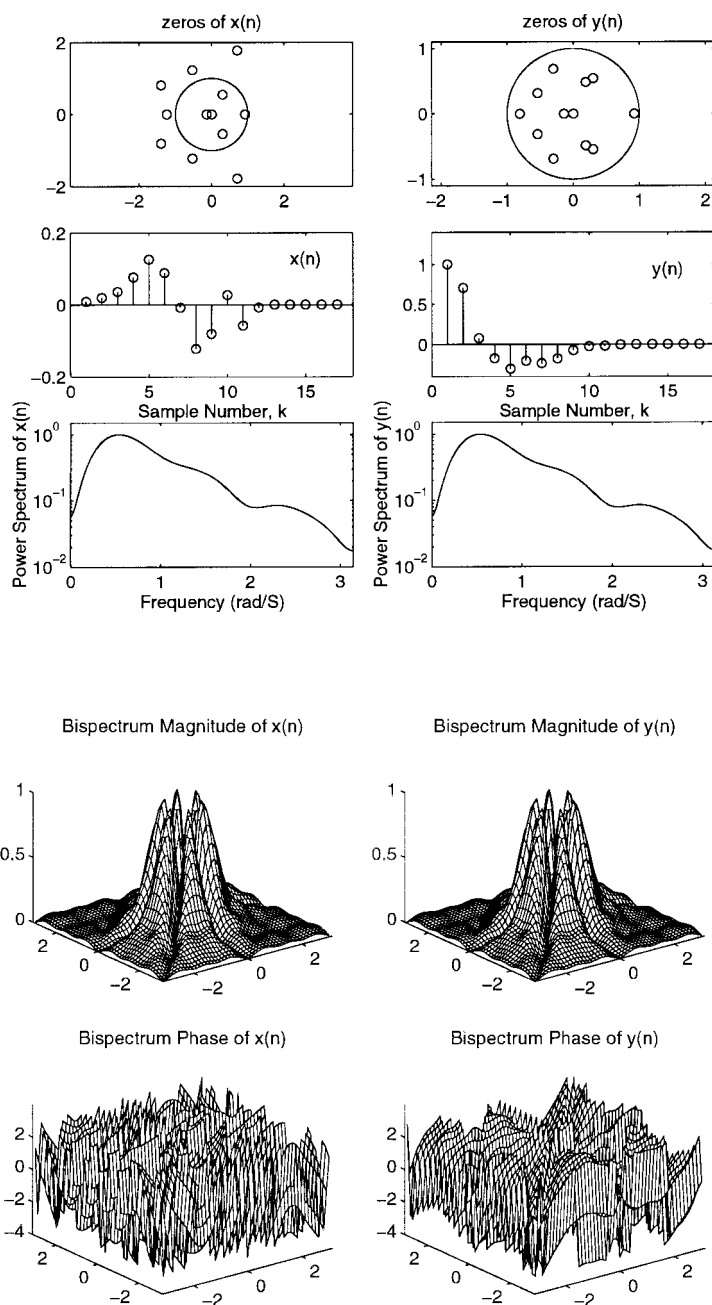

FIGURE 76.1: $x(n)$ is a nonminimum phase signal and $y(n)$ is a minimum phase one. Although their power spectra are identical, their bispectra are different because they contain phase information.

3rd order cumulants:

$$c_3^x(\tau_1, \tau_2) = m_3^x(\tau_1, \tau_2) - (m_1^x) [m_2^x(\tau_1) + m_2^x(\tau_2) + m_2^x(\tau_2 - \tau_1)] + 2(m_1^x)^3 \quad (76.6)$$

4th order cumulants:

$$\begin{aligned} c_4^x(\tau_1, \tau_2, \tau_3) = & m_4^x(\tau_1, \tau_2, \tau_3) - m_2^x(\tau_1) m_2^x(\tau_3 - \tau_2) - m_2^x(\tau_2) m_2^x(\tau_3 - \tau_1) \\ & - m_2^x(\tau_3) m_2^x(\tau_2 - \tau_1) \\ & - m_1^x [m_3^x(\tau_2 - \tau_1, \tau_3 - \tau_1) + m_3^x(\tau_2, \tau_3) + m_3^x(\tau_2, \tau_4) + m_3^x(\tau_1, \tau_2)] \\ & + (m_1^x)^2 [m_2^x(\tau_1) + m_2^x(\tau_2) + m_2^x(\tau_3) + m_2^x(\tau_3 - \tau_1) + m_2^x(\tau_3 - \tau_2) \\ & + m_1^x(\tau_2 - \tau_1)] - 6(m_1^x)^4 \end{aligned} \quad (76.7)$$

where $m_3^x(\tau_1, \tau_2)$ is the 3rd order moment sequence, and m_1^x is the mean. The general relationship between cumulants and moments can be found in [16].

Some important properties of moments and cumulants are summarized next.

[P1] If $X(k)$ is Gaussian, the $c_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = 0$ for $n > 2$. In other words, all the information about a Gaussian process is contained in its first and second-order cumulants. This property can be used to suppress Gaussian noise, or as a measure for non-Gaussianity in time series.

[P2] If $X(k)$ is symmetrically distributed, then $c_3^x(\tau_1, \tau_2) = 0$. Third-order cumulants suppress not only Gaussian processes, but also all symmetrically distributed processes, such as uniform, Laplace, and Bernoulli-Gaussian.

[P3] For cumulants additivity holds. If $X(k) = S(k) + W(k)$, where $S(k)$, $W(k)$ are stationary and statistically independent random processes, then $c_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = c_n^s(\tau_1, \tau_2, \dots, \tau_{n-1}) + c_n^w(\tau_1, \tau_2, \dots, \tau_{n-1})$. It is important to note that additivity does not hold for moments.

If $W(k)$ is Gaussian representing noise which corrupts the signal of interest, $S(k)$, then by means of (P2) and (P3), we get that $c_n^x(\tau_1, \tau_2, \dots, \tau_{n-1}) = c_n^s(\tau_1, \tau_2, \dots, \tau_{n-1})$, for $n > 2$. In other words, in higher-order cumulant domains the signal of interest propagates noise free. Property (P3) can also provide a measure of statistical dependence of two processes.

[P4] if $X(k)$ has zero mean, then $c_n^x(\tau_1, \dots, \tau_{n-1}) = m_n^x(\tau_1, \dots, \tau_{n-1})$, for $n \leq 3$.

Higher-order spectra are defined in terms of either cumulants (e.g., cumulant spectra) or moments (e.g., moment spectra).

Assuming that the n th order cumulant sequence is absolutely summable, the n th order **cumulant spectrum** of $X(k)$, $C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})$, exists, and is defined to be the $(n-1)$ -dimensional Fourier transform of the n th order cumulant sequence. In general, $C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})$ is complex, i.e., it has magnitude and phase. In an analogous manner, **moment spectrum** is the multi-dimensional Fourier transform of the moment sequence.

If $v(k)$ is a stationary non-Gaussian process with zero mean and n th order cumulant sequence

$$c_n^v(\tau_1, \dots, \tau_{n-1}) = \gamma_n^v \delta(\tau_1, \dots, \tau_{n-1}), \quad (76.8)$$

where $\delta(\cdot)$ is the delta function, $v(k)$ is said to be n th order white. Its n th order cumulant spectrum is then flat and equal to γ_n^v .

Cumulant spectra are more useful in processing random signals than moment spectra since they possess properties that the moment spectra do not share: (1) the cumulants of the sum of two independent random processes equals the sum of the cumulants of the process; (2) cumulant spectra of order > 2 are zero if the underlying process is Gaussian; (3) cumulants quantify the degree of statistical dependence of time series; and (4) cumulants of higher-order white noise are multidimensional impulses, and the corresponding cumulant spectra are flat.

76.3 HOS Computation from Real Data

The definitions of cumulants presented in the previous section are based on expectation operations, and they assume infinite length data. In practice we always deal with data of finite length; therefore, the cumulants can only be approximated. Two methods for cumulants and spectra estimation are presented next for the third-order case.

Indirect Method:

Let $X(k)$, $k = 1, \dots, N$ be the available data.

1. Segment the data into K records of M samples each. Let $X^i(k)$, $k = 1, \dots, M$, represent the i th record.
2. Subtract the mean of each record.
3. Estimate the moments of each segments $X^i(k)$ as follows:

$$m_3^{x_i}(\tau_1, \tau_2) = \frac{1}{M} \sum_{l=l_1}^{l_2} X^i(l) X^i(l + \tau_1) X^i(l + \tau_2) ,$$

$$l_1 = \max(0, -\tau_1, -\tau_2), \quad l_2 = \min(M - 1, M - 2), \\ |\tau_1| < L, \quad |\tau_2| < L, \quad i = 1, 2, \dots, K . \quad (76.9)$$

Since each segment has zero mean, its third-order moments and cumulants are identical, i.e., $c_3^{x_i}(\tau_1, \tau_2) = m_3^{x_i}(\tau_1, \tau_2)$.

4. Compute the average cumulants as:

$$\hat{c}_3^x(\tau_1, \tau_2) = \frac{1}{K} \sum_{i=1}^K m_3^{x_i}(\tau_1, \tau_2) \quad (76.10)$$

5. Obtain the third-order spectrum (bispectrum) estimate as

$$\hat{C}_3^x(\omega_1, \omega_2) = \sum_{\tau_1=-L}^L \sum_{\tau_2=-L}^L \hat{c}_3^x(\tau_1, \tau_2) e^{-j(\omega_1 \tau_1 + \omega_2 \tau_2)} w(\tau_1, \tau_2) , \quad (76.11)$$

where $L < M - 1$, and $w(\tau_1, \tau_2)$ is a two-dimensional window of bounded support, introduced to smooth out edge effects. The bandwidth of the final bispectrum estimate is $\Delta = 1/L$.

A complete description of appropriate windows that can be used in (76.11) and their properties can be found in [16]. A good choice of cumulant window is:

$$w(\tau_1, \tau_2) = d(\tau_1) d(\tau_2) d(\tau_1 - \tau_2) , \quad (76.12)$$

where

$$d(\tau) = \begin{cases} \frac{1}{\pi} |\sin \frac{\pi \tau}{L}| + (1 - \frac{|\tau|}{L}) \cos \frac{\pi \tau}{L} & |\tau| \leq L \\ 0 & |\tau| > L \end{cases} \quad (76.13)$$

which is known as the minimum bispectrum bias supremum [17].

Direct Method

Let $X(k)$, $k = 1, \dots, N$ be the available data.

1. Segment the data into K records of M samples each. Let $X^i(k)$, $k = 1, \dots, M$, represent the i th record.
2. Subtract the mean of each record.
3. Compute the Discrete Fourier Transform $F_x^i(k)$ of each segment, based on M points, i.e.,

$$F_x^i(k) = \sum_{n=0}^{M-1} X^i(n) e^{-j \frac{2\pi}{M} nk}, \quad k = 0, 1, \dots, M-1, \quad i = 1, 2, \dots, K. \quad (76.14)$$

4. The third-order spectrum of each segment is obtained as

$$C_3^{x_i}(k_1, k_2) = \frac{1}{M} F_x^i(k_1) F_x^i(k_2) F_x^{i*}(k_1 + k_2), \quad i = 1, \dots, K. \quad (76.15)$$

Due to the bispectrum symmetry properties, $C_3^{x_i}(k_1, k_2)$ need to be computed only in the triangular region $0 \leq k_2 \leq k_1$, $k_1 + k_2 < M/2$.

5. In order to reduce the variance of the estimate additional smoothing over a rectangular window of size $(M_3 \times M_3)$ can be performed around each frequency, assuming that the third-order spectrum is smooth enough, i.e.,

$$\tilde{C}_3^{x_i}(k_1, k_2) = \frac{1}{M_3^2} \sum_{n_1=-M_3/2}^{M_3/2-1} \sum_{n_2=-M_3/2}^{M_3/2-1} C_3^{x_i}(k_1 + n_1, k_2 + n_2). \quad (76.16)$$

6. Finally, the third-order spectrum is given as the average over all third-order spectra, i.e.,

$$\hat{C}_3^x(\omega_1, \omega_2) = \frac{1}{K} \sum_{i=1}^K \tilde{C}_3^{x_i}(\omega_1, \omega_2), \quad \omega_i = \frac{2\pi}{M} k_i, \quad i = 1, 2. \quad (76.17)$$

The final bandwidth of this bispectrum estimate is $\Delta = M_3/M$, which is the spacing between frequency samples in the bispectrum domain.

For large N , and as long as

$$\Delta \rightarrow 0, \text{ and } \Delta^2 N \rightarrow \infty \quad (76.18)$$

[32], both the direct and the indirect methods produce asymptotically unbiased and consistent bispectrum estimates, with real and imaginary part variances:

$$\begin{aligned} \text{var} \left(\text{Re} \left[\hat{C}_3^x(\omega_1, \omega_2) \right] \right) &= \text{var} \left(\text{Im} \left[\hat{C}_3^x(\omega_1, \omega_2) \right] \right) \\ &= \frac{1}{\Delta^2 N} C_2^x(\omega_1) C_2^x(\omega_2) C_2^x(\omega_1 + \omega_2) = \begin{cases} \frac{VL^2}{MK} C_2^x(\omega_1) C_2^x(\omega_2) C_2^x(\omega_1 + \omega_2) & \text{indirect} \\ \frac{M}{KM_3^2} C_2^x(\omega_1) C_2^x(\omega_2) C_2^x(\omega_1 + \omega_2) & \text{direct} \end{cases} \end{aligned} \quad (76.19)$$

where V is the energy of the bispectrum window.

From the above expressions, it becomes apparent that the bispectrum estimate variance can be reduced by increasing the number of records, or reducing the size of the region of support of the window in the cumulant domain (L), or increasing the size of the frequency smoothing window (M_3), etc. The relation between the parameters M , K , L , M_3 should be such that (76.18) is satisfied.

76.4 Linear Processes

Let $x(k)$ be generated by exciting a linear time-invariant (LTI) system with frequency response $H(\omega)$ with a non-Gaussian process $v(k)$. Its n th order spectrum can be written as

$$C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1}) = C_n^v(\omega_1, \omega_2, \dots, \omega_{n-1}) H(\omega_1) \cdots H(\omega_{n-1}) H^*(\omega_1 + \cdots + \omega_{n-1}) . \quad (76.20)$$

If $v(k)$ is n th order white then (76.20) becomes

$$C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1}) = \gamma_n^v H(\omega_1) \cdots H(\omega_{n-1}) H^*(\omega_1 + \cdots + \omega_{n-1}) , \quad (76.21)$$

where γ_n^v is a scalar constant and equals the n th order spectrum of $v(k)$. For a linear non-Gaussian random process $X(k)$, the n th order spectrum can be factorized as in (76.21) for every order n , while for a nonlinear process such a factorization might be valid for some orders only (it is always valid for $n = 2$).

If we express $H(\omega) = |H(\omega)| \exp\{j\phi_h(\omega)\}$, then (76.21) can be written as

$$|C_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})| = \gamma_n^v |H(\omega_1)| \cdots |H(\omega_{n-1})| |H^*(\omega_1 + \cdots + \omega_{n-1})| , \quad (76.22)$$

and

$$|\psi_n^x(\omega_1, \omega_2, \dots, \omega_{n-1})| = \phi_h(\omega_1) + \cdots + \phi_h(\omega_{n-1}) - \phi_h(\omega_1 + \cdots + \omega_{n-1}) , \quad (76.23)$$

where $\psi_n^x()$ is the phase of the n th order spectrum.

It can be shown easily that the cumulant spectra of successive orders are related as follows:

$$C_n^x(\omega_1, \omega_2, \dots, 0) = C_{n-1}^x(\omega_1, \omega_2, \dots, \omega_{n-2}) H(0) \frac{\gamma_n^v}{\gamma_{n-1}^v} . \quad (76.24)$$

As a result, the power spectrum of a Gaussian linear process can be reconstructed from the bispectrum up to a constant term, i.e.,

$$C_3^x(\omega, 0) = C_2^x(\omega) \frac{\gamma_3^v}{\gamma_2^v} . \quad (76.25)$$

To reconstruct the phase $\phi_h(\omega)$ from the bispectral phase $\psi_3^x(\omega_1, \omega_2)$ several algorithms have been suggested. A description of different phase estimation methods can be found in [14] and also in [16].

76.4.1 Nonparametric Methods

Consider $x(k)$ generated as shown in Fig. 76.2. The system transfer function can be written as

$$H(z) = cz^{-r} I(z^{-1}) O(z) = cz^{-r} \frac{\Pi_i(1 - a_i z^{-1})}{\Pi_i(1 - b_i z^{-1})} \Pi_i(1 - c_i z), \quad |a_i|, |b_i|, |c_i| < 1 , \quad (76.26)$$

where $I(z^{-1})$ and $O(z)$ are the minimum and maximum phase parts of $H(z)$, respectively; c is a constant; and r is an integer. The output n th order cumulant equals [2]

$$\begin{aligned} c_n^x(\tau_1, \dots, \tau_{n-1}) &= c_n^y(\tau_1, \dots, \tau_{n-1}) + c_n^w(\tau_1, \dots, \tau_{n-1}) \\ &= c_n^y(\tau_1, \dots, \tau_{n-1}) \end{aligned} \quad (76.27)$$

$$= \gamma_n^v \sum_{k=0}^{\infty} h(k) h(k + \tau_1) \cdots h(k + \tau_{n-1}), \quad n \geq 3 \quad (76.28)$$

FIGURE 76.2: Single channel model.

where the noise contribution in (76.27) was zero due to the Gaussianity assumption. The Z-domain equivalent of (76.28) for $n = 3$ is

$$C_3^x(z_1, z_2) = \gamma_3^v H(z_1) H(z_2) H(z_1^{-1} z_2^{-1}). \quad (76.29)$$

Taking the logarithm of $C_3^x(z_1, z_2)$ followed by an inverse 2-D Z-transform we obtain the output bicepstrum $b_x(m, n)$. The bicepstrum of linear processes is nonzero only along the axes ($m = 0, n = 0$) and the diagonal $m = n$ [21]. Along these lines the bicepstrum is equal to the complex cepstrum, i.e.,

$$b_x(m, n) = \begin{cases} \hat{h}(m) & m \neq 0, n = 0 \\ \hat{h}(n) & n \neq 0, m = 0 \\ \hat{h}(-n) & m = n, m \neq 0 \\ \ln(c\gamma_n^v) & m = n = 0, \\ 0 & \text{elsewhere} \end{cases} \quad (76.30)$$

where $\hat{h}(n)$ denotes complex cepstrum [20]. From (76.30), the system impulse response $h(k)$ can be reconstructed from $b_x(m, 0)$ (or $b_x(0, m)$, or $b_x(m, m)$), within a constant and a time delay, via inverse cepstrum operations. The minimum and maximum phase parts of $H(z)$ can be reconstructed by applying inverse cepstrum operations on $b_x(m, 0)u(m)$ and $b_x(m, 0)u(-m)$, respectively, where $u(m)$ is the unit step function.

To avoid phase unwrapping with the logarithm of the bispectrum which is complex, the bicepstrum can be estimated using the group delay approach:

$$b_x(m, n) = \frac{1}{m} F^{-1} \left\{ \frac{F[\tau_1 c_3^x(\tau_1, \tau_2)]}{C_3^x(\omega_1, \omega_2)} \right\}, \quad m \neq 0 \quad (76.31)$$

with $b_x(0, n) = b_x(n, 0)$, and $F\{\cdot\}$ and $F^{-1}\{\cdot\}$ denoting 2-D Fourier transform operator and its inverse, respectively.

The cepstrum of the system can also be computed directly from the cumulants of the system output based on the equation [21]:

$$\begin{aligned} \sum_{k=1}^{\infty} k \hat{h}(k) [c_3^x(m-k, n) - c_3^x(m+k, n+k)] + k \hat{h}(-k) [c_3^x(m-k, n-k) - c_3^x(m+k, n)] \\ = m c_3^x(m, n) \end{aligned} \quad (76.32)$$

If $H(z)$ has no zeros on the unit circle its cepstrum decays exponentially, thus (76.32) can be truncated to yield an approximate equation. An overdetermined system of truncated equations can be formed for different values of m and n , which can be solved for $\hat{h}(k)$, $k = \dots, -1, 1, \dots$. The system response $h(k)$ then can be recovered from its cepstrum via inverse cepstrum operations.

The bicepstrum approach for system reconstruction described above led to estimates with smaller bias and variance than other parametric approaches at the expense of higher computational complexity [21]. The analytic performance evaluation of the bicepstrum approach can be found in [25].

The inverse Z-transform of the logarithm of the trispectrum (fourth-order spectrum), or otherwise tricepstrum, $t_x(m, n, l)$, of linear processes is also zero everywhere except along the axes and the diagonal $m = n = l$. Along these lines it equals the complex cepstrum, thus $h(k)$ can be recovered from slices of the tricepstrum based on inverse cepstrum operations.

For the case of nonlinear processes, the bicepstrum will be nonzero everywhere [4]. The distinctly different structure of the bicepstrum corresponding to linear and nonlinear processes has led to tests of linearity [4].

A new nonparametric method has been recently proposed in [1, 26] in which the cepstrum $\hat{h}(k)$ is obtained as:

$$\hat{h}(-k) = \frac{\hat{p}_n^x(k; e^{j\beta_1}) - \hat{p}_n^x(k; e^{j\beta_2})}{e^{j(n-2)\beta_1 k} - e^{j(n-2)\beta_2 k}}, \quad k \neq 0, \quad n > 2 \quad (76.33)$$

where $p_n^x(k; e^{j\beta_i})$ is the time domain equivalent of the n th order spectrum slice defined as:

$$P_n^x(z; e^{j\beta_i}) = C_n^x(z, e^{j\beta_i}, \dots, e^{j\beta_i}). \quad (76.34)$$

The denominator of (76.33) is nonzero if

$$|\beta_1 - \beta_2| \neq \frac{2\pi l}{k(n-2)}, \quad \text{for every integer } k \text{ and } l. \quad (76.35)$$

This method reconstructs a complex system using two slices of the n th order spectrum. The slices, defined as shown above, can be selected arbitrarily as long as their distance satisfy (76.35). If the system is real, one slice is sufficient for the reconstruction. It should be noted that the cepstra appearing in (76.33) require phase unwrapping. The main advantage of this method is that the freedom to choose the higher-order spectra areas to be used in the reconstruction allows one to avoid regions dominated by noise or finite data length effects. Also, corresponding to different slice pairs various independent representations of the system can be reconstructed. Averaging out these representations can reduce estimation errors [26].

Along the lines of system reconstruction from selected HOS slices, another method has been proposed in [28, 29] where the $\log H(k)$ is obtained as a solution to a linear system of equations. Although logarithmic operation is involved, no phase unwrapping is required and the principal argument can be used instead of real phase. It was also shown that, as long as the grid size and the distance between the slices are coprime, reconstruction is always possible.

76.4.2 Parametric Methods

One of the popular approaches in system identification has been the construction of a white noise driven, linear time invariant model from a given process realization.

Consider the real autoregressive moving average (ARMA) stable process $y(k)$ given by:

$$\sum_{i=0}^p a(i)y(k-i) = \sum_{j=0}^q b(j)v(k-j) \quad (76.36)$$

$$x(k) = y(k) + w(k) \quad (76.37)$$

where $a(i)$, $b(j)$ represent the AR and MA parameters of the system, $v(k)$ is an independent identically distributed random process, and $w(k)$ represents zero-mean Gaussian noise.

Equations analogous to the Yule-Walker equations can be derived based on third-order cumulants of $x(k)$, i.e.,

$$\sum_{i=0}^p a(i)c_3^x(\tau - i, j) = 0, \quad \tau > q, \quad (76.38)$$

or

$$\sum_{i=1}^p a(i)c_3^x(\tau - i, j) = -c_3^x(\tau, j), \quad \tau > q, \quad (76.39)$$

where it was assumed $a(0) = 1$. Concatenating (76.39) for $\tau = q + 1, \dots, q + M$, $M \geq 0$ and $j = q - p, \dots, q$, the matrix equation

$$\underline{C}a = \underline{c} \quad (76.40)$$

can be formed, where \underline{C} and \underline{c} are a matrix and a vector, respectively, formed by third-order cumulants of the process according to (76.39), and the vector \underline{a} contains the AR parameters. If the AR order p is unknown and (76.40) is formed based on an overestimate of p , the resulting matrix \underline{C} always has rank p . In this case, the AR parameters can be obtained using a low-rank approximation of \underline{C} [5].

Using the estimated AR parameters, $\hat{a}(i)$, $i = 1, \dots, p$, a p th order filter with transfer function $\hat{A}(z) = 1 + \sum_{i=1}^p \hat{a}(i)z^{-1}$ can be constructed. Based on the filtered through $\hat{A}(z)$ process $x(k)$, i.e., $\tilde{x}(k)$, or otherwise known as the residual time series [5], the MA parameters can be estimated via any MA method [15], for example:

$$b(k) = \frac{c_3^{\tilde{x}}(q, k)}{c_3^{\tilde{x}}(q, 0)}, \quad k = 0, 1, \dots, q \quad (76.41)$$

known as the $c(q, k)$ formula [6].

Practical problems associated with the described approach are sensitivity to model order mismatch, and AR estimation errors that propagate in the estimation of the MA parameters. A significant amount of research has been devoted to the ARMA parameter estimation problem. A thorough review of existing ARMA system identification methods can be found in [15, 16]; a more recent method can be found in [24].

76.5 Nonlinear Processes

Despite the fact that progress has been established in developing the theoretical properties of nonlinear models, only a few statistical methods exist for detection and characterization of nonlinearities from a finite set of observations. In this section, we will consider nonlinear Volterra systems excited by Gaussian stationary inputs. Let $y(k)$ be the response of a discrete time invariant p th order Volterra filter whose input is $x(k)$. Then,

$$y(k) = h_0 + \sum_i \sum_{\tau_1, \dots, \tau_i} h_i(\tau_1, \dots, \tau_i) x(k - \tau_1) \cdots x(k - \tau_i), \quad (76.42)$$

where $h_i(\tau_1, \dots, \tau_i)$ are the Volterra kernels of the system, which are symmetric functions of their arguments; for causal systems $h_i(\tau_1, \dots, \tau_i) = 0$ for any $\tau_i < 0$.

The output of a second-order Volterra system when the input is zero-mean stationary is

$$y(k) = h_0 + \sum_{\tau_1} h_1(\tau_1)x(k - \tau_1) + \sum_{\tau_1} \sum_{\tau_2} h_2(\tau_1, \tau_2)x(k - \tau_1)x(k - \tau_2). \quad (76.43)$$

Equation (76.43) can be viewed as a parallel connection of a linear system $h_1(\tau_1)$ and a quadratic system $h_2(\tau_1, \tau_2)$ as illustrated in Fig. 76.3. Let

$$c_2^{xy}(\tau) = E \{x(k + \tau) [y(k) - m_1^y]\} \quad (76.44)$$

be the cross-covariance of input and output, and

$$c_3^{xxy}(\tau_1, \tau_2) = E \{x(k + \tau_1) x(k + \tau_2) [y(k) - m_1^y]\} \quad (76.45)$$

be the third-order cross-cumulant sequence of input and output.

FIGURE 76.3: Second-order Volterra system. Linear and quadratic parts are connected in parallel.

It can be shown that the system's linear part can be identified by

$$H_1(-\omega) = \frac{C_2^{xy}(\omega)}{C_2^x(\omega)}, \quad (76.46)$$

and the quadratic part by

$$H_2(-\omega_1, -\omega_2) = \frac{C_3^{xxy}(\omega_1, \omega_2)}{2C_2^x(\omega_1) C_2^x(\omega_2)}, \quad (76.47)$$

where $C_2^{xy}(\omega)$ and $C_3^{xxy}(\omega_1, \omega_2)$ are the Fourier transforms of $c_2^{xy}(\tau)$ and $c_3^{xxy}(\tau_1, \tau_2)$, respectively. It should be noted that the above equations are valid only for Gaussian input signals. More general results assuming non-Gaussian input have been obtained in [9, 27]. Additional results on particular nonlinear systems have been reported in [3, 33].

An interesting phenomenon caused by a second-order nonlinearity is the quadratic phase coupling. There are situations where nonlinear interaction between two harmonic components of a process contribute to the power of the sum and/or difference frequencies. The signal

$$x(k) = A \cos(\lambda_1 k + \theta_1) + B \cos(\lambda_2 k + \theta_2) \quad (76.48)$$

after passing through the quadratic system:

$$z(k) = x(k) + \epsilon x^2(k), \quad \epsilon \neq 0. \quad (76.49)$$

contains cosinusoidal terms in (λ_1, θ_1) , (λ_2, θ_2) , $(2\lambda_1, 2\theta_1)$, $(2\lambda_2, 2\theta_2)$, $(\lambda_1 + \lambda_2, \theta_1 + \theta_2)$, $(\lambda_1 - \lambda_2, \theta_1 - \theta_2)$. Such a phenomenon that results in phase relations that are the same as the frequency relations is called quadratic phase coupling [12]. Quadratic phase coupling can arise only among harmonically related components. Three frequencies are harmonically related when one of them is the sum or difference of the other two. Sometimes it is important to find out if peaks at harmonically related positions in the power spectrum are in fact phase coupled. Due to phase suppression, the power spectrum is unable to provide an answer to this problem.

As an example, consider the process [30]

$$X(k) = \sum_{i=1}^6 \cos(\lambda_i k + \phi_i) \quad (76.50)$$

where $\lambda_1 > \lambda_2 > 0$, $\lambda_4 + \lambda_5 > 0$, $\lambda_3 = \lambda_1 + \lambda_2$, $\lambda_6 = \lambda_4 + \lambda_5$, ϕ_1, \dots, ϕ_5 are all independent, uniformly distributed random variables over $(0, 2\pi)$, and $\phi_6 = \phi_4 + \phi_5$. Among the six frequencies, $(\lambda_1, \lambda_2, \lambda_3)$ and $(\lambda_4, \lambda_5, \lambda_6)$ are harmonically related, however, only λ_6 is the result of phase coupling between λ_4 and λ_5 . The power spectrum of this process consists of six impulses at λ_i , $i = 1, \dots, 6$ (see Fig. 76.4), offering no indication whether each frequency component is independent or result of frequency coupling. On the other hand, the bispectrum of $X(k)$, $C_3^x(\omega_1, \omega_2)$ (evaluate in its principal region) is zero everywhere, except at point (λ_4, λ_5) of the (ω_1, ω_2) plane, where it exhibits an impulse (Fig. 76.4(b)). The peak indicates that only λ_4, λ_5 are phase coupled.

The bicoherence index, defined as

$$P_3^x(\omega_1, \omega_2) = \frac{C_3^x(\omega_1, \omega_2)}{\sqrt{C_2^x(\omega_1) C_2^x(\omega_2) C_2^x(\omega_1 + \omega_2)}}, \quad (76.51)$$

has been extensively used in practical situations for the detection and quantification of quadratic phase coupling [12]. The value of the bicoherence index at each frequency pair indicates the degree of coupling among the frequencies of that pair. Almost all bispectral estimators can be used in (76.51). However, estimates obtained based on parametric modeling of the bispectrum have been shown to yield superior resolution [30, 31] than the ones obtained with conventional methods.

76.6 Applications/Software Available

Applications of HOS span a wide range of areas [19] such as oceanography (description of wave phenomena), earth sciences (atmospheric pressure, turbulence), crystallography, plasma physics (wave interaction, nonlinear phenomena), mechanical systems (vibration analysis, knock detection), economic time series, biomedical signal analysis (ultrasonic imaging, detection of wave coupling) image processing (texture modeling and characterization, reconstruction, inverse filtering), speech processing (pitch detection, voiced/unvoiced decision), communications (equalization, interference cancellation), array processing (direction of arrival estimation, estimation of number of sources, beamforming, source signal estimation, source classification), harmonic retrieval (frequency estimation), and time delay estimation. Over 500 references can be found in [37]. Additional references can be found in [16, 19, 23].

A software package for signal processing with HOS is the Hi-Spec toolbox, product of Mathworks, Inc. The functions included in Hi-Spec together with a short description are included in Table 76.1.

Acknowledgments

Most of the material presented in this chapter is based on the book *Higher-Order Spectra Analysis: A Non-Linear Signal Processing Framework* [16]. The author wishes to thank Dr. C.L. Nikias for his

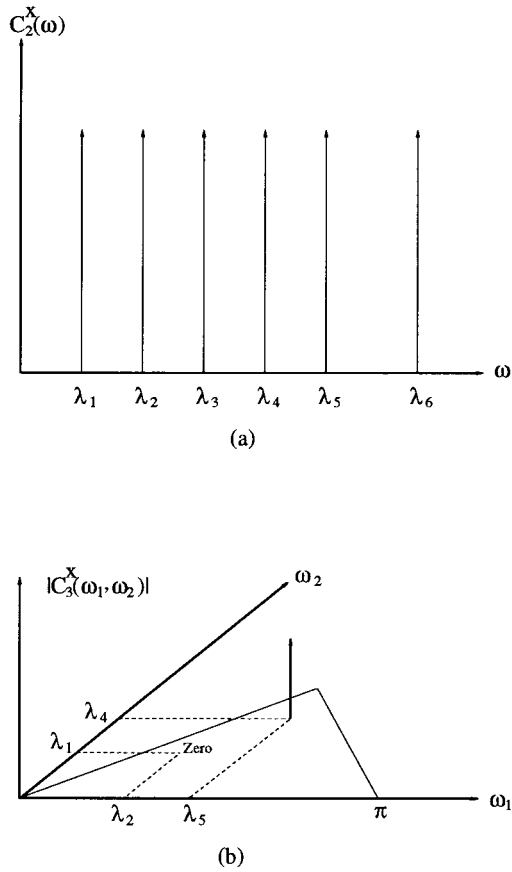

FIGURE 76.4: Quadratic phase coupling. (a) The power spectrum of the process described in Eq. (76.50) cannot determine what frequencies are coupled. (b) The corresponding magnitude bispectrum is zero everywhere in the principle region, except at points corresponding to phase coupled frequencies.

valuable input on the organization of the material. She also thanks U.R. Abeyratne for producing the figures in this chapter. Support for this work came from NSF under grant MIP-9553227 and the Whitaker Foundation.

TABLE 76.1 Functions Included in the Hi-Spec Package

Function name	Description
AR_RCEST	AR parameter estimation based on cumulants
ARMA_QS	ARMA parameter estimation via the Q-slice algorithm
ARMA_RTS	ARMA parameter estimation via the residual time series method
ARMA_SYN	Generates ARMA synthetics
BICEPS	System identification via the bicepstrum approach
BISPEC_D	Bispectrum estimation via the direct method
BISPEC_I	Bispectrum estimation via the indirect method
CUM_EST	Estimates 2nd, 3rd, or 4th order cumulants
CUM_TRUE	Computes the theoretical cumulants of an ARMA model
DOA	Direction-of-arrival estimation
DOA_GEN	Generates synthetics for direction-of-arrival estimation
GL_STAT	Detection statistics for Hinich's Gaussianity and linearity tests
HARM_EST	Estimates frequencies of harmonics in colored noise
HARM_GEN	Generates synthetics for the harmonic retrieval problem
MA_EST	MA parameters estimation
MATUL	System identification via the Matsuoka-Ulrych algorithm
QPC_GEN	Simulation generator for quadratic phase coupling
QPC_TOR	Detects quadratic phase coupling via parametric modeling of bispectrum
RP_ID	Generates samples of an i.i.d. random process
TDE	Estimates time delay between two signals using the parametric cross-cumulant method
TDE_GEN	Synthetics for time delay estimation

THE PRIMARY TRAITS OF EMBEDDED signal processing systems that distinguish them from general purpose computer systems are their *predictable* reactions to *real-time*¹ stimuli from the environment, their *form-* and *cost-*optimized design, and their compliance with *required* or *specified* modes of response behavior and functionality [1].

¹Real-time indicates behavior related to wall-clock time and does not necessarily imply a quick response.

Other traits that they share with other forms of digital products include the need for reliability, fault-tolerance, and maintainability, to name just a few. An embedded system usually consists of hardware components such as memories, application-specific ICs (ASICs), processors, DSPs, buses, analog-digital interfaces, and also software components that provide control, diagnostic, and application-specific capabilities required of it. In addition, they often contain electromechanical (EM) components such as sensors and transducers and operate in harsh environmental conditions. Unlike general purpose computers they may not allow much flexibility in support of a diverse range of programming applications, and it is not unusual to dedicate such systems to specific application. Embedded systems, thus, range from simple, low-cost sensor/actuator systems consisting of a few tens of lines of code and 8/16-bit processors (CPU) (e.g., bank ATM machines) to sophisticated high-performance signal processing systems consisting of runtime operating system support, tens of x86-class processors, digital signal processing (DSP) chips, interconnection networks, complex sensors, and other interfaces (e.g., radar-based tracking and navigational systems). Their lack of flexibility may be apparent when one considers that an ATM machine cannot be easily programmed to support additional image processing tasks, unless *upgraded* in terms of resources. Finally, embedded systems typically do not support direct *user* interaction in terms of higher order programming languages (HOLs) such as Fortran or C, but allow users to provide inputs that are sensor- or menu-driven. The debug and diagnostic interfaces, however, support HOLs and other lower level software and hardware programmability.

Embedded systems in general may be classified into one of the following four general categories of products. The prices are indicative of the multi-billion dollar marketplace in 1996, and their relative magnitudes are more significant than their actual values. The relationship of the categories to dollar cost is intentional and is an early harbinger of the fact that underlying cost and performance tradeoffs motivate and drive most of the system design and prototyping methodologies.

Commodity DSP Products: High-volume market and valued at less than \$ 300 a piece. These include CD players, recorders, VCRs, facsimile and answering machines, telemetry applications, simple signal processing filtering packages, etc., primarily aimed at the highly competitive mass-volume consumer market.

Portable DSP Products: High-volume market and valued at less than \$ 800. These include portable and hand-held low-power electronic products for man-machine communications such as DSP boards, digital audio, security systems, modems, camcorders, industrial controllers, scanners, communications equipment, and others.

Cost-Performance DSP Products: High-volume market, and valued at less than \$ 3000. These products trade off cost for performance, and include DSP products such as video teleconferencing equipment, laptops, audio, telecommunications switches, high-performance DSP boards and coprocessors, and DSP CAD packages for hardware and software design.

High-Performance Products: Low-to-moderate volume market, and valued at over \$8000. These products include high-end workstations with DSP coprocessors, real-time signal processors, real-time database processing systems, digital HDTV, radar signal processor systems, avionics and military systems, sensor and data processing hardware and software systems. This class of products contains a significant amount of software compared to the earlier classes, which often focus on large volume, low-cost, hardware-only solutions.

It may be useful to classify high-performance products further into three categories.

- *Real-time embedded control systems:* These systems are characterized by the following features: interrupt driven, large numerical processing requirements, small databases, tight real-time constraints, well-defined user interface, requirements and design driven by performance requirements. Examples include an aircraft control system, or a control system for a steel plant.
- *Embedded information systems:* These systems are characterized by the following features: transaction-based, moderate numerical/DSP processing, flexible time constraints, complex

user interfaces, requirements and design driven by user interface. Examples include accounting and inventory management systems.

- *Command, control, communication, and intelligence (C4I) systems*: These systems are characterized by large numerical processing, large databases, moderate to tight real-time constraints, flexible and complex user interfaces, requirements and design driven by performance and user interface. Examples include missile guidance systems, radar-tracking systems, and inventory and manufacturing control systems.

These four categories of embedded systems can be further distinguished in terms of other metrics such as computing speed (integer or floating point performance), input/output transfer rates, memory capacities, market volume, environmental issues, typical design and development budgets, lifetimes, reliability issues, upgrades, and other lifecycle support costs. Another interesting fact is that the higher the software value in a product, the greater its profitability margin. Recent studies by Andersen Consulting have shown that profit margin pressures are increasing due to increasing semiconductor content in systems' sales' values. In 1985, silicon represented 9.5 percent of a system's value. By 1995, that had shot up to 19.1 percent. The higher the silicon content, the greater the pressure on margins resulting in lower profits. In PCs, integrated circuit components represent 30 to 35 percent of the sales value and the ratio is steadily increasing. More than 50 percent of value of the new network computers (NCs) is expected to be in integrated circuits. In the area of DSPs, we estimate that this ratio is about 20 percent.

In this section, the chapter "Introduction to the TMS320 Family of Digital Signal Processors" by Panos Papamichalis, outlines the programmable DSP families developed by Texas Instruments, the leading organization in this area. In, "Rapid Design and Prototyping of DSP Systems", T. Egolf, M. Pettigrew, J. Debardeleben, R. Hezar, S. Famorzadeh, A. Kavipurapu, M. Khan, L.-R. Dung, K. Balemorthy, N. Desai, Y. Jung, and V. Madisetti, discuss how signal processing systems are designed and integrated using a novel top down design approach developed as part of DARPA's RASSP program.

This article discusses the architecture and the hardware characteristics of the TMS320 family of Digital Signal Processors. The TMS320 family includes several generations of programmable processors with several devices in each generation. Since the programmable processors are split between fixed-point and floating-point devices, both categories are examined in some detail. The TMS320C25 serves here as a simple example for the fixed-point processor family, while the TMS320C30 is used for the floating-point family.

77.1 Introduction

Since its introduction in 1982 with the TMS32010 processor, the TMS320 family of DSPs has been exceedingly popular. Different members of this family were introduced to address the existing needs for real-time processing, but then, designers capitalized on the features of the devices to create solutions and products in ways never imagined before. In turn, these innovations fed the architectural and hardware configurations of newer generations of devices.

Digital Signal Processing encompasses a variety of applications, such as digital filtering, speech and audio processing, image and video processing, and control. All DSP applications share some

common characteristics:

- The algorithms used are mathematically intensive. A typical example is the computation of an FIR filter, implemented as sum-of-products. This operation involves a lot of multiplications combined with additions.
- DSP algorithms must typically run in real time: i.e., the processing of a segment of the arriving signal must be completed before the next segment arrives, or else data will be lost.
- DSP techniques are under constant development. This implies that DSP systems should be flexible to support changes and improvements in the state of the art. As a result, programmable processors have been the preferred way of implementation. In recent times, though, fixed-function devices have also been introduced to address high-volume consumer applications with low-cost requirements.

These needs are addressed in the TMS320 family of DSPs by using appropriate architecture, instruction sets, I/O capabilities, as well as the raw speed of the devices. However, it should be kept in mind that these features do not cover all the aspects describing a DSP device, and especially a programmable one. Availability and quality of software and hardware development tools (such as compilers, assemblers, linker, simulators, hardware emulators, and development systems), application notes, third-party products and support, hot-line support, etc. play an important role on how easy it will be to develop an application on the DSP processor. The TMS320 family has very extensive such support, but its description goes beyond the scope of this article. The interested reader should contact the TI DSP hotline (Tel. 713-274-2320).

For the purposes of this article, two devices have been selected to be highlighted from the Texas Instruments TMS320 family of digital signal processors. One is the TMS320C25, a 16-bit, fixed-point DSP, and the other is the TMS320C30, a 32-bit, floating-point DSP. As a short-hand notation, they will be called 'C25 and 'C30, respectively. The choice was made so that both fixed-point issues are considered.

There have been newer (and more sophisticated) generations added to the TMS320 family but, since the objective of this article is to be more tutorial, they will be discussed as extensions of the 'C25 and the 'C30. Such examples are other members of the 'C2x and the 'C3x generations, as well as the TMS320C5x generation ('C5x for short) of fixed-point devices, and the TMS320C4x ('C4x) of floating-point devices. Customizable and fixed-function extensions of this family of processors will be also discussed.

Texas Instruments, like all vendors of DSP devices, publishes detailed User's Guides that explain at great length the features and the operation of the devices. Each of these User's Guides is a pretty thick book, so it is not possible (or desirable) to repeat all this information here. Instead, the objective of this article is to give an overview of the basic features for each device. If more detail is necessary for an application, the reader is expected to refer to the User's Guides. If the User's Guides are needed, it is very easy to obtain them from Texas Instruments.

77.2 Fixed-Point Devices: TMS320C25 Architecture and Fundamental Features

The Texas Instruments TMS320C25 is a fast, 16-bit, fixed-point digital signal processor. The speed of the device is 10 MHz, which corresponds to a cycle time of 100 ns. Since the majority of the instructions execute in a single cycle, the figure of 100 ns also indicates how long it takes to execute one instruction. Alternatively, we can say that the device can execute 10 million instructions per second (MIPS). The actual signal from the external oscillator or crystal has a frequency four times higher, at 40 MHz. This frequency is then divided on-chip to generate the internal clock with a

period of 100 ns. Figure 77.1 shows the relationship between the input clock CLKIN from the external oscillator, and the output clock CLKOUT. CLKOUT is the same as the clock of the device, and it is related to CLKIN by the equation $\text{CLKOUT} = \text{CLKIN} / 4$. Note that in Fig. 77.1 the shape of the signal is idealized ignoring rise and fall times.

FIGURE 77.1: Clock timing of the TMS320C25. CLKIN = external oscillator; CLKOUT = clock of the device.

Newer versions of the TMS320C25 operate in higher frequencies. For instance, there is a spinoff that has a cycle time of 80 ns, resulting in a 12.5 MIPS operation. There are also slower (and cheaper) versions for applications that do not need this computational power.

Figure 77.2 shows in a simplified form the key features of the TMS320C25. The major parts of the DSP processor are the memory, the Central Processing Unit (CPU), the ports, and the peripherals. Each of these parts will be examined in more detail later. The on-chip memory consists of 544 words of RAM (read/write memory) and 4K words of ROM (read-only memory). In the notation used here, 1K = 1024 words, and 4K = $4 \times 1024 = 4096$ words. Each word is 16 bits wide and, when some memory size is given, it is measured in 16-bit words, and not in bytes (as is the custom in microprocessors). Of the 544 words of RAM, 256 words can be used as either program or data memory, while the rest is only data memory. All 4K of on-chip ROM is program memory. Overall, the device can address 64K words of data memory and 64K words of program memory. Except for what resides on-chip, the rest of the memory is external, supplied by the designer.

The CPU is the heart of the processor. Its most important feature, distinguishing it from the traditional microprocessors, is a hardware multiplier that is capable of performing a 16×16 bit multiplication in a single cycle. To preserve higher intermediate accuracy of results, the full 32-bit product is saved in a product register. The other important part of the CPU is the Arithmetic Logic Unit (ALU) that performs additions, subtractions, and logical operations. Again, for increased intermediate accuracy, there is a 32-bit accumulator to handle all the ALU operations.

All the arithmetic and logical functions are accumulator-based. In other words, these operations have two operands, one of which is always the accumulator. The result of the operation is stored in the accumulator.

Because of this approach the form of the instructions is very simple indicating only what the other operand is. This architectural philosophy is very popular but it is not universal. For instance, as is discussed later, the TMS320C30 takes a different approach, where there are several “accumulators” in what is called a register file.

Other components of the TMS320C25 CPU are several shifters to facilitate manipulation of the data and increase the throughput of the device by performing shifting operations in parallel with other functions. As part of the CPU, there are also eight auxiliary registers that can be used as memory pointers or loop counters. There are two status registers, and an 8-deep hardware stack. The stack

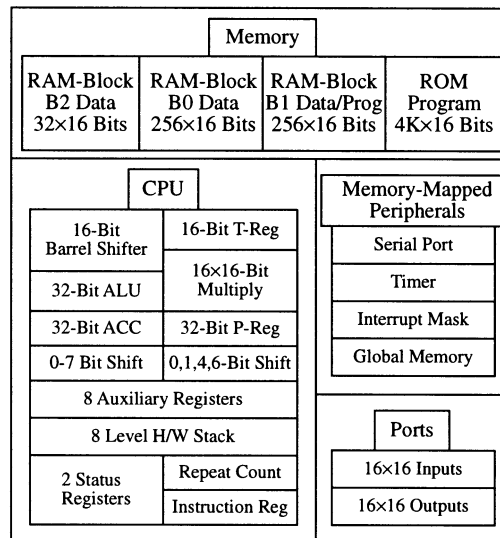

FIGURE 77.2: Key architectural features of the TMS320C25.

is used to store the memory address where the program will continue execution after a temporary diversion to a subroutine.

To communicate with external devices, the TMS320C25 has 16 input and 16 output parallel ports. It also has a serial port that can serve the same purpose. The serial port is one of the peripherals that have been implemented on chip. Other peripherals include the interrupt mask, the global memory capability, and a timer. The above components of the TMS320C25 are examined in more detail below.

The device has 68 pins that are designated to perform certain functions, and to communicate with other devices on the same board. The names of the signals and the corresponding definitions appear in Table 77.1. The first column of the table gives the pin names. Note that a bar over the name indicates that the pin is in the active position when it is electrically low. For instance, if the pins take the voltage levels of 0 V and 5 V, a pin indicated with an overbar is asserted when it is set at 0 V. Otherwise, assertion occurs at 5 V. The second column indicates if the pin is used for input to the device or output from the device or both. The third column gives a description of the pin functionality.

Understanding the functionality of the device pins is as important as understanding the internal architecture because it provides the designer with the tools available to communicate with the external world. The DSP device needs to receive data and, often, instructions from the external sources, and send the results back to the external world. Depending on the paths available for such transactions, the design of a program can take very different forms. Within this framework, it is up to the designer to generate implementations that are ingenious and elegant.

The TMS320C25 has its own assembly language to be programmed. This assembly language consists of 133 instructions that perform general-purpose and DSP-specific functions. Familiarity with the instruction set and the device architecture are the two components of efficient program implementation. High-level-language compilers have also been developed that make the writing of programs an easier task. For the TMS320C25, there is a C compiler available. However, there is always a loss of efficiency when programming in high-level languages, and this may not be acceptable in computation-bound real-time systems. Besides, for complete understanding of the device it is necessary to consider the assembly language.

TABLE 77.1 Names and Functionality of the 68 pins of the TMS320C25

Signals	I/O/Z ^a	Definition
V_{CC}	I	5-V supply pins
V_{SS}	I	Ground pins
X1	O	Output from internal oscillator for crystal
X2/CLKIN	I	Input to internal oscillator from crystal or external clock
CLKOUT1	O	Master clock output (crystal or CLKIN frequency/4)
CLKOUT2	O	A second clock output signal
D15-D0	I/O/Z	16-bit data bus D15 (MSB) through D0 (LSB). Multiplexed between program, data, and I/O spaces.
A15-A0	O/Z	16-bit address bus A15 (MSB) through A0 (LSB)
$\overline{P\overline{S}}$, $\overline{D\overline{S}}$, $\overline{I\overline{S}}$	O/Z	Program, data, and I/O space select signals
$\overline{R\overline{W}}$	O/Z	Read/write signal
$\overline{S\overline{T\overline{R\overline{B}}}}$	O/Z	Strobe signal
$\overline{R\overline{S}}$	I	Reset input
$\overline{I\overline{N\overline{T\overline{2}}}}$ - $\overline{I\overline{N\overline{T\overline{0}}}}$	I	External user interrupt inputs
$\overline{M\overline{P\overline{M\overline{C}}}}$	I	Microprocessor/microcomputer mode select pin
$\overline{M\overline{S\overline{C}}}$	O	Microstate complete signal
$\overline{I\overline{A\overline{C\overline{K}}}}$	O	Interrupt acknowledge signal
READY	I	Data ready input. Asserted by external logic when using slower devices to indicate that the current bus transaction is complete.
$\overline{B\overline{R}}$	O	Bus request signal. Asserted when the TMS320C25 requires access to an external global data memory space.
XF	O	External flag output (latched software-programmable signal)
$\overline{H\overline{O\overline{L\overline{D}}}}$	I	Hold input. When asserted, TMS320C25 goes into an idle mode and places the data, address, and control lines in the high impedance state.
$\overline{H\overline{O\overline{L\overline{D\overline{A}}}}}$	O	Hold acknowledge signal.
$\overline{S\overline{Y\overline{N\overline{C}}}}$	I	Synchronization input.
$\overline{B\overline{I\overline{O}}}$	I	Branch control input. Polled by BIOZ instruction
DR	I	Serial data receive input
CLKR	I	Clock for receive input for serial port
FSR	I	Frame synchronization pulse for receive input
DX	O/Z	Serial data transmit output
CLKX	I	Clock for transmit output for serial port
FSX	I/O/Z	Frame synchronization pulse for transmit. Configurable as either an input or an output.

^a I/O/Z denotes input/output/high-impedance state.

Note: The first column is the pin name; the second column indicates if it is an input or an output pin; the third column gives a description of the pin functionality.

A very important characteristic of the device is its Harvard architecture. In Harvard architecture (see Fig. 77.3), the program and data memory spaces are separated and they are accessed by different buses. One bus accesses the program memory space to fetch the instructions, while another bus is used to bring operands from the data memory space and store the results back to memory. The objective of this approach is to increase the throughput by bringing instructions and data in parallel. An alternate philosophy is the von Neuman architecture. The von Neuman architecture (see Fig. 77.4) uses a single bus and a unified memory space. Unification of the memory space is convenient for partitioning it between program and data, but it presents a bottleneck since both data and program instructions must use the same path and, hence, they must be multiplexed. The Harvard architecture of multiple buses is used in digital signal processors because the increased throughput is of paramount importance in real-time systems.

The difference of the architectures is important because it influences the programming style. In Harvard architecture, two memory locations can have the same address, as long as one of them is in the data space and the other is in the program space. Hence, when the programmer uses an address label, he has to be alert as to what space he is referring. Another restriction of the Harvard architecture is that the data memory cannot be initialized during loading because loading refers only to placing the program on the memory (and the program memory is separate from the data memory). Data memory can be initialized during execution only. The programmer must incorporate such initialization in his program code. As it will be seen later, such restrictions have been removed from the TMS320C30 while retaining the convenient feature of multiple buses.

Figure 77.5 shows a functional block diagram of the TMS320C25 architecture. The Harvard

FIGURE 77.3: Simplified block diagram of the Harvard architecture.

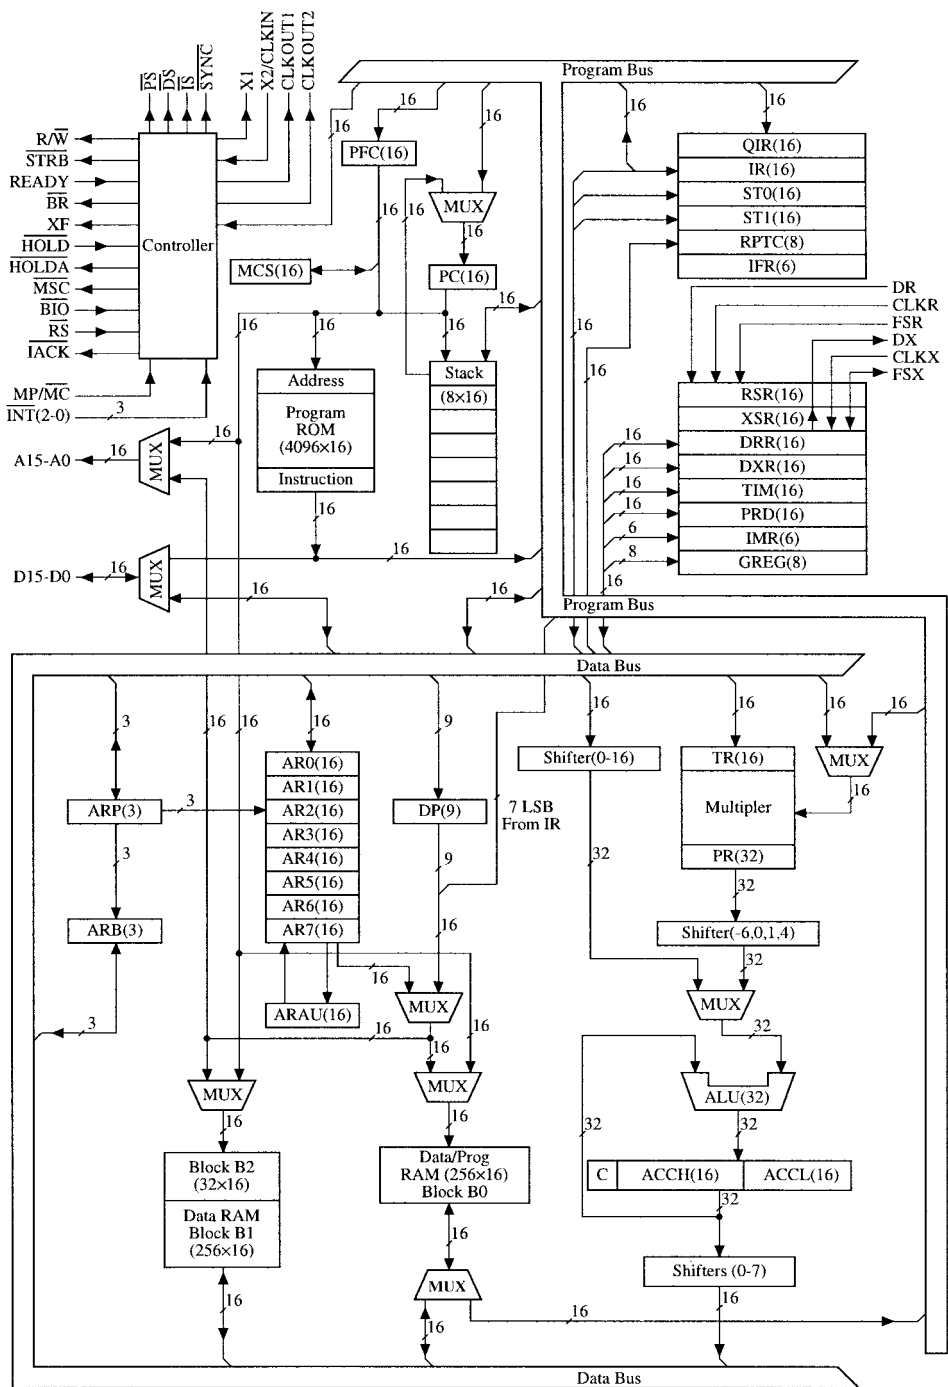

FIGURE 77.4: Simplified block diagram of the von Neuman architecture.

architecture of the device is immediately apparent from the separate program and data buses. What is not apparent is that the architecture has been modified to permit communication between the two buses. Through such communication, it is possible to transfer data between the program and memory spaces. Then, the program memory space also can be used to store tables. The transfer takes place by using special instructions such as TBLR (Table Read), TBLW (Table Write), and BLKP (Block transfer from Program memory).

As shown in the block diagram, the program ROM is linked to the program bus, while data RAM blocks B1 and B2 are linked to the data bus. The RAM block B0 can be configured either as program or data memory (using the instructions CNFP and CNFD), and it is multiplexed with both buses. The different segments, such as the multiplier, the ALU, the memories, etc. are examined in more detail below.

77.3 TMS320C25 Memory Organization and Access

Besides the on-chip memory (RAM and ROM), the TMS320C25 can access external memory through the external bus. This bus consists of the 16 address pins A0-A15, and the 16 data pins D0-D15. The address pins carry the address to be accessed, while the data pins carry the instruction word or the operand, depending on whether program or data memory is accessed. The bus can access either program or data memory, the difference indicated by which of the pins PS and DS (with overbars) becomes active. The activation is done automatically when, during the execution, an instruction or a piece of data needs to be fetched. Since the address is 16-bits wide, the maximum memory space

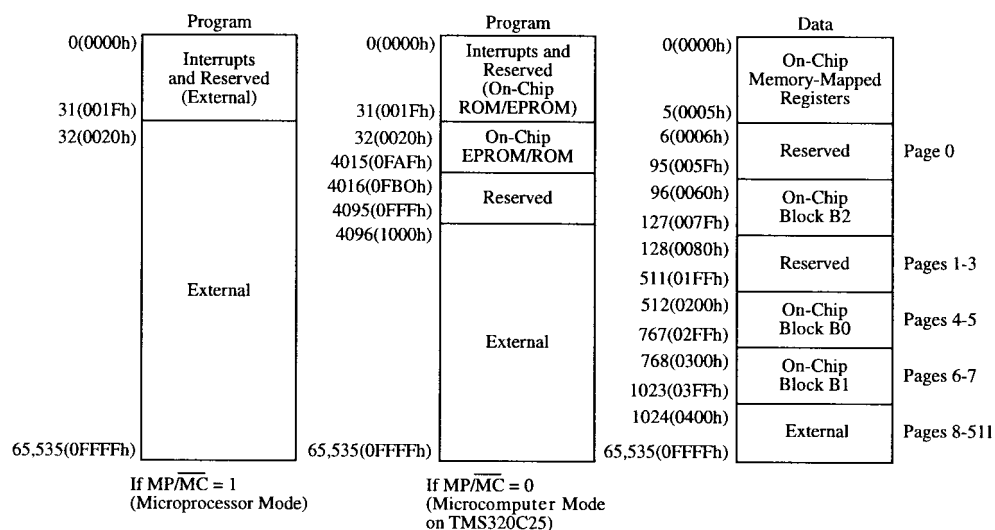

FIGURE 77.6: Memory maps for program and data memory of the TMS320C25.

is 64K words for program and 64K words for data.

The device starts execution after a reset signal, i.e., after the RS pin is pulled low for a short period of time. The execution always begins at program memory location 0, where there should be an instruction to direct the program execution to the appropriate location. This direction is accomplished by a branch instruction.

B PROG

which loads the program counter with the program memory address that has the label PROG (or any other label you choose). Then, execution continues from the address PROG, where, presumably, a useful program has been placed.

It is clear that the program memory location 0 is very important, and you need to know where it is physically located. The TMS320C25 gives you the flexibility to use as location 0 either the first location of the on-chip ROM, or the first location of the external memory. In the first case, we say that the device operates in the microcomputer mode, while in the second one it is in the microprocessor mode. In the microprocessor mode, the on-chip ROM is ignored altogether. You can choose between the two modes by pulling the device MP/MC high or low. The microcomputer mode is useful for production purposes, while for laboratory and development work the microprocessor mode is used exclusively.

Figure 77.6 shows the memory configuration of the TMS320C25, where the microprocessor and microcomputer configurations of the program memory are depicted separately. The data memory is partitioned in 512 sections, called pages, of 128 words each. The reason of the partitioning is for addressing purposes, as will be discussed below. Memory boundaries of the 64K memory space are shown in both decimal and hexadecimal notation (hexadecimal notation indicated by an "h" or "H" at the end.) Compare this map with the block diagram in Fig. 77.5.

As mentioned earlier, in two-operand operations, one of the operands resides in the accumulator, and the result is also placed in the accumulator. (The only exceptions is the multiplication operation examined later.) The other operand can either reside in memory or be part of the instruction. In the latter case, the value to be combined with the accumulator is explicitly specified in the instruction, and this addressing mode is called immediate addressing mode. In the TMS320C25 assembly language, the immediate addressing mode instructions are indicated by a "K" at the end of the instruction.

For example, the instruction

ADDK 5

increments the contents of the accumulator by 5.

If the value to be operated upon resides in memory, there are two ways to access it: either by specifying the memory address directly (direct addressing) or by using a register that holds the address of that number (indirect addressing).

As a general rule, it is desirable to describe an instruction as briefly as possible so that the whole description can be held in one 16-bit word. Then, when the program is executed, only one word needs to be fetched before all the information from the instruction is available for execution. This is not always possible and there are two-word instructions as well, but the chip architects always strive to achieve one-word instructions. In the direct addressing mode, full description of a memory address would require a 16-bit word by itself because the memory space is 64K words. To reduce that requirement, the memory space is divided in 512 pages of 128 words each. An instruction using direct addressing contains the 7 bits indicating what word you want to access within a page. The page number (9 bits) is stored in a separate register (actually, part of a register), called the Data Page pointer (DP). You store the page number in the DP pointer by using the instructions LDP (Load Data Page pointer) or LDPK (Load Data Page pointer immediate).

In the indirect addressing mode, the data memory address is held in a register that acts as a memory pointer. There are eight such registers available, called auxiliary registers, AR0-AR7. The auxiliary registers can also be used for other functions, such as loop counters, etc. To save bits in the instruction, the auxiliary register used as memory pointer is not indicated explicitly, but it is stored in a separate register (actually, part of a register), the auxiliary register pointer (ARP). In other words, there is the concept of the “current register”. In an operation using indirect addressing, the contents of the current auxiliary register point to the desired memory location. The current AR is specified by the contents of the ARP as shown in Fig. 77.7. In an instruction, indirect addressing is indicated by an asterisk.

FIGURE 77.7: Example of indirect addressing mode.

A “+” sign at the end of an instruction using indirect addressing means “after the present memory access, increment the contents of the current auxiliary register by 1”. This is done in parallel with the load-accumulator operation. The above autoincrementing of the auxiliary register is an optional operation that offers additional flexibility to the programmer. And it is not the only one available. The TMS320C25 has an auxiliary register arithmetic unit (ARAU, see Fig. 77.5) that can execute

such operations in parallel with the CPU, and increase the throughput of the device in this way. Table 77.2 summarizes the different operations that can be done while using indirect addressing. As seen from this table, the contents of an auxiliary register can be incremented or decremented by 1, incremented or decremented by the contents of AR0, and incremented or decremented by AR0 in a bit-reversed fashion. The last operation is useful when doing Fast Fourier Transforms. The bit-reversed addressing is implemented by adding AR0 with reverse carry propagation, an operation explained in the TMS320C25 User's Guide. Additionally, it is possible to load at the same time the ARP with a new value, thus saving an extra instruction.

TABLE 77.2 Operations That Can Be Performed in Parallel with Indirect Addressing

Notation	Operation
ADD *	No manipulation of AR or ARP
ADD *, Y	$Y \rightarrow \text{ARP}$
ADD *+	$\text{AR}(\text{ARP}) + 1 \rightarrow \text{AR}(\text{ARP})$
ADD *+, Y	$\text{AR}(\text{ARP}) + 1 \rightarrow \text{AR}(\text{ARP})$ $Y \rightarrow \text{ARP}$
ADD *-	$\text{AR}(\text{ARP}) - 1 \rightarrow \text{AR}(\text{ARP})$
ADD *-, Y	$\text{AR}(\text{ARP}) - 1 \rightarrow \text{AR}(\text{ARP})$ $Y \rightarrow \text{ARP}$
ADD *0+	$\text{AR}(\text{ARP}) + \text{AR0} \rightarrow \text{AR}(\text{ARP})$
ADD *0+, Y	$\text{AR}(\text{ARP}) + \text{AR0} \rightarrow \text{AR}(\text{ARP})$ $Y \rightarrow \text{ARP}$
ADD *0-	$\text{AR}(\text{ARP}) - \text{AR0} \rightarrow \text{AR}(\text{ARP})$
ADD *0-, Y	$\text{AR}(\text{ARP}) - \text{AR0} \rightarrow \text{AR}(\text{ARP})$ $Y \rightarrow \text{ARP}$
ADD *BR0+	$\text{AR}(\text{ARP}) + \text{rcAR0} \rightarrow \text{AR}(\text{ARP})$
ADD *BR0+, Y	$\text{AR}(\text{ARP}) + \text{rcAR0} \rightarrow \text{AR}(\text{ARP})$ $Y \rightarrow \text{ARP}$
ADD *BR0-	$\text{AR}(\text{ARP}) - \text{rcAR0} \rightarrow \text{AR}(\text{ARP})$
ADD *BR0-, Y	$\text{AR}(\text{ARP}) - \text{rcAR0} \rightarrow \text{AR}(\text{ARP})$ $Y \rightarrow \text{ARP}$

Note: $Y = 0, \dots, 7$ is the new "current" AR. $\text{AR}(\text{ARP})$ is the AR pointed to by the ARP. BR = bit reversed, rc = reverse carry.

77.4 TMS320C25 Multiplier and ALU

The heart of the TMS320C25 is the CPU consisting, primarily, of the multiplier and the arithmetic logic unit (ALU). The hardware multiplier can perform a 16 bit \times 16 bit multiplication in a single machine cycle. This capability is probably the major distinguishing feature of digital signal processors because it permits high throughput in numerically intensive algorithms.

Associated with the multiplier, there are two registers that hold operands and results. The T-register (for temporary register) holds one of the two factors. The other factor comes from a memory location. Again, this construct, with one implied operand residing in the T-register, permits more compact instruction words. When multiplier and multiplicand (two 16-bit words) are multiplied together, the result is 32-bits long. In traditional microprocessors, this product would have been truncated to 16 bits, and presented as the final result. In DSP applications, though, this product is only an intermediate result in a long stream of multiply-adds, and if truncated at this point, too much computational noise would be introduced to the final result. To preserve higher final accuracy, the full 32-bit result is held in the P-register (for product register). This configuration is shown in Fig. 77.8 which depicts the multiplier and the ALU of the TMS320C25.

Actually, the P-register is viewed as two 16-bit registers concatenated. This viewpoint is convenient

if you need to save the product using the instructions SPH (store product high) and SPL (store product low). Otherwise, the product can operate on the accumulator, which is also 32-bits wide. The contents of the product register can be loaded on the accumulator, overwriting whatever was there, using the PAC (product to accumulator) instruction. It can also be added to or subtracted from the accumulator using the instructions APAC or SPAC.

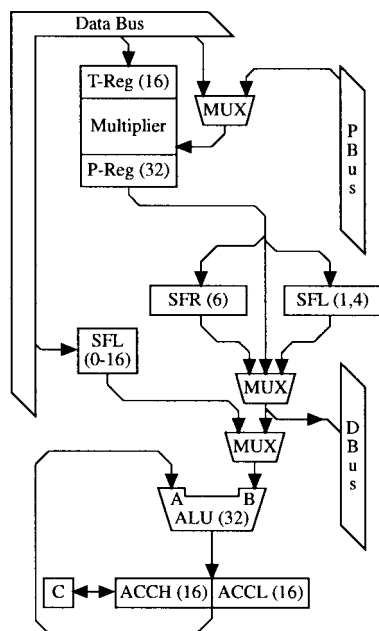

FIGURE 77.8: Diagram of the TMS320C25 multiplier and ALU.

When moving the contents of the T-register to the accumulator, you can shift this number using the built-in shifters. For instance you can shift the result left by 1 or 4 locations (essentially multiplying it by 2 or 16), or you can shift it right by 6 (essentially dividing it by 64). These operations are done automatically, without spending any extra machine cycles, simply by setting the appropriate product mode with SPM instruction. Why would you want to do such shifting? The left shifts have as a main purpose to eliminate any extra sign bits that would appear in computations. The right shift scales down the result and permits accumulation of several products before you start worrying about overflowing the accumulator.

At this point, it is appropriate to discuss the data formats supported on the TMS320C25. This device, as most fixed-point processors, uses two's-complement notation to represent the negative numbers. In two's complement notation, to form the negative of a given number, you take the complement of that number and you add 1. In two's-complement notation, the most significant bit (MSB, the left-most bit) of a positive number is zero, while the MSB of a negative number is one. In the 'C25, the two's complement numbers are sign-extended, which means that, if the absolute value of the number is not large enough to fill all the bits of the word, there will be more than one sign bits.

As seen from Fig. 77.8, the multiplier path is not the only way to access the accumulator. Actually, the ALU and the accumulator support a wealth of arithmetic (ADD, SUB, etc.) and logical (OR, AND, XOR, etc.) instructions, in addition to load and store instructions for the accumulator (LAC,

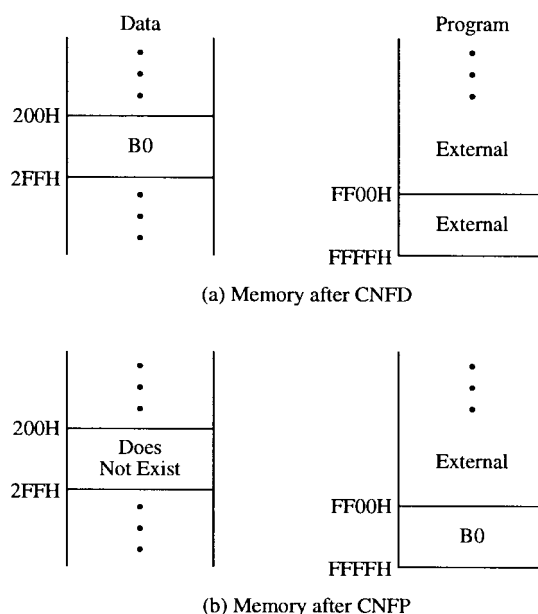

FIGURE 77.9: Partial memory configuration of the TMS320C25 after the CNFD and the CNFP instructions.

ZALH, SACL, SACH, etc.).

An interesting characteristic of the TMS320C25 architecture is the existence of several shifters that can perform such shifts in parallel with other operations. Except for the right shifter at the multiplier, all the other shifters are left shifters. An input shifter to the ALU and the accumulator can shift the input value to the left by up to 16 locations, while output shifters from the accumulator can shift either the high or the low part of the accumulator by up to 7 locations to the left.

A construct that appears very often in mathematical computations is the sum of products. Sums of products appear in the computation of dot products, in matrix multiplication, and in convolution sums for filtering, among other applications. Since it is important to carry out this computation as fast as possible for real-time operation, all digital signal processors have special instructions to speed up this particular function.

The TMS320C25 has the instruction LTA which loads the T-register and, in parallel with that, adds the previous product (which already resides in the P-register) to the accumulator. LTS subtracts the product from the accumulator. Another instruction, LTD, does the same thing as LTA, but it also moves the value that was just loaded on the T-register to the next higher location in memory. This move realizes the delay line that is needed in filtering applications. LTA, when combined with the MPY instruction, can implement very efficiently the sum of products.

For even higher efficiency, there is a MAC instruction that combines LTA and MPY. An additional MACD instruction combines LTD and MPY. The increased efficiency is achieved by using both the data and the program buses to bring in the operands of the multiplication. The data coming from the data bus can be traced in memory by an AR, using indirect addressing. The data coming from the program bus can be traced by the program counter (actually, the pre-fetch counter, PFC) and, hence, they must reside in consecutive locations of program memory. To be able to modify the data and then use it in such multiply-add operations, the TMS320C25 permits reconfiguration of block B0 in the on-chip memory. B0 can be configured either as program or as data memory, as shown in Fig. 77.9, using the CNFD and CNFP instructions.

77.5 Other Architectural Features of the TMS320C25

The TMS320C25 has many interesting features and capabilities that can be found in the user's guide [1]. Here, we present briefly only the most important of them.

The program counter is a 16-bit register, hidden from the user, which contains the address of the next instruction word to be fetched and executed. Occasionally, the program execution may be redirected, for instance, through a subroutine call. In this case, it is necessary to save the contents of the program counter so that the program flow continues from the correct instruction after the completion of the subroutine call. For this purpose, a hardware stack is provided to save and recover the contents of the program counter.

The hardware stack is a set of eight registers, of which only the top one is accessible to the user. Upon a subroutine call, the address after the subroutine call is pushed on the stack, and it is reinstated in the program counter when the execution returns from the subroutine call. The programmer has control over the stack by using the PUSH, PSHD, POP, and POPD instructions. The PUSH and POP operations push the accumulator on the stack or pop the top of the stack to the accumulator respectively. PSHD and POPD do the same functions but with memory locations instead of the accumulator.

Occasionally the program execution in a processor must be interrupted in order to take care of urgent functions, such as receiving data from external sources. In these cases, a special signal goes to the processor, and an interrupt occurs. The interrupts can be internal or external. During an interrupt, the processor stops execution, wherever it may be, pushes the address of the next instruction on the stack, and starts executing from a predetermined location in memory. The interrupt approach is appropriate when there are functions or devices that need immediate attention. On the TMS320C25, there are several internal and external interrupts, which are prioritized, i.e., when several of the interrupts occur at the same time, the one with the highest priority is executed first. Typically, the memory location where the execution is directed to during an interrupt contains a branch instruction. This branch instruction directs the program execution to an area in the program memory where an interrupt service routine exists. The interrupt service routine will perform the tasks that the interrupt has been designed for, and then return to the execution of the original program.

Besides the external hardware interrupts (for which there are dedicated pins on the device), there are internal interrupts generated by the serial port and the timer. The serial port provides direct communication with serial devices, such as codecs, serial analog-to-digital converters, etc. In these devices, the data are transmitted serially, one bit at a time, and not in parallel, which would require several parallel lines. When 16 bits have been input, the 16-bit word can be retrieved from the register DRR (data receive register). Conversely, to transmit a word, you put it in the DXR (data transmit register). These two registers occupy data memory locations 0 and 1, respectively, and they can be treated like any other memory location.

The timer consists of a period register and a timer register. At the beginning of the operation, the contents of the period register are loaded on the timer register, which is then decremented at every machine cycle. When the value of the timer register reaches zero, it generates a timer interrupt, the period register is loaded again on the timer register, and the whole operation is repeated.

77.6 TMS320C25 Instruction Set

The TMS320C25 has an instruction set consisting of 133 instructions. Some of these assembly language instructions perform general purpose operations, while others are more specific to DSP applications. This section discusses examples of instructions selected from different groups. For a detailed description of each instruction, the reader is referred to the TMS320C25 User's Guide [1].

Each instruction is represented by one or two 16-bit words. Part of the instruction is a unique code

identifying the operation to be performed, while the rest of the instruction contains information on the operation. For instance, this additional information determines if direct or indirect addressing is used, if there is a shift of the operand, what is the address of the operand, etc. In the case of two-word instructions, the second word is typically a 16-bit constant or program memory address. As it should be obvious, a two-word instruction takes longer to execute because it has to fetch two words, and it should be avoided if the same operation could be accomplished with a single-word instruction.

For example, if you want to load the accumulator with the contents of the memory location 3FH, shifting it to the left by 8 locations at the same time, you can write the instruction

LAC 3FH,8

The above instruction, when encoded, is represented by the word 283FH. The left-most four bits in this example, i.e., 0010, represent the “opcode” of the instruction. The opcode is the unique identifier of the instruction. The next four bits, 1000, are the shift of the operand. Then there is one bit (zero in this case) to signal that the direct addressing mode is used, and the last 7 bits are the operand address 3Fh (in hexadecimal).

Below, some of the more typical instructions are listed, and the ones that have an important interpretation are discussed. It is a good idea to review carefully the full set of instructions so that you know what tools you have available to implement any particular construct. The instructions are grouped here by functionality.

The accumulator and memory reference instructions involve primarily the ALU and the accumulator. Note that there is a symmetry in the instruction set. The addition instructions have counterparts for subtraction, the direct and indirect-addressing instructions have complementary immediate instructions, and so on.

ABS	Absolute value of accumulator
ADD	Add to accumulator with shift
ADDH	Add to high accumulator
ADDK	Add to accumulator short immediate
AND	Logical AND with accumulator
LAC	Load accumulator with shift
SACH	Store high accumulator with shift
SACL	Store low accumulator with shift
SUB	Subtract from accumulator with shift
SUBC	Subtract conditionally
ZAC	Zero accumulator
ZALH	Zero low accumulator and load high accumulator.

Operations involving the accumulator have versions affecting both the high part and the low part of the accumulator. This capability gives additional flexibility in scaling, logical operations, and double-precision arithmetic.

For example, let location A contain a 16-bit word that you want to scale down dividing by 16, and store the result in B. The following instructions perform this operation:

LAC	A,12	; Load ACC with A shifted by 12 locations
SACH	B	; Store ACCH to B: B = A/16

The auxiliary registers and data page pointer instructions deal with loading, storing, and modifying the auxiliary registers and the data page pointer. Note that the auxiliary registers and the ARP can also be modified during operations using indirect addressing. Since this last approach has the advantage of making the modifications in parallel with other operations, it is the most common method of AR modification.

LAR	Load auxiliary register
LARP	Load auxiliary register pointer
LDP	Load data memory page pointer
MAR	Modify auxiliary register
SAR	Store auxiliary register

The multiplier instructions are more specific to signal processing applications.

APAC	Add P-register to accumulator
LT	Load T-register
LTD	Load T-register, accumulate previous product, and move data
MAC	Multiply and accumulate
MACD	Multiply and accumulate with data move
MPY	Multiply
MPYK	Multiply immediate
PAC	Load accumulator with P-register
SQRA	Square and accumulate

Note that the instructions that perform multiplication and accumulation at the same time do not accumulate the present product but the result of an earlier multiplication. This result is found in the P-register. The square and accumulate function, SQRA, is a special case of the multiplication that appears often enough to prompt the inclusion of this specific instruction.

The branch instructions correspond to the GOTO instruction of high-level languages. They redirect the flow of the execution either unconditionally or depending on some previous result.

B	Branch unconditionally
BANZ	Branch on auxiliary register non zero
BGEZ	Branch if accumulator ≥ 0
CALA	Call with subroutine address in the accumulator
CALL	Call subroutine
RET	Return from subroutine

The CALL and RET instructions go together because the first one pushes the return address on the stack, while the second one pops the address from the stack into the program counter. The BANZ instruction is very helpful in loops where an AR is used as a loop counter. BANZ tests the AR, modifies it, and branches to the indicated address.

The I/O operations are, probably, among the most important in terms of final system configuration, because they help the device interact with the rest of the world. Two instructions that perform that function are the IN and OUT instructions.

BLKD	Block move from data memory to data memory
IN	Input data from port
OUT	Output data to port
TBLR	Table read
TBLW	Table write

The IN and OUT instructions read from or write to the 16 input and the 16 output ports of the TMS320C25. Any transfer of data goes to a specified memory location. The BLKD instruction permits movement of data from one memory location to another without going through the accumulator. To make such a movement effective, though, it is recommended to use BLKD with a repeat instruction, in which case every data move takes only one cycle.

The TBLR and TBLW instructions represent a modification to the Harvard architecture of the device. Using them, data can be moved between the program and the data spaces. In particular, if any tables have been stored in the program memory space they can be moved to data memory before they can be used. That is how the terminology of the instructions originated.

Some other instructions include:

DINT	Disable interrupts
EINT	Enable interrupts
IDLE	Idle until interrupt
RPT	Repeat instruction as specified by data memory value
RPTK	Repeat instruction as specified by immediate value

77.7 Input/Output Operations of the TMS320C25

During program execution on a digital signal processor, the data is moved between the different memory locations, on-chip and off-chip, as well as between the accumulator and the memory locations. This movement is necessary for the execution of the algorithm that is implemented on the processor. However, there is a need to communicate with the external world in order to receive data that will be processed, and return the processed results.

Devices communicate with the external world through their external memory or through the serial and parallel ports. Such a communication can be achieved, for instance, by sharing the external memory. Most often, the communication with the external world takes place through the external parallel or serial ports that the device has. Some devices may have ports of only one kind, serial or parallel, but most modern processors have both types. The two kinds of ports differ in the way in which the bits are read. In a parallel port, there is a physical line (and a processor pin) dedicated to every bit of a word. For example, if the processor reads in words that are 16 bits wide, as is the case with the TMS320C25, it has 16 lines available to read a whole word in a single operation. Typically, the same pins that are used for accessing external memory are also used for I/O.

The TMS320C25 has 16 input and 16 output ports that are accessed with the IN and OUT instructions. These instructions transfer data between memory locations and the I/O port specified.

77.8 Subroutines, Interrupts, and Stack on the TMS320C25

When writing a large program, it is advisable to structure it in a modular fashion. Such modularity is achieved by segmenting the program in small, self-contained tasks that are encoded as separate routines. Then, the overall program can be simply a sequence of calls to these subroutines, possibly with some “glue” code. Constructing the program as a sequence of subroutines has the advantage that it produces a much more readable algorithm that can greatly help in debugging and maintaining it. Furthermore, each subroutine can be debugged separately, which is far easier than trying to uncover programming errors in a “spaghetti-code” program.

Typically, the subroutine is called during the program execution with an instruction such as `CALL SUBRTN`

where `SUBRTN` is the address where the subroutine begins. In this example, `SUBRTN` would be the label of the first instruction of the subroutine. The assembler and the linker resolve what the actual value is. Calling a subroutine has the following effects:

- Increments the program counter (PC) by one and pushes its contents on the top of the stack (TOS). The TOS now contains the address of the instruction to be executed after returning from the subroutine.
- Loads the address `SUBRTN` on the PC.
- Starts execution from where the PC is pointing at (i.e., from location `SUBRTN`).

At the end of the subroutine execution, a return instruction (`RET`) will pop the contents of the top of the stack on the program counter, and the program will continue execution from that location.

The stack is a set of memory locations where you can store data, such as the contents of the PC. The difference from regular memory is that the stack keeps track of the location where the most recent data was stored. This location is the TOS. The stack is implemented either in hardware or software.

The TMS320C25 has a hardware stack that is eight locations deep. When a piece of data is put (“pushed”) on the stack, everything already there is moved down by one location. Notice that the contents of the last location (bottom of the stack) are lost. Conversely, when a piece of data is retrieved from the stack (it is “popped”), all the other locations are moved up by one location. Pushing and popping always occur at the top of the stack.

The interrupt is a special case of subroutine. The TMS320C25 supports interrupts generated either internally or from external hardware. An interrupt causes a redirection of the program execution in order to accomplish a task. For instance, data may be present at an input port, and the interrupt forces the processor to go and “service” this port (inputting the data). As another example, an external D/A converter may need a sample from the processor, and it uses an interrupt to indicate to the DSP device that it is ready to receive the data. As a result, when the processor is interrupted, it “knows” by the nature of the interrupt that it has to go and do a specific task, and it does just that.

The performance of the designated task is done by the interrupt service routine (ISR). An ISR is like a subroutine with the only difference on the way it is accessed, and in the functions performed upon return. When an interrupt occurs, the program execution is automatically redirected to specific memory locations, associated with each interrupt. As explained earlier, the TMS320C25 continues execution from a specified memory location which, typically, contains a branch instruction to the actual location of the interrupt service routine.

The return from the interrupt service routine, like in a subroutine, pops the top of the stack to the program counter. However, it has the additional effect of re-enabling the interrupts. This is necessary because when an interrupt is serviced, the first thing that happens is that all interrupts are disabled to avoid confusion from additional interrupts. Re-enabling is done explicitly in the TMS320C25 (by using the EINT command).

77.9 Introduction to the TMS320C30 Digital Signal Processor

The Texas Instruments TMS320C30 is a floating-point processor that has some commonalities with the TMS320C25, but that also has a lot of differences. The differences are due more to the fact that the TMS320C30 is a newer processor than that it is a floating-point processor. The TMS320C30 is a fast, 32-bit, digital signal processor that can handle both fixed-point and floating-point operations. The speed of the device is 16.7 MHz, which corresponds to a cycle time of 60 ns. Since the majority of the instructions execute in a single cycle (after the pipeline is filled), the figure of 60 ns also indicates how long it takes to execute one instruction. Alternatively, we can say that the device can execute 16.7 MIPS. Another figure of merit is based on the fact that the device can perform a floating-point multiplication and addition in a single cycle. Then, it is said that the device has a (maximum) throughput of 33 million floating-point operations per second (MFLOPS).

The actual signal from the external oscillator or crystal has a frequency twice that of the internal device speed, at 33.3 MHz (and period of 30 ns). This frequency is then divided on-chip to generate the internal clock with a period of 60 ns. Newer versions of the TMS320C30 and other members of the ‘C3x generation operate in higher frequencies.

Figure 77.10 shows in a simplified form the key features of the TMS320C30. The major parts of the DSP processor are the memory, the CPU, the peripherals, and the direct memory access (DMA) unit. Each of these parts will be examined in more detail later in this article. The on-chip memory consists of 2K words of RAM and 4K words of ROM. There is also a 64-word long program cache. Each word is 32-bits wide and the memory sizes for the TMS320C30 are measured in 32-bit words, and not in bytes. The memory (RAM or ROM) can be used to store either program instructions or data. This presents a departure from the practice of separating the two spaces that the TMS320C25 uses, combining features of a von Neuman architecture with a Harvard architecture. Overall, the device can address 16 M words of memory through two external buses. Except for what resides on-chip, the rest of the memory is external, supplied by the designer.

The CPU is the heart of the processor. It has a hardware multiplier that is capable of performing a multiplication in a single cycle. The multiplication can be between two 32-bit floating point numbers, or between two integers. To achieve a higher intermediate accuracy of results, the product of two floating-point numbers is saved as a 40-bit result. In integer multiplication, two 24-bit numbers are

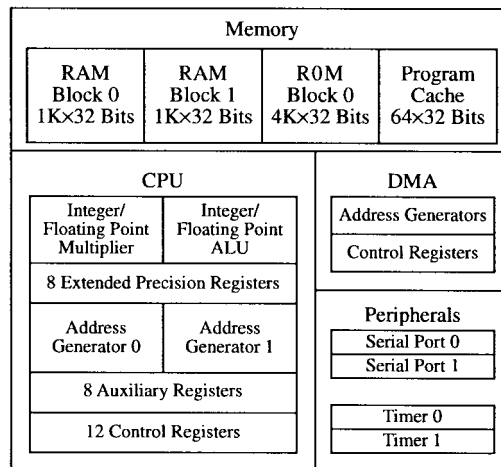

FIGURE 77.10: Key architectural features to the TMS320C30.

multiplied together to give a 32-bit result. The other important part of the CPU is the arithmetic logic unit (ALU) that performs additions, subtractions, and logical operations. Again, for increased intermediate accuracy, the ALU can operate on 40-bit long floating-point numbers and generates results that are also 40-bit long.

The 'C30 can handle both integers and floating-point numbers using corresponding instructions. There are three kinds of floating-point numbers, as shown in Fig. 77.11: short, single-precision, and extended-precision. In all three kinds, the number consists of an exponent e , a sign s and a mantissa f . Both the mantissa (part of which is the sign) and the exponent are expressed in two's-complement notation.

- Short Floating-Point Format

- Single-Precision Floating-Point Format

- Extended-Precision Floating-Point Format

FIGURE 77.11: TMS320C30 floating point formats.

In the short floating-point format, the mantissa consists of 12 bits and the exponent of 4 bits. The short format is used only in immediate operands, where the actual number to operate upon becomes part of the instruction. The single-precision format is the regular format representing the numbers in the TMS320C30, which is a 32-bit device. It has 24 bits for mantissa and 8 bits for exponent.

Finally, the extended-precision format is encountered only in the extended-precision registers, to be discussed below. In this case, the exponents is also 8-bits long, but the mantissa is 32 bits, giving extra precision. The mantissa is normalized so that it has a magnitude $|f|$ such that $1.0 \leq |f| < 2.0$.

The integer formats supported in the TMS320C30 are shown in Fig. 77.12. Both the short and the single-precision integer formats represent the numbers in two's complement notation. The short format is used in immediate operands, where the actual number to be operated upon is part of the instruction itself.

FIGURE 77.12: TMS320C30 integer (fixed-point) formats.

All the arithmetic and logical functions are register-based. In other words, the destination and at least one source operand in every instruction are register file associated with the TMS320C30 CPU. Figure 77.13 shows the components of the register file. There are eight extended-precision registers, R0-R7, that can be used as general purpose accumulators for both integer and floating-point arithmetic. These registers are 40-bits wide. When they are used in floating-point operations, the top 8 bits are the exponent and the bottom 32 bits are the mantissa of the number. When they are used as integers, the bottom 32 bits are the integer, while the top 8 bits are ignored and are left intact.

FIGURE 77.13: TMS320C30 register file.

The eight auxiliary registers, AR0-AR7, are designated to be used as memory pointers or loop counters. When treated as memory pointers, they are used during the indirect addressing mode, to be examined below. AR0-AR7 can also be used as general-purpose registers but only for integer arithmetic.

Additionally, there are 12 control registers designated for specific purposes. These registers too can be treated as general purpose registers for integer arithmetic if they are not used for their designated purpose. Examples of such control registers are the status register, the stack pointer, the block repeat registers, and the index registers.

To communicate with the external world, the TMS320C30 has two parallel buses, the primary bus and the expansion bus. It also has two serial ports that can serve the same purpose. The serial ports are part of the peripherals that have been implemented on chip. Other peripherals include the direct memory access (DMA) unit, and two timers. These components of the TMS320C30 are examined in more detail in the following.

The device has 181 pins that are designated to perform certain functions, and to communicate with other devices on the same board. The names of the signals and the corresponding definitions appear in Table 77.3. The first column of the table gives the pin names; the second one indicates if the pin is used for input or output; the third column gives a description of the pin functionality. Note that a bar over the name indicates that the pin is in the active position when it is electrically low. The second column indicates if the pin is used for input to the device, output from the device, or both.

TABLE 77.3 Names and Functionality of the 181 Pins of the TMS320C30

<i>Signal</i>	<i>I/O</i>	<i>Description</i>
D(31-0)	I/O	32-bit data port of the primary bus
A(23-0)	O	24-bit address port of the primary bus
$\overline{R/W}$	O	Read/write signal for primary bus interface
\overline{STRB}	O	External access strobe for the primary bus
\overline{RDY}	I	Ready signal
\overline{HOLD}	I	Hold signal for primary bus
\overline{HOLDA}	O	Hold acknowledge signal for primary bus
XD(31-0)	I/O	32-bit data port of the expansion bus
XA(12-0)	O	13-bit address port of the expansion bus
$\overline{XR/W}$	O	Read/write signal for expansion bus interface
\overline{MSTRB}	O	External access strobe for the expansion bus
\overline{IOSTRB}	O	External access strobe for the expansion bus
\overline{XRDY}	I	Ready signal
\overline{RESET}	I	Reset
\overline{INT} (3-0)	I	External interrupts
\overline{LACK}	O	Interrupt acknowledge signal
$\overline{MC/MP}$	I	Microcomputer/microprocessor mode pin
XF(1-0)	I/O	External flag pins
CLKX(1-0)	I/O	Serial port (1-0) transmit clock
DX(1-0)	O	Data transmit output for port (1-0)
FSX(1-0)	I/O	Frame synchronization pulse for transmit
CLKR(1-0)	I/O	Serial port (1-0) receive clock
DR(1-0)	I	Data receive for serial port (1-0)
FSR(1-0)	I	Frame synchronization pulse for receive
TCLK(1-0)	I/O	Timer (1-0) clock
V_{DD} , etc.	I	12 + 5 V supply pins
V_{SS} , etc.	I	11 ground pins
X1	O	Output pin from internal oscillator for the crystal
X2/CLKIN	I	Input pin to the internal oscillator from the crystal
H1, H3	O	External H1, H3 clock. H1 = H3 = 2 CLKIN
EMU, etc.	I/O	20 reserved and miscellaneous pins

The TMS320C30 has its own assembly language consisting of 114 instructions that perform general-purpose and DSP-specific functions. High-level-language compilers have also been developed that make the writing of programs an easier task. The TMS320C30 was designed with a high-level language compiler in mind, and its architecture incorporates some appropriate features. For instance, the

presence of the software stack, the register file, and the large memory space were to a large extent motivated by compiler considerations.

The TMS320C30 combines the features of the Harvard and the von Neuman architectures to offer more flexibility. The memory is a unified space where the designer can select the places for loading program instructions or data. This von Neuman feature maximizes the efficient use of the memory. On the other hand, there are multiple buses to access the memory in a Harvard style, as shown in Fig. 77.14. Two of the buses are used for the program, to carry the instruction address and fetch the instruction. Three buses are associated with data: two of those carry data addresses, so that two memory accesses can be done in the same machine cycle. The third bus carries the data. The reason that one bus is sufficient to carry the data is that the device needs only one-half of a machine cycle to fetch an operand from the internal memory. As a result, two data fetches can be accomplished in one cycle over the same bus.

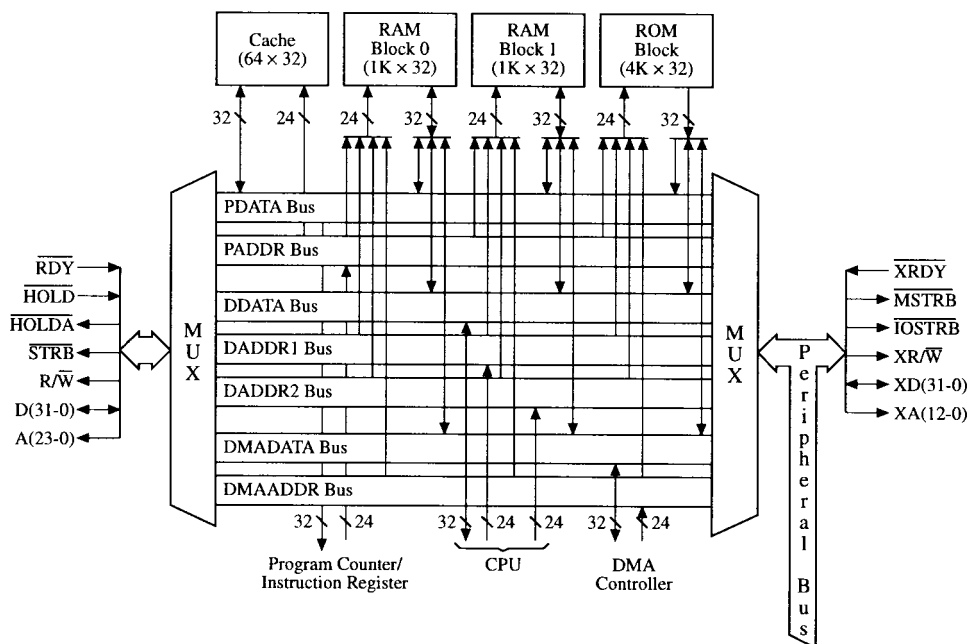

FIGURE 77.14: Internal bus structure of the TMS320C30.

The last two buses are associated with the DMA unit, which transfers data in parallel with and transparently to the CPU. Because of the multiple buses, program instructions and data operands can be moved simultaneously increasing the throughput of the device. Of course, it is conceivable that too many accesses can be attempted to the same memory area, causing access conflicts. However, the TMS320C30 has been designed to resolve such conflicts automatically by inserting the appropriate delays in instruction execution. Hence, the operations always give the correct results.

Figure 77.15 shows a functional block diagram of the TMS320C30 architecture with the buses, the CPU, and the register file. It also points out the peripheral bus with the associated peripherals. Because of the peripheral bus, all the peripherals are memory-mapped, and any operations with them are seen by the programmer as accesses (reads/writes) to the memory.

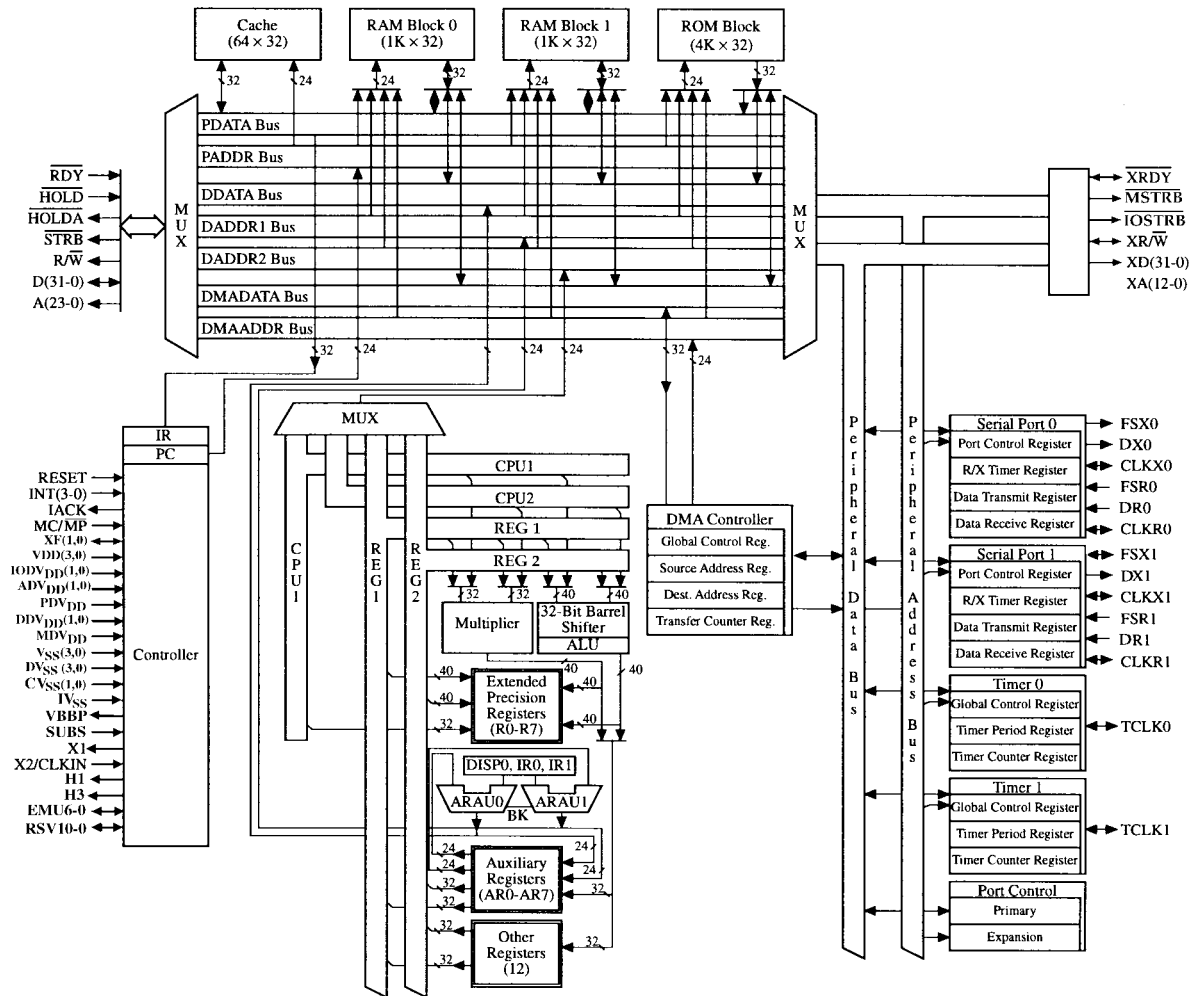

FIGURE 77.15: Functional block diagram of the TMS320C30 architecture.

77.10 TMS320C30 Memory Organization and Access

The TMS320C30 has on-chip 2K words (32-bits wide) of RAM and 4K of ROM. This memory can be accessed twice in a single cycle, a fact that is reflected in the instruction set, which includes three-operand instructions: two of the operands reside in memory, while the third operand is the register where the result is placed.

Besides the on-chip memory, the TMS320C30 can access external memory through two external buses, the primary and the expansion. The primary bus consists of 24 address pins A0-A23, and 32 data pins D0-D31. As the number of address pins suggests, the maximum memory space available is 16M words. Not all of that, though, resides on the primary bus. The primary bus has 16M words minus the on-chip memory, and minus the memory available on the expansion bus.

The expansion bus has 13 address pins, XA0-XA12, and 32 data pins, XD0-XD31. The 13 address pins can address 8K words of memory. However, there are two strobes, MSTRB and IOSTRB, that select two different segments of 8K of memory. In other words, the total memory available on the expansion bus is 16K. The differences between the two strobes is in timing. The timing differences can make one of the memory spaces more preferable to the other in certain applications, such as peripheral devices.

As mentioned earlier, the destination operand is always a register in the register file (except for storing a result, where, of course, the destination is a memory location.) The register can also be one of the source operands. It is possible to specify a source operand explicitly and include it in the instruction. This addressing mode is called immediate addressing mode. The immediate constant should be accommodated by a 16-bit wide word, as discussed earlier in the data formats.

For example, if it is desired to increment the (integer) contents of the register R0 by 5, the following instruction can be used:

```
ADDI    5,R0
```

To increment the (floating-point) contents of the register R3 by -2.75, you can use the instruction

```
ADDF    -2.75,R3
```

If the value to be operated upon resides in memory, there are two ways to access it: either by specifying the memory address directly (direct addressing) or by using an auxiliary register holding that address and, hence, pointing to that number indirectly (indirect addressing). In the direct addressing mode, full description of a memory address would require a 24-bit word because the memory space is 16M words. To reduce that requirement, the memory space is divided in 256 pages of 64K words each. An instruction using direct addressing contains the 16 bits indicating what word you want to access within a page. The page number (8 bits) is stored in one of the control registers, the data page (DP) pointer. The DP pointer can be modified by using either a load instruction or the pseudo-instruction LDP. During assembly time, LDP picks the top 8 bits of a memory address and places them in the DP register.

Of course, if several locations need to be accessed in the same page, you can set the DP pointer only once. Since the majority of the routines written are expected to be less than 64K words long, setting the DP register at the beginning of the program suffices. The exception to that would be placing the code over the boundary of two consecutive pages.

In the indirect addressing mode, the data memory address is held in a register that acts as a memory pointer. There are eight such registers available, AR0-AR7. These registers can also be used for other functions, such as loop counters or general purpose registers. If they are used as memory pointers, they are explicitly specified in the instruction. In an instruction, indirect addressing is indicated by an asterisk preceding the auxiliary register.

For example, the instruction

```
LDF      *AR3++,R0    ; Load R0 with -612
```

loads R0 with the contents of the memory location pointed at by AR3.

The “++” sign in the above instruction means “after the present memory access, increment the contents of the current auxiliary register by 1”. This is done in parallel with the load-register operation.

The above autoincrementing of the auxiliary register is an optional operation that offers additional flexibility to the programmer, and it is not the only one available. The TMS320C30 has two auxiliary register arithmetic units (ARAU0 and ARAU1) that can execute such operations in parallel with the CPU, and increase the throughput of the device in this way. The primary function of ARAU0 and ARAU1 is to generate the addresses for accessing operands.

Table 77.4 summarizes the different operations that can be done while using indirect addressing. As seen from this table, the contents of an auxiliary register can be incremented or decremented before or after accessing the memory location. In the case of pre-modification, this modification can be permanent or temporary. When an auxiliary register ARn, n = 0-7, is modified, the displacement disp is either a constant (0-255) or the contents of one of the two index registers IR0, IR1 in the register file. If the displacement is missing, a 1 is implied. The auxiliary register contents can be incremented or decremented in a circular fashion, or incremented by the contents of IR0 in a bit-reversed fashion.

TABLE 77.4 Operations That Can Be Performed in Parallel with Indirect Addressing in the TMS320C30

Notation	Operation	Description
*ARn	addr = ARn	Indirect without modification
*+ARn(displ)	addr = ARn + disp	With predisplacement add
*-ARn(displ)	addr = ARn - disp	With predisplacement subtract
*++ARn(displ)	addr = ARn + disp ARn = ARn + disp	With predisplacement add and modify
*--ARn(displ)	addr = ARn - disp ARn = ARn - disp	With predisplacement subtract and modify
*ARn++(displ)	addr = ARn ARn = ARn + disp	With postdisplacement add and modify
*ARn--(displ)	addr = ARn ARn = ARn - disp	With postdisplacement subtract and modify
*ARn++(displ)%	addr = ARn ARn = circ(ARn + disp)	With postdisplacement add and circular modify
*ARn--(displ)%	addr = ARn ARn = circ(ARn - disp)	With postdisplacement subtract and circular modify
*ARn++(IR0)B	addr = ARn ARn = rc(ARn + IR0)	With postdisplacement add and bit-reversed modify

Note: circ = circular modification, B = bit reversed, rc = reverse carry.

The last two kinds of operation have special purposes. Circular addressing is used to create a circular buffer, and it is helpful in filtering applications. Bit-reversed addressing is useful when doing Fast Fourier Transforms. The bit-reversed addressing is implemented by adding IR0 with reverse carry propagation, an operation explained in the TMS320C30 User's Guide.

The TMS320C30 has a software stack that is part of its memory. The software stack is implemented by having one of the control registers, the SP, point to the next available memory location. Whenever a subroutine call occurs, the address to return to after the subroutine completion is pushed on the stack (i.e., it is written on the memory location that SP is pointing at), and SP is incremented by one. Upon return from a subroutine, the SP is decremented by one and the value in that memory location is copied on the program counter.

Since the SP is a regular register, it can be read or written to. As a result, you can specify what part of the memory is used for the stack by initializing SP to the appropriate address. There are specific instructions to push on or pop from the stack any of the registers in the register file: PUSH, POP for integer values, PUSHF, POPF for floating-point numbers. Such instructions can use the stack to pass arguments to subroutines or to save information during an interrupt. In other words, the stack is a convenient scratch-pad that you designate at the beginning, so that you do not have to worry where to store some temporary values.

77.11 Multiplier and ALU of the TMS320C30

The heart of the TMS320C30 is the CPU consisting, primarily, of the multiplier and the ALU. The CPU configuration is shown in Fig. 77.16 which depicts the multiplier and the ALU of the TMS320C30. The hardware multiplier can perform both integer and floating-point multiplications in a single machine cycle.

FIGURE 77.16: Central processing unit (CPU) of the TMS320C30.

The inputs to the multiplier come from either the memory or the registers of the register file. The outputs are placed in the register file. When multiplying floating-point numbers, the inputs are 32-bits long (8 bits exponent and 24 bits mantissa), and the result is 40-bits wide directed to one of the extended precision registers. If the input is longer than 32 bits (extended precision) or shorter than 32 bits (short format) it is truncated or extended, respectively, by the device to become a 32-bit number before the operation. Multiplication of integers consists of multiplying two 24-bit numbers to generate a 32-bit result. In this case, the registers used can be any of the registers in the register file.

The other major part of the CPU is the ALU. The ALU can also take inputs from either the memory or

the register file and perform arithmetic or logical operations. Operations on floating-point numbers can be done on 40-bit wide inputs (8 bits exponent and 32 bits mantissa) to give also 40-bit results. Integer operations are done on 32-bit numbers. Associated with the ALU, there is a barrel shifter that can perform either a right-shift or a left-shift of a register's contents for any number of locations in a single cycle. The instructions for shifting are ASH (Arithmetic SHift) and LSH (Logical SHift).

77.12 Other Architectural Features of the TMS320C30

The TMS320C30 has many interesting features and capabilities. For a full account, the reader is urged to look them up in the User's Guide [2]. Here, we briefly present only the most important of them so that you have a global view of the device and its salient characteristics.

The TMS320C30 is a very fast device, and it can execute very efficiently instructions from the on-chip memory. Often, though, it is necessary to use external memory for program storage. The existing memory devices either are not as fast as needed, or are quite expensive. To ameliorate this problem, the TMS320C30 has 64 words of program cache on-chip. When executing a program from external memory, every instruction is stored on the cache as it is brought in. Then, if the same instruction needs to be executed again (as is the case for instructions in a loop), it is not fetched from the external memory but from the cache. This approach speeds up the execution, but it also frees the external bus to fetch, for instance, operands. Obviously, the cache is most effective for loops that are shorter than 64 words long, something usual in DSP applications. On the other hand, it does not offer any advantages in the case of straight-line code. However, the structure of DSP problems suggests that the cache is a feature that can be put to good use.

In the instruction set of the 'C30 there is the RPTS (RePeaT Single) instruction

RPTS N

that repeats the following instruction N+1 times. A more generalized repeated mode is implemented by the RPTB (RePeaT Block) instruction that repeats a number of times all the instructions between RPTB and a label that is specified in the block-repeat instruction. The number of repetitions is one more than the number stored in the repeat count register, RC, one of the control registers in the register file.

For example the following instructions are repeated one time more than the number included in the RC.

LDI	63,RC		; The loop is to be repeated 64 times
	RPTB	LOOP	; Repeat up to the label LOOP
	LDI	*AR0,R0	; Load the number on R0
	ADDI	1,R0	; Increment it by 1
LOOP	STI	R0,*AR0++	; Store the result; point to the next ; number; and loop back

Besides RC, there are two more control registers used with the block repeat instruction. The repeat-start (RS) contains the beginning of the loop, and the repeat-end (RE) the end of the loop. These registers are initialized automatically by the processor, but they are available to the user in case he needs to save them.

On the TMS320C30, there are several internal and external interrupts, which are prioritized, i.e., when several of the interrupts occur at the same time, the one with the highest priority is executed first.

Besides the reset signal, there are 4 external interrupts, INT0-INT3. Internally, there are the receive and transmit interrupts of the serial ports, and the timer interrupts. There is also an interrupt associated with the DMA. Typically, the memory location where the execution is directed to during an interrupt contains the address where an interrupt service routine starts. The interrupt service routine will perform the tasks for which the interrupt has been designed, and then return to the execution of the original program. All the interrupts (except the reset) are maskable, i.e., they can be ignored by

setting the interrupt enable (IE) register to appropriate values. Masking of interrupts, as well as the memory locations where the interrupt addresses are stored, are discussed in the TMS320C30 User's Guide [2].

Each of the two serial ports provides direct communication with serial devices, such as codes, serial analog-to-digital converters, etc. In these devices, the data are transmitted serially, one bit at a time, and not in parallel, which would require several parallel lines. The serial ports have the flexibility to consider the incoming stream as 8-, 16-, 24-, or 32-bit words. Since they are memory-mapped, the programmer goes to certain memory locations to read in or write out the data.

Each of the two timers consists of a period register and a timer register. At the beginning of the operation, the contents of the timer register are incremented at every machine cycle. When the value of the timer register becomes equal to the one in the period register, it generates a timer interrupt, the period register is zeroed out, and the whole operation is repeated.

A very interesting addition to the TMS320C30 architecture is the DMA unit. The DMA can transfer data between memory locations in parallel with the CPU execution. In this way, blocks of data can be transferred transparently, leaving the CPU free to perform computational tasks, and thus increasing the device throughput.

The DMA is controlled by a set of registers, all of which are memory mapped: you can modify these registers by writing to certain memory locations. One register is the source address from where the data is coming. The destination address is where the data is going. The transfer count register specifies how many transfers will take place. A control register determines if the source and the destination addresses are to be incremented, decremented, or left intact after every access. The programmer has several options of synchronizing the DMA data transfers with interrupts or leaving them asynchronous.

77.13 TMS320C30 Instruction Set

The TMS320C30 has an instruction set consisting of 114 instructions. Some of these instructions perform general purpose operations, while others are more specific to DSP applications. The instruction set of the TMS320C30 presents an interesting symmetry that makes programming very easy. Instructions that can be used with integer operands are distinguished from the same instructions for floating-point numbers with the suffix "I" vs. "F". Instructions that take three operands are distinguished from the ones with two operands by using the suffix "3". However, since the assembler permits elimination of the symbol "3", the notation becomes even simpler.

A whole new class of TMS320C30 instructions (as compared to the TMS320C25) are the parallel instructions. Any multiplier or ALU operation can be performed in parallel with a store instruction. Additionally, two stores, two loads, or a multiply and an add/subtract can be performed in parallel. Parallel instructions are indicated by placing two vertical lines in front of the second instruction.

For example, the following instruction adds the contents of *AR3 to R2 and puts the result in R5. At the same time, it stores the previous contents of the R5 into the location *AR0.

```

      ADDF  *AR3++,R2,R5
||  STF    R5,*AR0--

```

Note that the parallel instructions are not really two instructions but one, which is also different from its two components. However, the syntax used helps remembering the instruction mnemonics. One of the most important parallel instructions for DSP applications is the parallel execution of a multiplication with an addition or subtraction. This single-cycle multiply-accumulate is very important in the computation of dot products appearing in vector arithmetic, matrix multiplication, digital filtering, etc.

For example, assume that we want to take the dot product of two vectors having 15 points each. Assume that AR0 points to one vector and AR1 to the other. The dot product can be computed with the following code:

```

LDF    0.0,R2                ; Initialize R2=0.0
LDF 0.0,R0                    ; Initialize R0=0.0
RPTS 14                       ; Repeat loop (single instruction)
MPYF *AR0++, *AR1++, R0      ; Multiply two points, and
||  ADDF R0,R2                ; Accumulate previous product
    ADDF R0,R2                ; Accumulate last product

```

After the operation is completed, R2 holds the dot product.

Before proceeding with the instructions, it is important to understand the working of the device pipeline. At every instant in time, there are 4 execution units operating in parallel in the TMS320C30: the fetch, decode, read, and execute unit, in order of increasing priority. The fetch unit fetches the instruction; the decode unit decodes the instruction and generates the addresses; the read unit reads the operands from the memory or the registers; and the execute unit performs the operation specified in the instruction. Each one of these units takes one cycle to complete. So, an instruction in isolation takes, actually, four cycles to complete. Of course, you never run a single instruction alone.

In the pipeline configuration, as shown in Fig. 77.17, when an instruction is fetched, the previous instruction is decoded. At the same time, the operands of the instruction before that are read, while the third instruction before the present one is executed. So, after the pipeline is full, each instruction takes a single cycle to execute.

FIGURE 77.17: Pipeline structure of the TMS320C30.

Is it true that all the instructions take a single cycle to execute? No. There are some instructions, like the subroutine calls and the repeat instructions, that need to flush the pipeline before proceeding. The regular branch instructions also need to flush the pipeline. All the other instructions, though, should take one cycle to execute, if there are no pipeline conflicts.

There are a few reasons that can cause pipeline conflicts, and if the programmer is aware of where the conflicts occur, he can take steps to reorganize his code and eliminate them. In this way, the device throughput is maximized. The pipeline conflicts are examined in detail in the User's Guide [2].

The load and store instructions can load a word into a register, store the contents of a register to memory, or manipulate data on the system stack. Note that the instructions with the same functionality that operate on integers or floating-point numbers are presented together in the following selective listing.

LDF, LDI	Load a floating-point or integer value
LDFcond, LDIcond	Load conditionally
POPF, POP	Pop value from stack
PUSHF, PUSH	Push value on stack
STF, STI	Store value to memory

The conditional loads perform the indicated load only if the condition tested is true. The condition tested is, typically, the sign of the last performed operation.

The arithmetic instructions include both multiplier and ALU operations.

ABSF, ABSI	Absolute value
ADDF, ADDI	Add
CMPE, CMPI	Compare values
FIX, FLOAT	Convert between fixed- and floating-point
MPYF, MPYI	Multiply
NEGF, NEGI	Negate
SUBF, SUBI	Subtract
SUBRF, SUBRI	Reverse subtract

The difference between the subtract and the reverse subtract instructions is that the first one subtracts the first operand from the second, while the second one subtracts the second operand from the first.

The logical instructions always operate on integer (or unsigned) operands.

AND	Bitwise logical AND
ANDN	Bitwise logical AND with complement
LSH	Logical shift
NOT	Bitwise logical complement
OR	Bitwise logical OR
XOR	Bitwise exclusive OR

The logical shift differs from an arithmetic shift (which is part of the arithmetic instructions) in that, on a right shift, the logical shift fills the bits to the left with zeros. The arithmetic shift sign-extends the (integer) number.

The program control instructions include the branch instructions (corresponding to GOTO of a high-level languages), and the subroutine call and return instructions.

Bcond[D]	Branch conditionally [with delay]
CALL, CALLcond	Call or call conditionally a subroutine
RETIcond, RETScond	Return from interrupt or subroutine conditionally
RPTB, RPTS	Repeat block or repeat a single instruction

The branch instructions can have an optional “D” at the end to convert them into delayed branches. The delayed branch does the same operation as a regular branch but it takes fewer cycles. A regular branch needs to flush the pipeline before proceeding with the next instruction because it is not known in advance if the branch will be taken or not. As a result, a regular branch costs four machine cycles. If, however, there are three instructions that can be executed no matter if the branch is taken or not, a delayed branch can be used. In a delayed branch, the three instructions following the branch instruction are executed before the branch takes effect. This reduces the effective cost of the delayed branch to one cycle.

77.14 Other Generations and Devices in the TMS320 Family

So far, the discussion in this article has focused on two specific devices of the TMS320 family in order to examine in detail their features. However, the TMS320 family consists of five generations (three fixed-point and two floating-point) of digital signal processors (as well as the latest addition, the TMS320C8x generation, also known as MVP, Multimedia Video Processors). The fixed-point devices

are members of the TMS320C1x, TMS320C2x, or TMS320C5x generation, and the floating-point devices belong to the TMS320C3x or TMS320C4x generation.

The TMS320C5x generation is the highest-performance generation of the TI 16-bit fixed-point digital signal processors. The 'C5x performance level is achieved through a faster cycle time, larger on-chip memory space, and systematic integration of more signal-processing functions. As an example, the TMS320C50 (Fig. 77.18) features large on-chip RAM blocks. It is source-code upward-compatible with the first- and second-generation TMS320 devices.

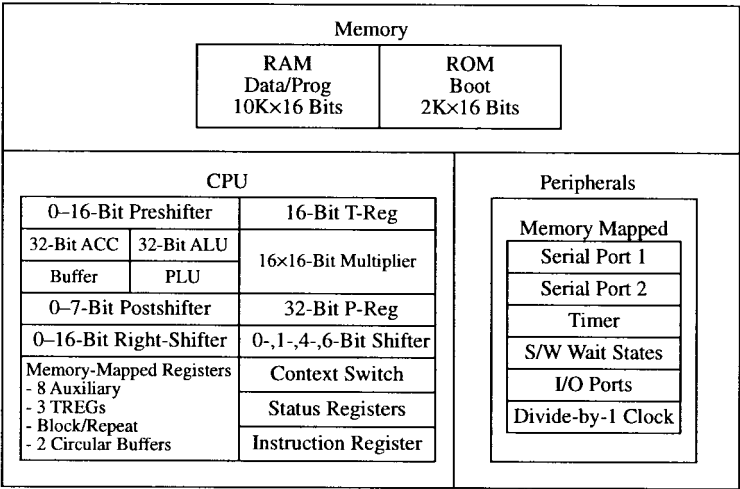

FIGURE 77.18: TMS320C50 Block diagram.

Some of the key features of the TMS320C5x generation are listed below. Specific devices that have a particular feature are enclosed in parentheses.

- CPU
 - 25-, 35-, 50-ns single-cycle instruction execution time
 - Single-cycle multiply/accumulate for program code
 - Single-cycle/single-word repeats and block repeats for program code
 - Block memory moves
 - Four-deep pipeline
 - Indexed-addressing mode
 - Bit-reversed/indexed-addressing mode to facilitate FFTs
 - Power-down modes
 - 32-bit ALU, 32-bit accumulator, and 32-bit accumulator buffer
 - Eight auxiliary registers with a dedicated arithmetic unit for indirect addressing
 - 16-bit parallel logic unit (PLU)
 - 16×16-bit parallel multiplier with a 32-bit product capacity
 - 0- to 16-bit right and left barrel-shifters
 - 64-bit incremental data shifter
 - Two indirectly addressed circular data buffers for circular addressing

- Peripherals

- Eight-level hardware stack
- 11 context-switch registers to shadow the contents of strategic CPU-controlled registers during interrupts
- Full-duplex, synchronous serial port, which directly interfaces to codec
- Time-division multiplexed (TDM) serial port (TMS320C50/C51/C53)
- Interval timer with period and control registers for software stops, starts, and resets
- Concurrent external DMA performance, using extended holds
- On-chip clock generator
- Divide-by-one clock generator (TMS320C50/C51/C53)
- Multiply-by-two clock generator (TMS320C52)

- Memory

- 10K×16-bit single cycle on-chip program/data RAM (TMS320C50)
- 2K×16-bit single cycle on-chip program/data RAM (TMS320C51)
- 1K×16 RAM (TMS320C52)
- 4K×16 RAM (TMS320C53)
- 2K×16-bit single cycle on-chip boot ROM (TMS320C50)
- 8K×16-bit single cycle on-chip boot ROM (TMS320C51)
- 4K×16 ROM (TMS320C52)
- 16K×16 ROM (TMS320C53)
- 1056X16-bit dual-access on-chip data/program RAM

- Memory interfaces

- 16 programmable software wait-state generators for program, data, and I/O memories
- 224K-word × 16-bit maximum addressable external memory space

Table 77.5 shows the overall TMS320 family. It provides a tabulated overview of each member's memory capacity, number of I/O ports (by type), cycle time, package type, technology, and availability.

Many features are common among these TMS320 processors. When the term TMS320 is used, it refers to all five generations of DSP devices. When referring to a specific member of the TMS320 family (e.g., TMS320C15), the name also implies enhanced-speed in MHz (-14, -25, etc.), erasable/programmable (TMS320E15), low-power (TMS320LC15), and one-time programmable (TMS320P15) versions. Specific features are added to each processor to provide different cost/performance alternatives.

The Rapid Prototyping of Application-Specific Signal Processors (RASSP) [1, 2, 3] program of the U.S. Department of Defense (ARPA and Tri-Services) targets a 4X improvement in the design, prototyping, manufacturing, and support processes (relative to current practice). Based on a current practice study (1993) [4], the prototyping time from system requirements definition to production and deployment, of multiboard signal processors, is between 37 and 73 months. Out of this time, 25 to 49 months are devoted to detailed hardware/software (HW/SW) design and integration (with 10 to 24 months devoted to the latter task of integration). With the utilization of a promising top-down hardware-less codesign methodology based on VHDL models of HW/SW components at multiple abstractions, reduction in design time has been shown especially in the area of hardware/software integration [5]. The authors describe a top-down design approach in VHDL starting with the capture of system requirements in an executable form and through successive stages of design refinement, ending with a detailed

hardware design. This hardware/software codesign process is based on the RASSP program design methodology called virtual prototyping, wherein VHDL models are used throughout the design process to capture the necessary information to describe the design as it develops through successive refinement and review. Examples are presented to illustrate the information captured at each stage in the process. Links between stages are described to clarify the flow of information from requirements to hardware.

78.1 Introduction

We describe a RASSP-based design methodology for application specific signal processing systems which supports reengineering and upgrading of legacy systems using a virtual prototyping design process. The VHSIC Hardware Description Language (VHDL) [6] is used throughout the process for the following reasons. One, it is an IEEE standard with continual updates and improvements; two, it has the ability to describe systems and circuits at multiple abstraction levels; three, it is suitable for synthesis as well as simulation; and four, it is capable of documenting systems in an executable form throughout the design process.

A *Virtual Prototype* (VP) is defined as an executable requirement or specification of an embedded system and its stimuli describing it in operation at multiple levels of abstraction. *Virtual prototyping* is defined as the top-down design process of creating a virtual prototype for hardware and software cospecification, codesign, cosimulation, and coverification of the embedded system. The proposed top-down design process stages and corresponding VHDL model abstractions are shown in Fig. 78.1. Each stage in the process serves as a starting point for subsequent stages. The testbench developed for requirements capture is used for design verification throughout the process. More refined subsystem, board, and component level testbenches are also developed in-cycle for verification of these elements of the system.

The process begins with requirements definition which includes a description of the general algorithms to be implemented by the system. An algorithm is here defined as a system's signal processing transformations required to meet the requirements of the high level paper specification. The model abstraction created at this stage, the *executable requirement*, is developed as a joint effort between contractor and customer in order to derive a top-level design guideline which captures the customer intent. The executable requirement removes the ambiguity associated with the written specification. It also provides information on the types of signal transformations, data formats, operational modes, interface timing data and control, and implementation constraints. A description of the executable requirement for an MPEG decoder is presented later. Section 78.4 addresses this subject in more detail.

Following the executable requirement, a top-level *executable specification* is developed. This is sometimes referred to as functional level VHDL design. This executable specification contains three general categories of information: (1) the system timing and performance, (2) the refined internal function, and (3) the physical constraints such as size, weight, and power. System timing and performance information include I/O timing constraints, I/O protocols, and system computational latency. Refined internal function information includes algorithm analysis in fixed/floating point, control strategies, functional breakdown, and task execution order. A functional breakdown is developed in terms of primitive signal processing elements which map to processing hardware cells or processor specific software libraries later in the design process. A description of the executable specification of the MPEG decoder is presented later. Section 78.5 investigates this subject in more detail.

The objective of data and control flow modeling is to refine the functional descriptions in the executable specification and capture concurrency information and data dependencies inherent in the algorithm. The intent of the refinement process is to generate multiple implementation independent

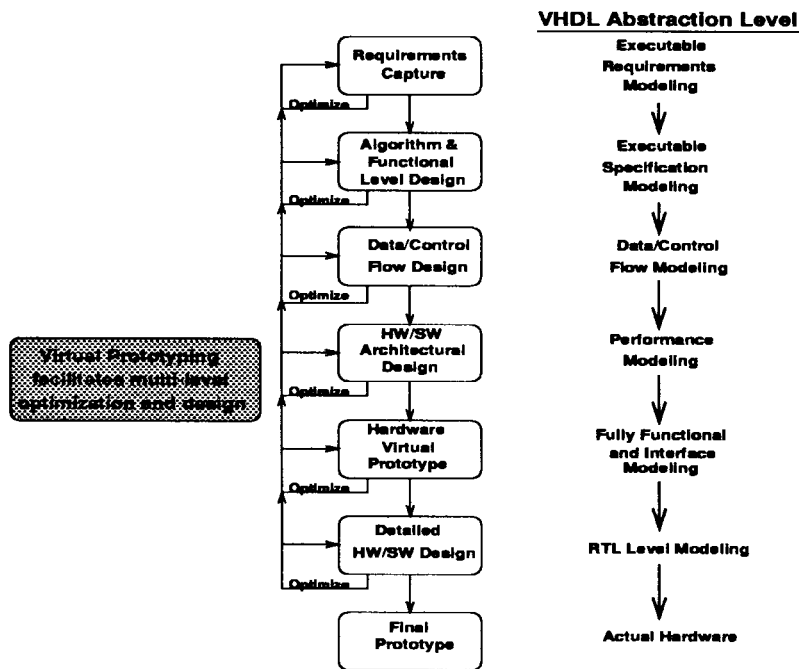

FIGURE 78.1: The VHDL top-down design process.

representations of the algorithm. The implementations capture potential parallelism in the algorithm at a primitive level. The primitives are defined as the set of functions contained in a design library consisting of signal processing functions such as Fourier transforms or digital filters at course levels and of adders and multipliers at more fine-grained levels. The control flow can be represented in a number of ways ranging from finite state machines for low level hardware to run-time system controllers with multiple application data flow graphs. Section 78.6 investigates this abstraction model.

After defining the functional blocks, data flow between the blocks, and control flow schedules, hardware-software design trade-offs are explored. This requires architectural design and verification. In support of architecture verification, *performance level modeling* is used. The performance level model captures the time aspects of proposed design architectures such as system throughput, latency, and utilization. The proposed architectures are compared using cost function analysis with system performance and physical design parameter metrics as input. The output of this stage is one or few optimal or nearly optimal system architectural choice(s). In this stage, the interaction between hardware and software is modeled and analyzed. In general, models at this abstraction level are not concerned with the actual data in the system but rather the flow of data through the system. An abstract VHDL data type known as a token captures this flow of data. Examples of performance level models are shown later. Sections 78.7 and 78.8 address architecture selection and architecture verification, respectively.

Following architecture verification using performance level modeling, the structure of the system in terms of processing elements, communications protocols, and input/output requirements is established. Various elements of the defined architecture are refined to create hardware virtual prototypes. *Hardware virtual prototypes* are defined as *software simulatable* models of hardware components, boards, or systems containing sufficient accuracy to guarantee their successful realization in actual hardware. At this abstraction level, fully functional models (FFMs) are utilized. FFMs capture both

internal and external (interface) functionality completely. Interface models capturing only the external pin behavior are also used for hardware virtual prototyping. Section 78.9 describes this modeling paradigm.

Application specific component designs are typically done in-cycle and use register transfer level (RTL) model descriptions as input to synthesis tools. The tool then creates gate level descriptions and final layout information. The RTL description is the lowest level contained in the virtual prototyping process and will not be discussed in this paper because existing RTL methodologies are prevalent in the industry.

At least six different hardware/software codesign methodologies have been proposed for rapid prototyping in the past few years. Some of these describe the various process steps without providing specifics for implementation. Others focus more on implementation issues without explicitly considering methodology and process flow. In the next section, we illustrate the features and limitations of these approaches and show how they compare to the proposed approach.

Following the survey, Section 78.3 lays the groundwork necessary to define the elements of the design process. At the end of the paper, Section 78.10 describes the usefulness of this approach for life cycle support and maintenance.

78.2 Survey of Previous Research

The codesign problem has been addressed in recent studies by Thomas et al. [7], Kumar et al. [8], Gupta et al. [9], Kalavade et al. [10, 11], and Ismail et al. [12]. A detailed taxonomy of HW/SW codesign was presented by Gajski et al. [13]. In the taxonomy, the authors describe the desired features of a codesign methodology and show how existing tools and methods try to implement them. However, the authors do not propose a method for implementing their process steps. The features and limitations of the latter approaches are illustrated in Fig. 78.2 [14]. In the table, we show how these approaches compare to the approach presented in this chapter with respect to some desired attributes of a codesign methodology. Previous approaches lack automated architecture selection tools, economic cost models, and the integrated development of test benches throughout the design cycle. Very few approaches allow for true HW/SW cosimulation where application code executes on a simulated version of the target hardware platform.

78.3 Infrastructure Criteria for the Design Flow

Four enabling factors must be addressed in the development of a VHDL model infrastructure to support the design flow mentioned in the introduction. These include model verification/validation, interoperability, fidelity, and efficiency.

Verification, as defined by IEEE/ANSI, is the process of evaluating a system or component to determine whether the products of a given development phase satisfy the conditions imposed at the start of that phase. Validation, as defined by IEEE/ANSI, is the process of evaluating a system or component during or at the end of the development process to determine whether it satisfies the specified requirements. The proposed methodology is broken into the design phases represented in Figure 78.1 and uses black- and white-box software testing techniques to verify, via a structured simulation plan, the elements of each stage. In this methodology, the concept of a reference model, defined as the next higher model in the design hierarchy, is used to verify the subsequently more detailed designs. For example, to verify the gate level model after synthesis, the test suite applied to the RTL model is used. To verify the RTL level model, the reference model is the fully functional model. Moving test creation, test application, and test analysis to higher levels of design abstraction, the test description developed by the test engineer is more easily created and understood. The higher functional models are less complex than their gate level equivalents. For system and subsystem verification, which include the integration of multiple component models, higher level models improve the overall simulation time. It has been shown that a processor model at the fully functional level can operate over 1000 times faster than its gate level equivalent while maintaining clock cycle accuracy [5]. Verification also requires efficient techniques for test creation via automation and reuse and requirements compliance capture and test application via structured testbench development.

Interoperability addresses the ability of two models to communicate in the same simulation environment. Interoperability requirements are necessary because models usually developed by multiple design teams and from external vendors must be integrated to verify system functionality. Guidelines and potential standards for all abstraction levels within the design process must be defined when current descriptions do not exist. In the area of fully functional and RTL modeling, current practice is to use IEEE Std. 1164 — 1993 nine-valued logic packages [15]. Performance modeling standards are an ongoing effort of the RASSP program.

Fidelity addresses the problem of defining the information captured by each level of abstraction within the top-down design process. The importance of defining the correct fidelity lies in the fact that information not relevant within a model at a particular stage in the hierarchy requires unnecessary simulation time. Relevant information must be captured efficiently so simulation times improve as one moves toward the top of the design hierarchy. Figure 78.3 describes the RASSP taxonomy [16] for accomplishing this objective. The diagram illustrates how a VHDL model can be described using five resolution axes; temporal, data value, functional, structural, and programming level. Each line is continuous and discrete labels are positioned to illustrate various levels ranging from high to low resolution. A full specification of a model's fidelity requires two charts, one to describe the internal attributes of the model and the second for the external attributes. An “X” through a particular axis implies the model contains no information on the specific resolution. A compressed textual representation of this figure will be used throughout the remainder of the paper. The information is captured in a 5-tuple as follows,

$$\{(\text{Temporal Level}), (\text{Data Value}), (\text{Function}), (\text{Structure}), (\text{Programming Level})\}$$

The temporal axis specifies the time scale of events in the model and is analogous to precision as distinguished from accuracy. At one extreme, for the case of purely functional models, no time is modeled. Examples include Fast Fourier Transform and FIR filtering procedural calls. At the other extreme, time resolutions are specified in gate propagation delays. Between the two extremes,

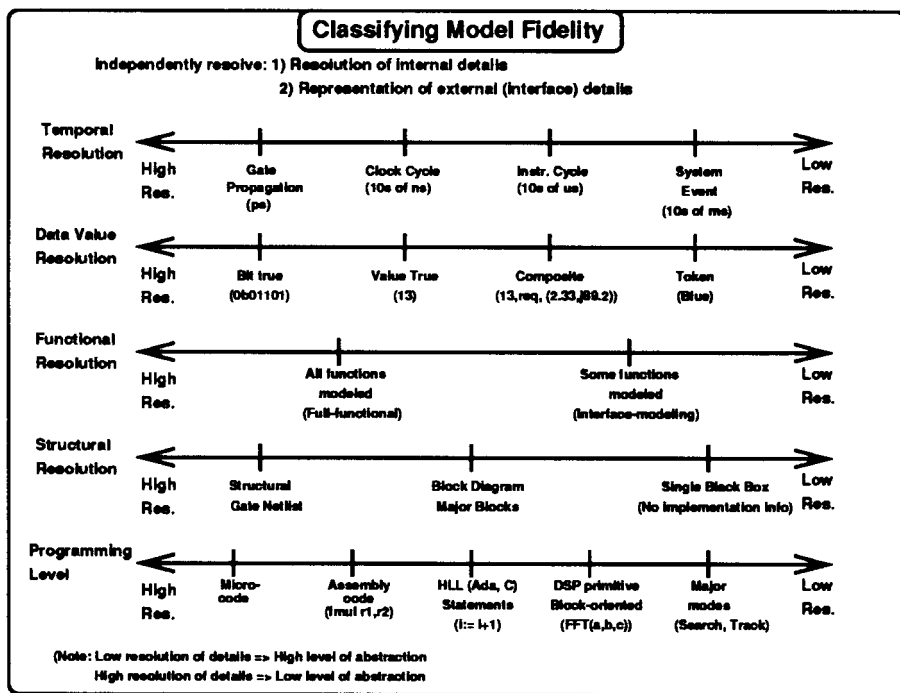

FIGURE 78.3: A model fidelity classification scheme.

models may be time accurate at the clock level for the case of fully functional processor models, at the instruction cycle level for the case of performance level processor models, or at the system level for the case of application graph switching. In general, higher resolution models require longer simulation times due to the increased number of event transactions.

The data value axis specifies the data resolution used by the model. For high resolution models, data is represented with bit true accuracy and is commonly found in gate level models. At the low end of the spectrum, data is represented by abstract token types where data is represented by enumerated values, for example, *blue*. Performance level modeling uses tokens as its data type. The token only captures the control information of the system and no actual data. For the case of no data, the axis would be represented with an "X". At intermediate levels, data is represented with its correct value but at a higher abstraction (i.e., integer or composite types, instead of the actual bits). In general, higher resolutions require more simulation time.

Functional resolution specifies the detail of device functionality captured by the model. At one extreme, no functions are modeled and the model represents the processing functionality as a simple time delay (i.e., no actual calculations are performed). At the high end, all the functions are implemented within the model. As an example, for a processor model, a time delay is used to represent the execution of a specific software task at low resolutions while the actual code is executed on the model for high resolution simulations. As a rule of thumb, the more functions represented, the slower the model executes during simulation.

The structural axis specifies how the model is constructed from its constituent elements. At the low end, the model looks like a black box with inputs and outputs but no detail as to the internal contents. At the high end the internal structure is modeled with very fine detail, typically as a structural net list of lower level components. In the middle, the major blocks are grouped according to related functionality.

The final level of detail needed to specify a model is its programmability. This describes the granularity at which the model interprets software elements of a system. At one extreme, pure hardware is specified and the model does not interpret software, for example, a special purpose FFT processor hard wired for 1024 samples. At the other extreme, the internal micro-code is modeled at the detail of its datapath control. At this resolution, the model captures precisely how the micro-code manipulates the datapath elements. At decreasing resolutions the model has the ability to process assembly code and high level languages as input. At even lower levels, only DSP primitive blocks are modeled. In this case, programming consists of combining functional blocks to define the necessary application. Tools such as MATLAB/Simulink provide examples for this type of model granularity. Finally, models can be programmed at the level of the major modes. In this case, a run-time system is switched between major operating modes of a system by executing alternative application graphs.

Finally, efficiency issues are addressed at each level of abstraction in the design flow. Efficiency will be discussed in coordination with the issues of fidelity where both the model details and information content are related to improving simulation speed.

78.4 The Executable Requirement

The methodology for developing signal processing systems begins with the definition of the system requirement. In the past, common practice was to develop a textual specification of the system. This approach is flawed due to the inherent ambiguity of the written description of a complex system. The new methodology places the requirements in an executable format enforcing a more rigorous description of the system. Thus, VHDL's first application in the development of a signal processing system is an *executable requirement* which may include signal transformations, data format, modes of operation, timing at data and control ports, test capabilities, and implementation constraints [17]. The executable requirement can also define the minimum required unit of development in terms of performance (e.g., SNR, throughput, latency, etc.). By capturing the requirements in an executable form, inconsistencies and missing information in the written specification can also be uncovered during development of the requirements model.

An executable requirement creates an “environment” wherein the surroundings of the signal processing system are simulated. Figure 78.4 illustrates a system model with an accompanying testbench. The testbench generates control and data signals as stimulus to the system model. In addition, the testbench receives output data from the system model. This data is used to verify the correct operation of the system model. The advantages of an executable requirement are varied. First, it serves as a mechanism to define and refine the requirements placed on a system. Also, the VHDL source code along with supporting textual description becomes a critical part of the requirements documentation and life cycle support of the system. In addition, the testbench allows easy examination of different command sequences and data sets. The testbench can also serve as the stimulus for any number of designs. The development of different system models can be tested within a single simulation environment using the same testbench. The requirement is easily adaptable to changes that can occur in lower levels of the design process. Finally, executable requirements are formed at all levels of abstraction and create a documented history of the design process. For example, at the system level, the environment may consist of image data from a camera while at the ASIC level it may be an interface model of another component.

The RASSP program, through the efforts of MIT Lincoln Laboratory, created an executable requirement [18] for a synthetic aperture radar (SAR) algorithm and documented many of the lessons learned in implementing this stage in the top-down design process. Their high level requirements model served as the baseline for the design of two SAR systems developed by separate contractors, Lockheed Sanders and Martin Marietta Advanced Technology Labs. A test bench generation system for capturing high level requirements and automating the creation of VHDL is presented in [19]. In

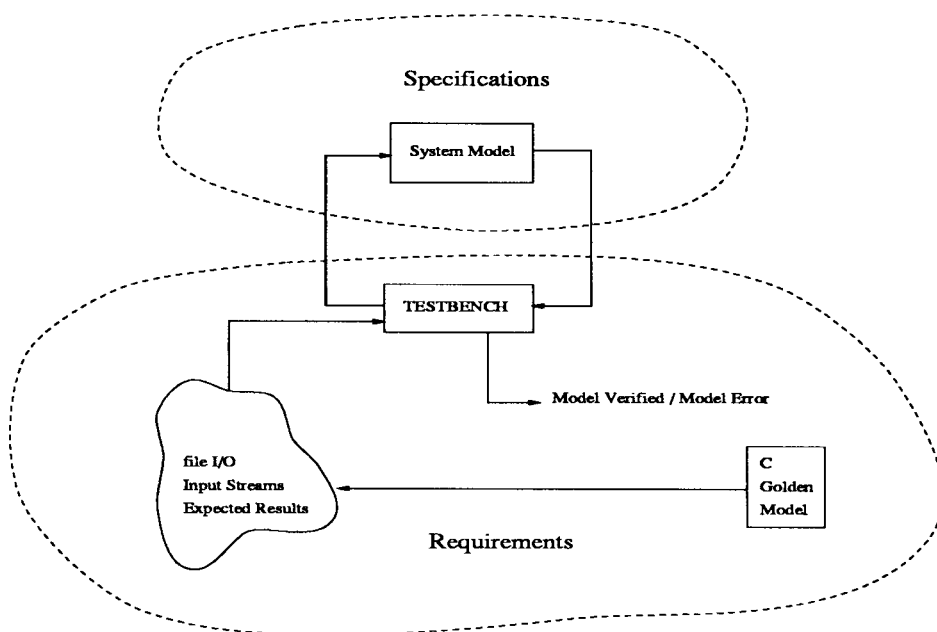

FIGURE 78.4: Illustration of the relation between executable requirements and specifications.

the following sections, we present the details of work done at Georgia Tech in creating an executable requirement and specification for an MPEG-1 decoder.

78.4.1 An Executable Requirements Example: MPEG-1 Decoder

MPEG-1 is a video compression-decompression standard developed under the International Standard Organization originally targeted at CD-ROMs with a data rate of 1.5 Mbits/sec [20]. MPEG-1 is broken into 3 layers: system, video, and audio. Table 78.1 depicts the system clock frequency requirement taken from layer 1 of the MPEG-1 document.¹ The system time is used to control when video frames are decoded and presented via decoder and presentation time stamps contained in the ISO 11172 MPEG-1 bitstream. A VHDL executable rendition of this requirement is illustrated in 78.5.

TABLE 78.1 MPEG-1 System Clock Frequency Requirement Example

Layer 1 - System requirement example from ISO 11172 standard	
System clock frequency	The value of the system clock frequency is measured in Hz and shall meet the following constraints: $90,000 - 4.5 \text{ Hz} \leq \text{system_clock_frequency} \leq 90,000 + 4.5 \text{ Hz}$ Rate of change of system_clock_frequency $\leq 250 * 10^{-6} \text{ Hz/s}$

The testbench of this system uses an MPEG-1 bitstream created from a “golden C model” to ensure

¹Our efforts at Georgia Tech have only focused on layers 1 and 2 of this standard.

```

- system_time_clk process is a clock process that counts at a rate
- of 90kHz as per MPEG-I requirement. In addition, it is updated by
- the value of the incoming SCR fields read from the ISO11172 stream.
-
system_time_clock : PROCESS(stc_strobe,sys_clk)
    VARIABLE clock_count : INTEGER := 0;
    VARIABLE SCR_system_time_var : bit33;
    CONSTANT clock_divider : INTEGER := 2;
BEGIN
    IF mpeg_go = '1' THEN
        - if stc_strobe is high then update system_time value to latest SCR
        IF (stc_strobe = '1') AND (stc_strobe'EVENT) THEN
            system_time <= system_clock_ref;
            clock_count := 0; - reset counter used for clock downsample
        ELSIF (sys_clk = '1') AND (sys_clk'EVENT) THEN
            clock_count := clock_count + 1;
            IF clock_count MOD clock_divider = 0 THEN
                system_time_var := system_time + one;
                system_time <= system_time_var;
            END IF;
        END IF;
    END IF;
END PROCESS system_time_clock;

```

FIGURE 78.5: System clock frequency requirement example translated to VHDL.

correct input. A public-domain C version of an MPEG encoder created at UCAL-Berkeley [21] was used as the golden C model to generate the input for the executable requirement. From the testbench, an MPEG bitstream file is read as a series of integers and transmitted to the MPEG decoder model at a constant rate of 174300 Bytes/sec along with a system clock and a control line named *mpeg_go* which activates the decoder. Only 50 lines of VHDL code are required to characterize the top level testbench. This is due to the availability of the golden C MPEG encoder and a shell script which wraps around the output of the golden C MPEG encoder bitstream with system layer information. This script is necessary because there are no *complete* MPEG software codecs in the public domain, i.e., they do not include the system information in the bitstream. Figure 78.6 depicts the process of verification using golden C models. The golden model generates the bitstream sent to the testbench. The testbench reads the bitstream as a series of integers. These are in turn sent as data into the VHDL MPEG decoder model driven with appropriate clock and control lines. The output of the VHDL model is compared with the output of the golden model (also available from Berkeley) to verify the correct operation of the VHDL decoder. A warning message alerts the user to the status of the model's integrity.

The advantage of the configuration illustrated in Figure 78.6 is its reusability. An obvious example is MPEG-2 [22], another video compression-decompression standard targeted for the all-digital transmission of broadcast TV quality video at coded bit rates between 4 and 9 Mbits/sec. The same testbench structure could be used by replacing the golden C models with their MPEG-2 counterparts. While the system layer information encapsulation script would have to be changed, the testbench itself remains the same because the interface between an MPEG-1 decoder and its surrounding environment is identical to the interface for an MPEG-2 decoder. In general, this testbench configuration could be used for a wide class of video decoders. The only modifications would be the golden C models and the interface between the VHDL decoder model and the testbench. This would involve making only minor alterations to the testbench itself.

78.5 The Executable Specification

The executable specification depicted in Fig. 78.4 processes and responds to the outside stimulus, provided by the executable requirement, through its interface. It reflects the particular function and timing of the intended design. Thus, the executable specification describes the behavior of the design and is timing accurate without consideration of the eventual implementation. This allows the user to evaluate the completeness, logical correctness, and algorithmic performance of the system through

FIGURE 78.6: MPEG-1 decoder executable requirement.

the test bench. The creation of this formal specification helps identify and correct functional errors at an early stage in the design and reduce total design time [13, 16, 23, 24].

The development of an executable specification is a complex task. Very often, the required functionality of the system is not well-understood. It is through a process of learning, understanding, and defining that a specification is crystallized. To specify system functionality, we decompose it into elements. The relationship between these elements is in terms of their execution order and the data passing between them. The executable specification captures:

- the refined internal functionality of the unit under development (some algorithm parallelism, fixed/floating point bit level accuracies required, control strategies, functional breakdown, task execution order)
- physical constraints of the unit such as size, weight, area, and power
- unit timing and performance information (I/O timing constraints, I/O protocols, computational complexity)

The purpose of VHDL at the executable specification stage is to create a formalization of the elements in a system and their relationships. It can be thought of as the high level design of the unit under development. And although we have restricted our discussion to the system level, the executable specification may describe any level of abstraction (algorithm, system, subsystem, board, device, etc.).

The allure of this approach is based on the user's ability to see what the performance "looks" like. In addition, a stable test mechanism is developed early in the design process (note the complementary relation between the executable requirement and specification). With the specification precisely defined, it becomes easier to integrate the system with other concurrently designed systems. Finally, this executable approach facilitates the re-use of system specifications for the possible redesign of the system.

In general, when considering the entire design process, executable requirements and specifications can potentially cover any of the possible resolutions in the fidelity classification chart. However, for any particular specification or requirement, only a small portion of the chart will be covered. For

example, the MPEG decoder presented in this and the previous section has the fidelity information represented by the 5-tuple below,

Internal: {(Clock cycle), (Bit true \rightarrow Value true), (All), (Major blocks), (X)}
External: {(Clock cycle), (Value true), (Some), (Black box), (X)},

where (Bit true \rightarrow Value true) means all resolutions between bit true and value true inclusive.

From an internal viewpoint, the timing is at the system clock level, data is represented by bits in some cases and integers in others, the structure is at the major block level, and all the functions are modeled. From an external perspective, the timing is also at the system clock level, the data is represented by a stream of integers, the structure is seen as a single black box fed by the executable requirement and from an external perspective the function is only modeled partially because this does not represent an actual chip interface.

78.5.1 An Executable Specification Example: MPEG-1 Decoder

As an example, an MPEG-1 decoder executable specification developed at Georgia Tech will be examined in detail. Figure 78.7 illustrates how the system functionality was broken into a discrete number of elements. In this diagram each block represents a process and the lines connecting them are signals. Three major areas of functionality were identified from the written specification: memory, control, and the video decoder itself. Two memory blocks, *video_decode_memory* and *system_level_memory* are clearly labeled. The *present_frame_to_decode_file* process contains a frame reorder buffer which holds a frame until its presentation time. All other VHDL processes with the exception of *decode_video_frame_process* are control processes and pertain to the systems layer of the MPEG-1 standard. These processes take the incoming MPEG-1 bitstream and extract system layer information. This information is stored in the *system_level_memory* process where other control processes and the video decoder can access pertinent data. After removing the system layer information from the MPEG-1 bitstream, the remainder is placed in the *video_decode_memory*. This is the input buffer to the video decoder. It should be noted that although MPEG-1 is capable of up to 16 simultaneous video streams multiplexed into the MPEG-1 bitstream only one video stream was selected for simplicity.

The last process, *decode_video_frame_process*, contains all the subroutines necessary to decode the video bitstream from the video buffer (*video_decode_memory*). MPEG video frames are broken into 3 types: (I)ntra, (P)redictive, and (B)idirectional. I frames are coded using block discrete cosine transform (DCT) compression. Thus, the entire frame is broken into 8×8 blocks, transformed with a DCT and the resulting coefficients transmitted. P frames use the previous frame as a prediction of the current frame. The current frame is broken into 16×16 blocks. Each block is compared with a corresponding search window (e.g., 32×32 , 48×48) in the previous frame. The 16×16 block within the search window which best matches the current frame block is determined. The motion vector identifies the matching block within the search window and is transmitted to the decoder. B frames are similar to P frames except a previous frame and a future frame are used to estimate the best matching block from either of these frames or an average of the two. It should be noted that this requires the encoder and decoder to store these 2 reference frames.

The functions contained in the *decode_video_frame_process* are shown in Fig. 78.8. In the diagram, there are three main paths representing the procedures or functions in the executable specification which process the I, P, or B frame, respectively. Each box below a path encloses all the procedures executed from within that function. Beneath each path is an estimate of the number of computations required to process each frame type. Comparing the three executable paths in this diagram, one observes the large similarity between each path. Overall, only 25 unique routines are called to process the video frame. By identifying key functions within the video decoding algorithm itself,

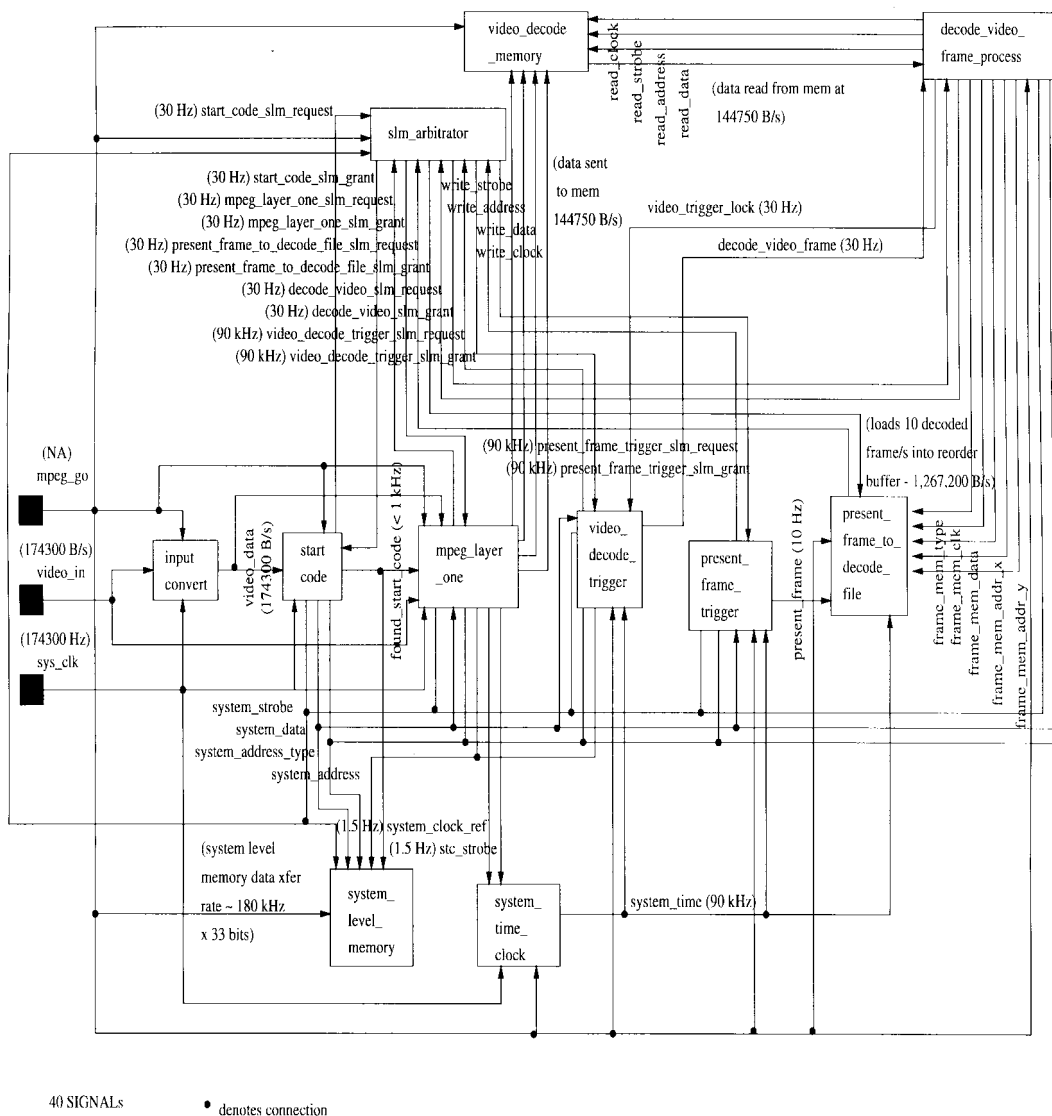

FIGURE 78.7: System functionality breakdown for MPEG-1 decoder.

efficient and reusable code can be created. For instance, the data transmitted from the encoder to the decoder is compressed using a Huffman scheme. The procedures *vlc*, *advance_bit*, and *extract_n_bits* perform the Huffman decode function and miscellaneous parsing of the MPEG-1 video bitstream. Thus, this set of procedures can be used in each frame type execution path. Reuse of these procedures can be applied in the development of an MPEG-2 decoder executable specification. Since MPEG-2 is structured as a super set of the syntax defined in MPEG-1, there are many procedures that can be utilized with only minor modifications. Other procedures such as *motion_compensate_forward* and *idct* can be reused in a variety of DCT-based video compression algorithms.

The executable specification also allows detailed analysis of the computational complexity on a procedural level. Table 78.2 lists the computational complexity of some of the procedures identified in Fig. 78.8. This breakdown identifies what areas of the algorithm are the most computationally intensive and the numbers were arrived at through a data flow analysis of the VHDL code. Within the MPEG-1 video decoder algorithm, the most intense computational loads occur in the inverse DCT and motion compensation procedures. Thus, such an analysis can alert the user early in the design process to potential design issues. While parallelism is a logical topic for the data and control flow

TABLE 78.2 Computational Complexity of Some Specification Procedures

modeling section, preliminary investigations can be made from the executable specification itself. With the specifications captured in a language, execution order and data passing between procedures are known precisely. This knowledge facilitates the user in extracting potential parallelism from the specification. From the MPEG-1 decoder executable specification, potential parallelism can be seen in several areas. In an I frame, no data dependencies are present between each 8×8 block. Therefore, an inverse DCT could potentially be performed on each 8×8 block in parallel. In P and B frames, data dependencies occur between consecutive 16×16 blocks (called macroblocks) but no data dependencies occur between slices (a grouping of consecutive macroblocks). Thus, parallelism is potentially exploitable at the slice and macroblock level. This information is passed to the data/control flow modeling phase where more detailed analysis of parallelism is done.

It is also possible to delve into implementation requirement issues at the executable specification level. Fixed vs. floating point trade-offs can be examined in detail. The necessary accuracy and resolution required to meet system requirements can be determined through the use of floating and fixed point packages written in VHDL. At Georgia Tech, fixed point packages have been developed. These packages allow the user to experiment with the executable specification and see the effect finite bit accuracy has on the system model. In addition, packages have been developed which implement specific arithmetic architectures such as the ADSP 2100 [25]. This analysis results in additional design requirements being passed to hardware and software developers in later design phases.

Finally, the executable specification allows the explicit capture of internal timing and control flow requirements of the MPEG-1 decoding algorithm itself. The written document is imprecise about the details of how timing considerations for presentation and decoder time stamps will be handled. The control necessary to trigger present and decode video frame events is difficult to articulate in a written form. The most difficult aspects of coding the executable specification for a

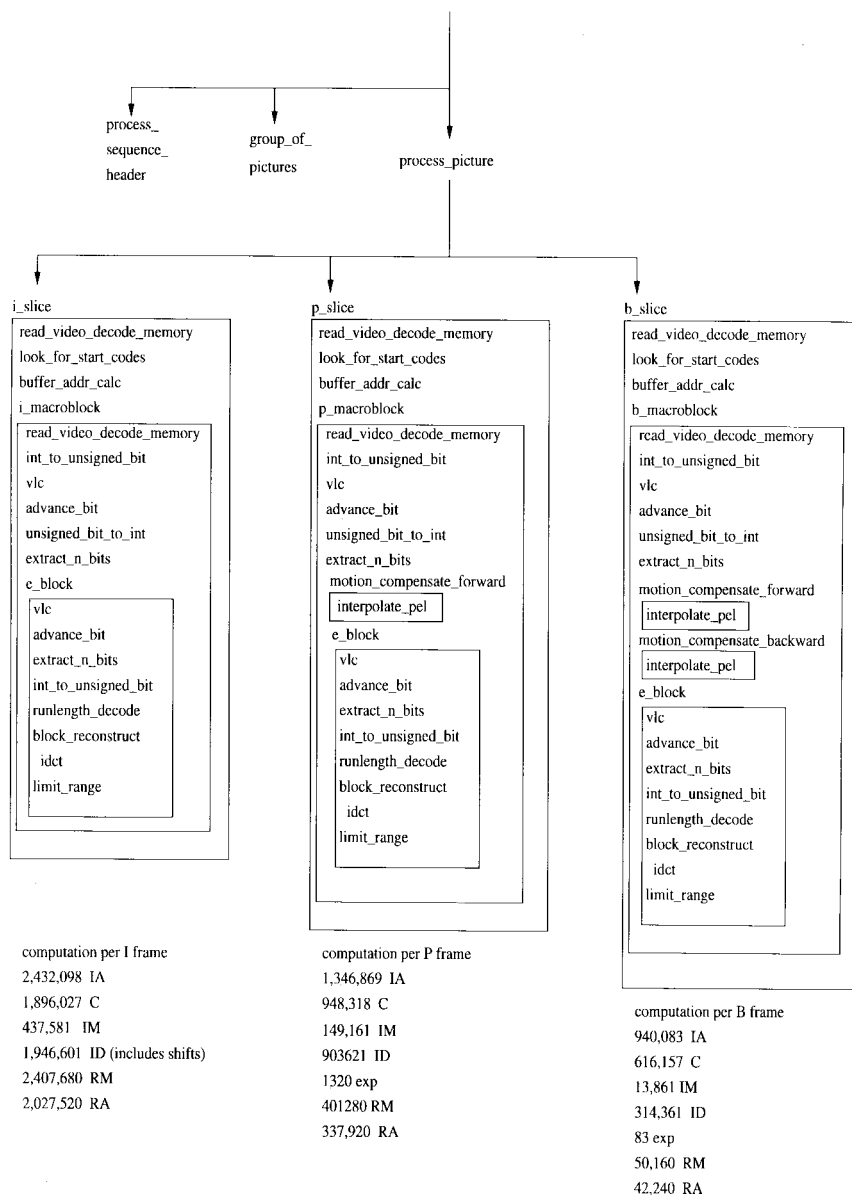

FIGURE 78.8: Description of procedural flow within MPEG-1 decoder executable specification.

MPEG-1 decoder were these considerations. The decoder itself hinges on developing a mechanism for robustly determining when to decode or present a frame in the buffer. Events must be triggered using a system time clock which is updated from the input bitstream itself. This task is handled by five processes (*start_code*, *mpeg_layer_one*, *video_decode_trigger*, *present_frame_trigger*, *present_frame_to_decode_file*) grouped around a common memory (*system_level_memory*). This memory was necessary to allow each concurrent process to access timing information extracted from the system layer of the input bitstream. These timing and control considerations had to fit into a larger system timing requirement. For a MPEG-1 decoder, the most critical timing constraints are initial latency and the fixed presentation rate (e.g., 30 frames/sec). All other timing considerations were driven by this requirement.

78.6 Data and Control Flow Modeling

This modeling level captures data and control flow information in the system algorithms. The objective of data flow modeling is to refine the functional descriptions in the executable specification and capture concurrency information and data dependencies inherent in the algorithm. The output of the refinement process is one or a few manually generated implementation independent representations of the algorithm. These multiple implementations capture potential algorithmic parallelism at a primitive level where primitives are defined as that set of functions contained in a design library. The primitives are signal processing functions such as Fast Fourier Transforms or filter routines at coarse-grained levels to adders and multipliers at more fine-grained levels. The breakdown of primitive elements depend on the granularity exploited by the algorithm as well as potential architectural design paradigms to which the algorithm is mapped. For example, if the design paradigm demands architectures using multiple commercial-off-the-shelf (COTS) RISC processors, the primitives consist of signal processing functional block level elements such as FFTs or FIR filters which exist as performance optimized library elements available for the specific processor. For custom computationally intense designs, the data flow of the algorithm may be dissected into lower primitive components such as adders and multipliers using bit-slice architectures. In our design flow, the fidelity captured by data/control flow models is shown below:

Internal: { (X), (Value true \rightarrow Composite), (All), (X), (Major modes) }
 External: { (X), (Value true \rightarrow Composite), (X), (X), (X) }.

Because the models are purely functional and their major objective is to refine the internal representation of the algorithm, there is no time information captured by its internal or external representation as illustrated by the “X”. The internal data processed by the model and external data loaded into the model are typically represented by standard data types such as *float* and/or *integer* and in some cases by composite data types such as records or arrays. All internal functionality is represented and is verified using the same data presented to the executable specification. No function is captured via external interfaces since data is input to the model through file input/output. The data processed by the executable specification is also processed by the data/control flow model. No internal or external structural information is captured since the model is implementation independent. Its level of programmability is represented at the application graph level. The applications are major modes of the system under investigation and hence at a low resolution. In general, because the primitive elements can represent adders and/or multipliers, programmability for data/control flow models can resolve to higher resolutions including the microcode level.

The implementation independent representations are compared with the executable specification using the test data supplied by the requirements development phase to verify compliance with the original algorithm design. The representations are then input to the architecture selection phase and, with additional metrics, determine the final architecture of the system.

Signal processing applications inherently follow the data flow execution model. Processing Graph Methodology (PGM) [26] from Naval Research Laboratory was developed specifically to capture signal processing applications. PGM supports specification of full system data flow and its associated control. An application is first captured as a graph, where nodes of the graph represent processing and edges represent queues that hold intermediate data between nodes. The scheduling criteria for each node is based on the state of its corresponding input/output queues. Each queue in the graph can be linked to one node at a time. Associated with each queue is a control block structure containing information such as size, current amount of data, and threshold. A run-time system provides a set of procedures used by each node to check the availability of data from the upstream queue or available space in the downstream queue. Applications consist of one or more graphs, one or more I/O procedures, and a run-time system interfaced with one or more command programs. The PGM graphs serve as the implementation independent representation of the algorithm discussed earlier. An example of a 2-D FFT PGM graph is presented in the next section.

Under the support of the RASSP program, a set of tools is being developed by Management Communications and Control, Inc. (MCCI) and Lockheed Martin Advance Technology Laboratories [27, 28]. The toolset automates the translation of software architecture specifications to design implementations of application and control software for a signal processing system. Hardware/software architectures are presented to the autocoding toolset as PGM application data flow graphs along with a candidate architectures file and graph partition lists. The lists are generated by hardware/software partitioning tools. The proposed partitions are then simulated for performance and verified against the top level specification for correct functionality. The verified partition graphs are then used as inputs to detailed design level autocode tools that generate actual source code. The source code implements the partitions processing specifications using the target processor's math library. It also produces a memory map converting all queues and variables to static buffers. Finally the application graph, with its set of source files, are translated to run-time data structures that are used by the run-time system to create an executable image of the application as distributed tasks on the target processors.

Other tools provide paths from specification to hardware and are briefly mentioned. The Ptolemy [29, 30] design system from the University of California at Berkeley provides a synchronous data flow domain which can be used to perform system level simulations. Silage, another product of UC Berkeley is a data flow modeling language. Data Flow Language (DFL), a commercial version of Silage is used in Mentor Graphics' DSP Station to perform algorithm/architecture tradeoffs. It also provides a path to synthesis as a high-level design entry tool.

78.6.1 Data and Control Flow Example

An example of a small PGM application is presented in Fig. 78.9. The graph represents a two dimensional FFT program implemented in PGM. The graph captures both the functionality and the data flow aspects of the application. The source data is read from a file and represents the I/O processor that would normally provide the input data stream. The data are then distributed to a number of queues serving as inputs to the FFT primitives that perform the operations on the rows of the input stream. The output of the FFT primitives flow to another set of queues that are input to the corner turn graph. Once the data are sorted correctly, they are sent to the input queues of the column FFT primitives. The graph is then executed by the simulator where the functionality, queue sizes, and communication between nodes are examined. This same graph is input to the hardware/software partitioning tools that generate the partition list. Given the partition list and the hardware configuration file, the autocode tool set generates the load image for the target platform.

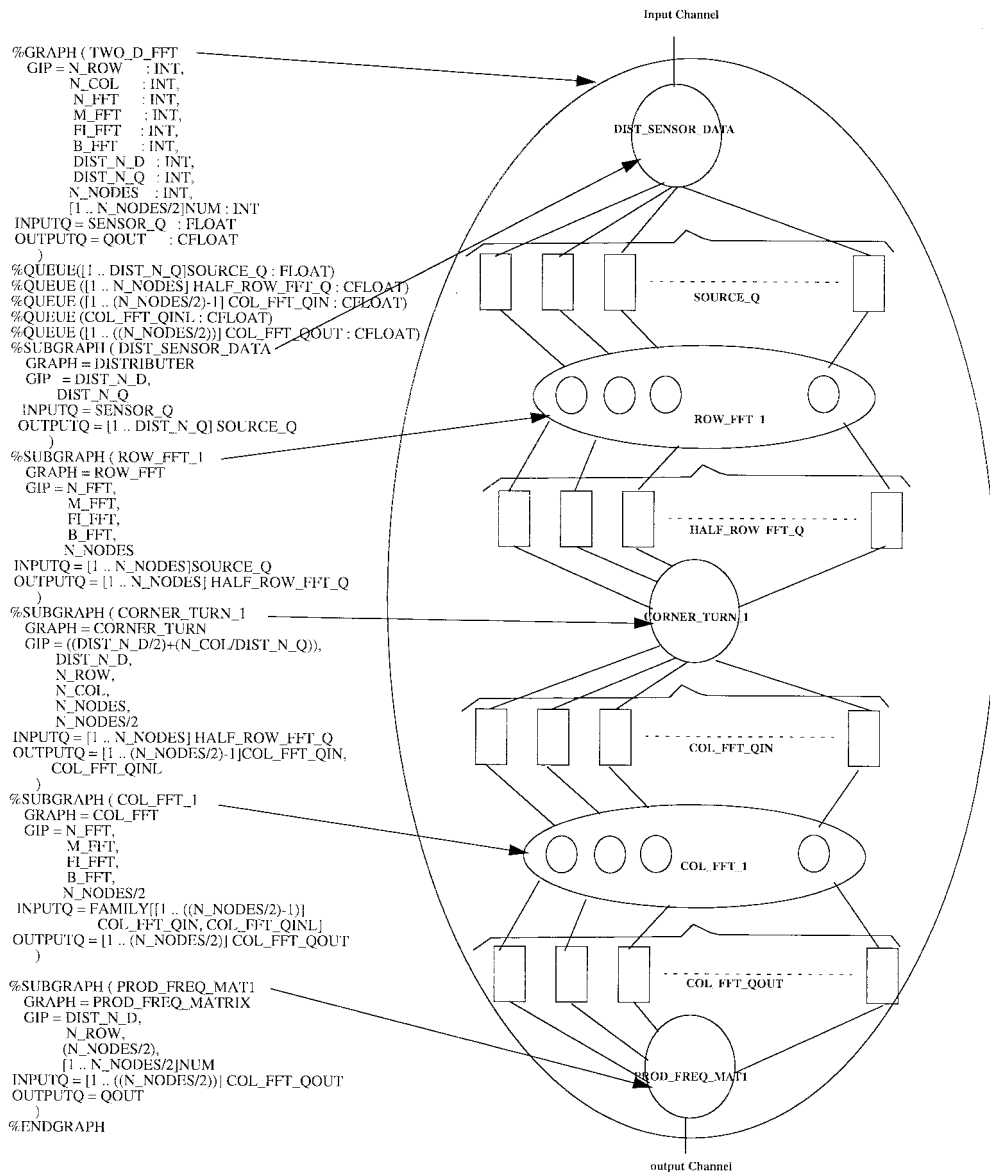

FIGURE 78.9: Example PGM application graph.

78.7 Architectural Design

Signal processing systems are characterized as having high throughput requirements as well as stringent physical constraints. However, due to economic objectives, signal processing systems must also be developed and produced at minimal cost, while meeting time-to-market constraints in order to maximize product profits. Such cost-effective systems can only be produced by applying a high degree of cost emphasis during the early stages of design. Although the conceptual design process typically involves less than 4% of the total prototyping time and cost, it accounts for more than 70% of a system's life cycle cost. Consequently, the goal of the architecture designer is to optimize preliminary architectural design decisions with respect to the dominant system-level cost elements such as acquisition costs, maintenance costs, and time-to-market costs, while satisfying performance and physical constraints.

78.7.1 Cost Models

Current rapid prototyping design methodologies have overlooked an important characteristic of software prototyping. Various parametric studies based on historical project data show that software is difficult to design and test if “slack” margins for hardware CPU and memory resources are overly restrictive [31]. Severe resource constraints may require software developers to interact directly with the operating system and/or hardware in order to optimize the code to meet system requirements. Such constrained architectures particularly increase the integration and test phase because resource constraints usually are not pushed until all software pieces come together. In systems in which most hardware is simply commercial-off-the-shelf (COTS) parts, the time and cost of software prototyping and design can dominate the schedule and budget. If physical constraints permit, the hardware platform can be relaxed to achieve significant reductions in overall development cost and time. This principle of software prototyping is illustrated in Fig. 78.10 [14, 32]. The figure shows how system costs are dominated by software costs, especially at low production volumes, when CPU and memory utilization is high. However, as the utilization of these hardware resources is reduced, the software costs decrease drastically. Most parametric software cost estimation models quantitatively represent this principle. For example, the embedded mode Revised Intermediate COCOMO (REVIC) [33] software development cost and time models can be written as follows:

$$S_C = C_s \left[3.312 \times L^{1.2} \times F_E \times F_M \times \prod_{i=1}^{17} F_i \right] \quad (78.1)$$

$$S_T = 4.376 \left[3.312 \times L^{1.2} \times F_E \times F_M \times \prod_{i=1}^{17} F_i \right]^{0.32} \quad (78.2)$$

S_C refers to the software development cost in dollars. S_T depicts development time in months. C_s is the software labor cost per person-month of effort. L denotes the number of delivered source instructions (thousands) including application code, OS kernel services, control and diagnostics, and support software. The F_i s represent additional cost drivers which model the effect of personnel, computer, product, and project attributes on software cost. F_E and F_M are effort adjustment factors which denote the effect of the execution time margin and storage margin on development cost. The relation between these effort adjustment factors and CPU and memory utilization is shown in Table 78.3. Linear interpolation is used to determine the effort multiplier values for utilizations between the given data points displayed in the table.

Despite the fact that many signal processing systems are being implemented with purely software solutions due to flexibility and scalability requirements, the combination of high throughput requirements and stringent form factor constraints sometimes necessitate the need for implementing part

TABLE 78.3 Execution Time and
Main Storage Constraint Effort
Multipliers

Rating	Utilization	F_E	F_M
Nominal	Up to 50%	1.00	1.00
High	70%	1.11	1.06
Very high	85%	1.30	1.21
Extra high	95%	1.66	1.56

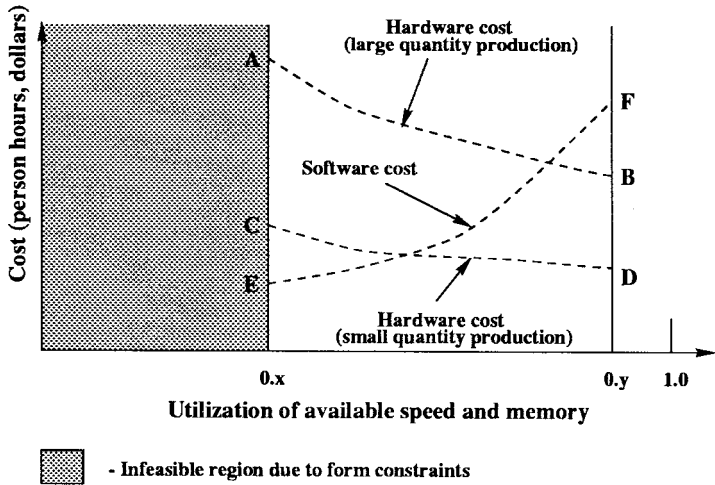

FIGURE 78.10: Hardware/software prototyping costs.

of the system with dedicated hardware elements such as ASICs or FPGAs. Even though ASICs can provide sizable increases in performance and size efficiency, they come with a heavy development cost penalty which can usually only be justified by high volume production. In order to quantify this effect for trade-off analysis, parametric hardware cost models can be used. For example, the parametric cost model presented in [34, 35] for ASIC design provides the following hardware development time and cost relations for ASIC development:

$$H_C = C_h \left\{ (1 + D)^{YR} \left[A + B(S_h)^H \right] \right\} \tag{78.3}$$

$$H_T = 3.5 \left\{ (1 + D)^{YR} \left[A + B(S_h)^H \right] \right\}^{0.34} \tag{78.4}$$

YR is 1984 minus the year of the bulk of the design effort, C_h is the hardware labor cost per person-month, and A , B , D , and H are parameters of the model. D is the average annual improvement factor; A is the startup manpower; B is a measure of the productivity; and H is a measure of economies/diseconomies of scale. FPGAs provide more flexibility and lower cost penalties than ASICs at the expense of performance and size efficiency. From the FPGA cost model presented in [36], we will assume that FPGA development time and cost can be modeled as roughly one-third of that obtained for a comparable size ASIC. Although rising HW/SW development costs have very detrimental effects on life cycle cost, the effect of an increase in development time can be much more devastating.

Time-to-market costs can often outweigh design, prototyping, and production costs. A recent survey showed that being six months late to market resulted in an average of 33% profit loss. Engineering managers stated that they would rather have a 100% overrun in design and prototyping

costs than be three months late to market with a product. Early market entry allows for increased brand name recognition, market share, and product yields. Market research performed by Logic Automation has shown that the demand and potential profits for a new HW/SW product can be modeled by a triangular window of opportunity as shown in Fig. 78.11 [36]. Figure 78.11 illustrates the effect of delivering a product to market late. The shaded region of the triangle signifies the loss of revenue due to late entry in the market. This loss in revenue can be quantitatively stated as follows:

$$R_L = R_0 \times D(3W - D) / (2W^2) \quad (78.5)$$

R_0 refers to the expected product revenue, D is the delay (months) in delivering a product to market, and W is half the product lifetime (months). Therefore, in order to maximize profits, the product must be on the market by the start of the demand window.

FIGURE 78.11: Time-to-market cost model.

78.7.2 Architectural Design Model

In this section, we present a cost-driven approach to conceptual architecture design. The conceptual architecture design process consists of HW/SW partitioning, architecture selection, and software partitioning. As input, this design stage accepts the application data/control flow graph, system-level performance requirements, form factor constraints, schedule constraints, and HW/SW reuse library parameters. As output, this stage produces an architecture candidate which serves as input to the architectural verification stage. VHDL performance models, described in the next section, are used to verify the architecture candidate. This model is known as the *conceptual prototype* of the system. If the conceptual prototype does not meet performance specifications, updated performance parameters are back annotated to the architecture design process, and the process is repeated.

The architectural design problem can be modeled as a constrained optimization problem. The objective of cost-effective architecture design is to choose a HW/SW architecture which minimizes total life cycle cost, while maximizing potential product profits subject to performance and form factor constraints. Our approach quantitatively models the architecture design process by formulating it as a

non-linear mixed-integer programming problem. In order to provide support for high performance signal processing applications, we assume a distributed memory architecture composed of multiple programmable processors, ASICs, I/O devices, and/or FPGAs connected over a crossbar network. The goal of the architectural design process in this context is to determine the number and type of programmable processors (i860, SHARC, etc.), the memory capacity, the number of dedicated hardware elements (ASIC, FPGA), and to map the data/control flow graph nodes to the architectural elements in a manner that optimally meets design and economic objectives.

An example mathematical programming formulation that can be used to model the architecture design process is shown in Fig. 78.12. The major decision variables of the model are defined as

Objective: Minimize software development costs, hardware dev./prod. costs, NRE costs, and revenue losses

$$\sum_{i=1}^2 C_h h_i + C_{NRE} \sum_{j=1}^N \sum_{i=1}^N a_i^{asic} \delta_{ij} + V(C^{mem} \mu) + V(\sum_{i=1}^M C_i^{proc} \rho_i) + V(\sum_{j=1}^N \sum_{i=1}^N C_{fpga} a_i^{fpga} \beta_{ij}) + V(\sum_{j=1}^N \sum_{i=1}^N C^{asic} a_i^{asic} \delta_{ij}) + R_{od}(3W - d) / (2W^2) + C_s s$$

subject to:

Software development cost definition constraint

$$-Zw_{ij} \leq (s - 3.312L^{1.2} f_j^E f_j^M \prod_{i=1}^{17} F_i) \leq Zw_{ij} \text{ where } f_j^E = 1, f_j^M = 1 \\ f_2^E = 0.55u_p + 0.725, f_3^M = 0.3u_m + 0.85 \\ f_3^E = 1.27u_p + 0.223, f_4^M = u_m + 0.36 \\ f_4^E = 3.6u_p - 1.76, f_4^M = 3.5u_m + 1.765$$

Software development time definition constraint

$$4.376s^{0.32} - (d_s^+ - d_s^-) = T_s$$

ASIC development cost definition constraint

$$h_1 - (1 + D)^{YR} [A + B(\sum_{j=1}^N \sum_{i=1}^N a_i^{asic} \delta_{ij})^H] = 0$$

ASIC development time definition constraint

$$h_2 \geq (1 + D)^{YR} [A + B(\sum_{i=1}^N a_i^{asic} \delta_{ij})^H] \text{ for } j = 1, \dots, N \\ 3.5h_2^{0.34} - (d_{asic}^+ - d_{asic}^-) = T_s$$

FPGA development cost definition constraint

$$h_2 - \{(1 + D)^{YR} [A + B(\sum_{j=1}^N \sum_{i=1}^N a_i^{fpga} \beta_{ij})^H]\} / 3 = 0$$

FPGA development time definition constraint

$$h_2' \geq (1 + D)^{YR} [A + B(\sum_{i=1}^N a_i^{fpga} \beta_{ij})^H] \text{ for } j = 1, \dots, N \\ (3.5(h_2')^{0.34}) / 3 - (d_{fpga}^+ - d_{fpga}^-) = T_s$$

System-level performance constraint

$$\sum_{k=1}^N \sum_{j=1}^M \sum_{i=1}^N t_{ij}^{proc} \alpha_{ijk} + \sum_{j=1}^N \sum_{i=1}^N t_{ij}^{asic} \delta_{ij} + \sum_{j=1}^N \sum_{i=1}^N t_{ij}^{fpga} \beta_{ij} - \sum_{i=1}^M \rho_i (O_i^P + (O^M (\rho_i - 1))) - C_{comm} + \sum_{k=1}^N \sum_{j=1}^M \sum_{i=1}^{N-1} c_{il} \alpha_{ijk} \alpha_{ijk} + \sum_{j=1}^N \sum_{i=1}^{N-1} \sum_{k=i+1}^N c_{ik} \beta_{ij} \beta_{kj} + \sum_{j=1}^N \sum_{i=1}^{N-1} \sum_{k=i+1}^N c_{ik} \delta_{ij} \delta_{kj} \geq T_{SYS}$$

Hardware/Software partitioning constraint

$$\sum_{k=1}^N \sum_{j=1}^M \alpha_{ijk} + \sum_{j=1}^N (\beta_{ij} + \delta_{ij}) = 1 \text{ for } i = 1, 2, \dots, N$$

Time-to-market Constraints

$$d \geq d_s^+, d \geq d_{asic}^+, d \geq d_{fpga}^+ \\ d \leq W$$

Memory utilization definition constraint

$$u_m \mu = \sum_{k=1}^N \sum_{j=1}^M \sum_{i=1}^N m_i \alpha_{ijk} + O^{MEM}$$

Local memory size definition

$$u_m l_{jk}^m = \sum_{i=1}^N m_i \alpha_{ijk} + O^{lm} \text{ for all } j, k$$

Total number of programmable processors definition

$$Zn_{jk} \geq \sum_{i=1}^N \alpha_{ijk} \text{ for all } j, k$$

$$\rho_i = \sum_{j=1}^N n_{ij} \text{ for } i = 1, 2, \dots, M$$

ASIC Yield constraint

$$\sum_{i=1}^N a_i^{asic} \delta_{ij} \leq (1/K) \ln(1/Y), \text{ where } j = 1, 2, \dots, N$$

FPGA size constraint

$$\sum_{i=1}^N a_i^{fpga} \beta_{ij} \leq U_{fpga} \text{ for all } j$$

System-level area and power constraints

$$\sum_{i=1}^M a_i^{proc} \rho_i + a_{mem} \mu + \sum_{j=1}^N \sum_{i=1}^N a_i^{asic} \delta_{ij} + \sum_{j=1}^N \sum_{i=1}^N a_i^{fpga} \beta_{ij} \leq U_A \\ \sum_{i=1}^M p_i^{proc} \rho_i + p_{mem} \mu + \sum_{j=1}^N \sum_{i=1}^N p_i^{asic} \delta_{ij} + \sum_{j=1}^N \sum_{i=1}^N p_i^{fpga} \beta_{ij} \leq U_P$$

Load Balancing Constraints

$$u_p - \Delta_p - Z(1 - n_{jk}) \leq (\sum_{i=1}^N t_{ij}^{proc} \alpha_{ijk} + O_j^P) / S_j \leq u_p + \Delta_p + Z(1 - n_{jk}) \text{ for all } j, k$$

Processor utilization definition constraint

$$u_p (\sum_{i=1}^N S_i \rho_i) = \sum_{k=1}^N \sum_{j=1}^M \sum_{i=1}^N t_{ij}^{proc} \alpha_{ijk} + \sum_{i=1}^M \rho_i (O_i^P + O^M (\rho_i - 1))$$

Interval Relation

$$w_{ij} = 1 - y_{ij} \text{ for } i, j = 1, 2, 3, 4$$

Memory Utilization Interval Constraints

$$u_m \leq 0.5g_1 + 0.7g_2 + 0.85g_3 + 0.95g_4 \\ u_m \geq 0.5g_2 + 0.7g_3 + 0.85g_4, \sum_{i=1}^4 g_i = 1$$

Processor Utilization Interval Constraints

$$u_p \leq 0.5y_1 + 0.7y_2 + 0.85y_3 + 0.95y_4 \\ u_p \geq 0.5y_2 + 0.7y_3 + 0.85y_4 \\ \text{where } \sum_{i=1}^4 y_i = 1$$

FIGURE 78.12: Architecture design model.

follows:

$$\alpha_{ijk} = \begin{cases} 1, & \text{if DFG task } i \text{ is implemented on the } k\text{th programmable processor of type } j, \\ 0; & \text{otherwise} \end{cases} \\ \beta_{ij} = \begin{cases} 1, & \text{if DFG task } i \text{ is implemented on the } j\text{th FPGA,} \\ 0; & \text{otherwise} \end{cases} \\ \delta_{ij} = \begin{cases} 1, & \text{if DFG task } i \text{ is implemented on the } j\text{th ASIC,} \\ 0; & \text{otherwise} \end{cases}$$

ρ_i	=	the number of programmable processors of type i in the architecture;
μ	=	the number of DRAM chips in the architecture;
d	=	the delay in delivering the product to market(months);
u_p	=	the overall processor utilization;
u_m	=	the overall memory utilization;
y_i	=	is a binary variable which signifies the processor utilization interval;
g_i	=	is a binary variable which signifies the memory utilization interval;
f_i^E	=	the execution time constraint effort multiplier for processor utilization interval i ;
f_i^M	=	the memory constraint effort multiplier for memory utilization interval i ;
s	=	the software development effort (person-months);
h_i	=	the hardware development effort for dedicated hardware type i (person-months);
n_{ij}	=	1 if processor j of type i is included in the architecture, otherwise 0;
l_{jk}^m	=	the local memory allocated to processor k of type j .

Additional model parameters include:

C_{NRE}	=	the overall non-recurring engineering cost per unit ASIC die area
N	=	the number of tasks (nodes) in the data/control flow graph; also, the maximum number of computational elements in the architecture
V	=	the production volume
C_i^{proc}	=	the procurement cost for a programmable processor of type i
C^{mem}	=	the procurement cost for per DRAM chip
M	=	the number of different types of programmable processors
C^{fpga}	=	the production cost per unit size for an FPGA
C^{asic}	=	the production cost per unit size for an ASIC
T_S	=	the amount of time after system concept when the product should be delivered to market
Z	=	a very large number
Y	=	the minimum allowable ASIC yield
K	=	the process defect density
U^{fpga}	=	the size limit on a single FPGA
U_A	=	the area limit on the system
U_P	=	the power limit on the system
S_i	=	the peak throughput of processor i
t_{ij}^{proc}	=	the throughput of task i implemented on processor j
t_i^{asic}	=	the throughput of task i implemented on an asic
t_i^{fpga}	=	the throughput of task i implemented on an fpga
O_i^P	=	the processor overhead (scheduling, resource management, dispatching, context switching) (ops/sec)
O^M	=	multiprocessor overhead factor
T_{sys}	=	the minimum required system level throughput
m_i	=	the memory requirement for task i
O^{MEM}	=	the total memory required for OS services, control and diagnostics, and support software
O^{lm}	=	the local memory required for OS services, control and diagnostics, and support software
Δ_p	=	is a constant that defines the desired utilization range on a processor
c_{kl}	=	the throughput penalty for transferring data between tasks k and l off-chip
C_{comm}	=	the worst case total throughput penalty due to transferring data between tasks off-chip

We are currently using the GAMS [37] optimization system to solve examples of this form. More specifically, the GAMS/DICOPT non-linear mixed-integer programming package is being employed. DICOPT utilizes non-linear optimization programs such as MINOS or CONOPT and mixed-integer programming packages such as OSL to rigorously solve these problems. Linearization techniques

such as those described in [38] are also being applied to the models to improve computational efficiency.

Interestingly, while the rapid prototyping community has largely ignored rigorous integer programming methods for “quick” simplified heuristics, the communications industry (e.g., AT&T, Airlines reservation systems, etc.) routinely uses optimization algorithms with variables numbering in a few tens of thousands and more. The authors feel that complex nonlinear and multiobjective functions cannot be optimized via the “human-in-the-optimization-loop” methods, and any extra effort spent in the conceptual phase of the design process is time well spent.

78.8 Performance Modeling and Architecture Verification

The selection process for possible system architectures was discussed in the previous section. Performance models [39, 40, 41, 42] are used to verify that the architectures adhere to specific time-critical system constraints. The advantages of performance models include:

- They capture the time aspects of the system under development (i.e., throughput, latency, and resource utilization) and present this information for rapid evaluation.
- They verify the performance of proposed architectures found in the architectural design stage.
- They allow for true HW/SW codesign by simulating the behavior of software on performance models of processor hardware. The model of software can take many forms, one being a simple delay which models the performance of a library software primitive executing on a specific processor. For example, an Analog Devices SHARC 2106X chip executes a Fast Fourier Transform (FFT) in shorter time than a Texas Instruments C30 processor. The performance model captures this information through the use of *generic* parameters and when simulated, uses this parameter to determine how long the processor will be utilized while performing the function [40, 41].
- They provide the capability for modeling operating system effects on multiprocessor network architectures [41].
- Performance model development time is shorter when compared with that of fully functional models and hence library population can be done in-cycle.

The fidelity attributes of token-based performance models used for system architecture verification through simulation are listed below:

Internal: {(Clock cycle → System event), (X), (X), (X), (Assembly → Primitive)}
External: {(Clock cycle → System event), (X), (X), (Full Structure → Black box), (X)}.

Temporal information for both the internal and external attributes are captured at multiple levels depending on the application modeled. For example, the system event level can capture large blocks of data passing over an interconnect network or the simulating of a large time slice of processing on a single processor. System events occur in the 10s of microseconds to 10s of milliseconds time span and potentially could contain millions of actual clock cycles. The clock cycles, however, are not simulated, only the time events where information is interchanged or processed. At higher resolutions, details may be required to capture how an interconnect network handles data streams from multiple processors at the clock cycle level. The performance models we use for architecture verification fall into these categories and an example is presented later. Performance level models do not capture the function or data values of the system but focus on its time aspects. Internally, a performance model has no structure, but externally, the structure can be represented by any level in the resolution hierarchy. For example, a network architecture model consisting of multiple processors

and interconnect ASICs could be described by first instantiating each of the components in a network model, then by connecting them using a performance model of a particular bus or interconnect protocol. At the other extreme, the model may be represented by a black box that outputs tokens based on a specified control input with the internal details represented by abstract behavior. On the RASSP program, the programmability generally was captured at the DSP function primitive level where signal processing procedures (FFT, etc.) are scheduled on performance models of processors. The processor models can, however, be defined for much higher resolutions where the primitives represent assembly level instructions.

The efficiency of these models is very high because the code is written at the behavioral level of abstraction in VHDL. Signals are used to pass abstract data types known as tokens between component elements. The tokens are record types in VHDL and take the form as shown in Fig. 78.13. All protocol handling information is carried within it. This data type is referred to as *cue* throughout the remainder of the paper. The *cue* data type is used as a virtual packet to pass information between elements in a system architecture. It contains fields for capturing statistical information about how the data is passed through a processor network (priority, collisions, retries, routes), information on the source and destination of packet (src_id, dest_id), packet size (c_size, resp_size), packet identification number (c_id), and transmission status (c_state). There are also user defined fields that allow the performance model designer to implement model specific details (int_user1, int_user2, real_user1, real_user2).

FIGURE 78.13: The declaration of *cue*. The information of each communication transaction is contained in three fields — basic information field, protocol field, and user-defined field.

Interoperability is determined by the ability of models with a similar external fidelity to communicate. For performance models to achieve this goal, a token format must be defined and standardized. Currently, there are no standards to meet this demand. Protocol converters can be developed to link performance models with alternate token structures but a standard is encouraged. RASSP is pursuing a standard.

78.8.1 A Performance Modeling Example: SCI Networks

A Scalable Coherent Interface (SCI) performance model has been developed as an example. The executable SCI model can serve as an executable specification for the communication protocol. Figure 78.14 illustrates the SCI node interface structure. **Linc** transmits or bypasses packets, and performs the primary SCI protocols. **REC_QUEUE** and **TR_QUEUE** are First-In-First-Out buffers which store receive packets and transmit packets. **Processor** contains a **responder** and a **res_handler**; **responder** generates the response packets for the request packets who ask for responses, and **res_handler** serves as a response packet consumer. The **packet generator** is used to create cues according to the required communication patterns. Connecting the SCI node interface, designers can easily construct an SCI network and create their inputs to evaluate the performance results.

Among the processes of the SCI node, **mux_process** dominates the primary communication protocol. The SCI protocol can be converted to the state diagram shown in Fig. 78.15. Based on the state diagram, the VHDL representation of **mux_process** at the performance level is written as shown in Fig. 78.16. *MUX.Process* is activated by *st_pkt*, *bf_pkt*, *tr_pkt*, and *MUX.State* and changes *MUX.State* according to the state diagram.

78.8.2 Deterministic Performance Analysis for SCI

A key requirement of real-time DSP architectures is determinism. Most designers would like to know the guaranteed worst-case performance rather than the average or peak performance. In order to make the performance determinable, an SCI network must satisfy the following constraints:

- Step 1. *The size of each packet is deterministic.*
- Step 2. *The interprocessor communications are deterministic.*
- Step 3. *All arrival packets are accepted.* That is to say, packets should not be retransmitted in an SCI ring. The retry packets might prevent sending the fresh packets and make the throughput and latency unpredictable.

DEFINITION 78.1 If a packet is retransmitted from the transmit queues, it is called a retry packet. If a packet is transmitted for the first time, it is called a fresh packet.

A basic SCI network is a unidirectional SCI ring. The maximum number of nodes traversed by a packet is equal to N in an SCI ring, and the worst-case path contains a MUX, a stripper, and $(N - 2)$ links. So, we find the worst case latency, $L_{\text{worst-case}}$, is :

$$L_{\text{worst-case}} = T_{\text{MUX}} + T_{\text{wire}} + T_{\text{stripper}} + (N - 2) \cdot T_{\text{link}} \quad (78.6)$$

$$= (N - 1) \cdot T_{\text{link}} - T_{\text{FIFO}} \quad (78.7)$$

where the link delay, T_{link} , is equal to $T_{\text{MUX}} + T_{\text{FIFO}} + T_{\text{stripper}} + T_{\text{wire}}$, T_{MUX} is the MUX delay, T_{wire} is the wire delay between nodes, T_{stripper} is the stripper delay, and T_{FIFO} is the full bypass FIFO delay.

The SCI link bandwidth, BW_{link} , is equal to 1 byte per second per link; the maximum bandwidth of an SCI ring is proportional to the number of nodes:

$$BW_{\text{ring}} = N \cdot BW_{\text{link}} \text{ (bytes/second)} \quad (78.8)$$

where N is the number of nodes. Now let us consider the bandwidth of an SCI node. Since each link transmits the packets issued by all nodes in the ring, BW_{link} is shared by not only transmitting packets but passing packets, echo packets, and idle symbols.

$$BW_{\text{link}} = bw_{\text{transmitting}} + bw_{\text{passing}} + bw_{\text{echo}} + bw_{\text{idle}} \quad (78.9)$$

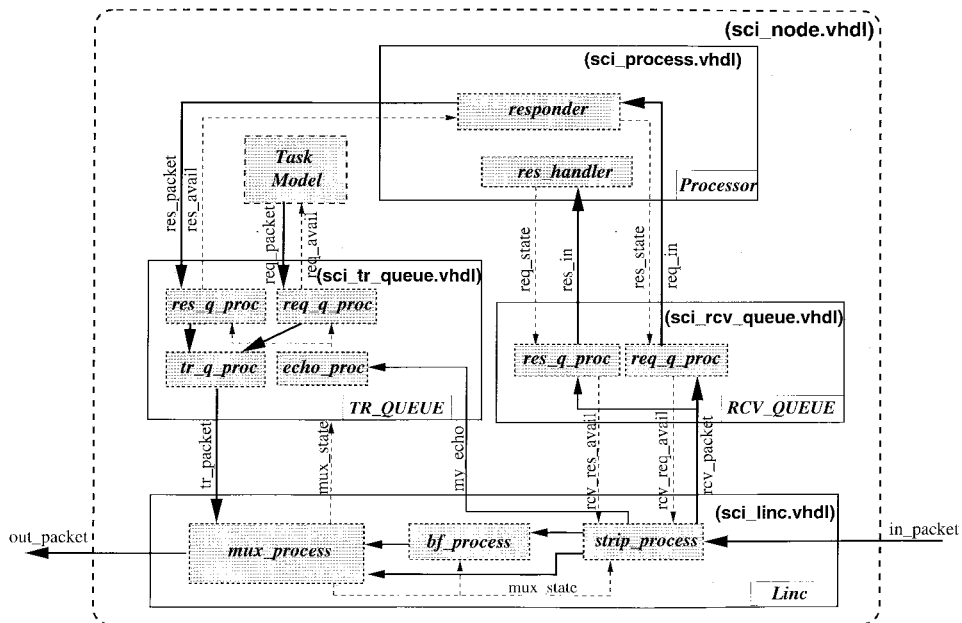

FIGURE 78.14: The SCI node interface performance model.

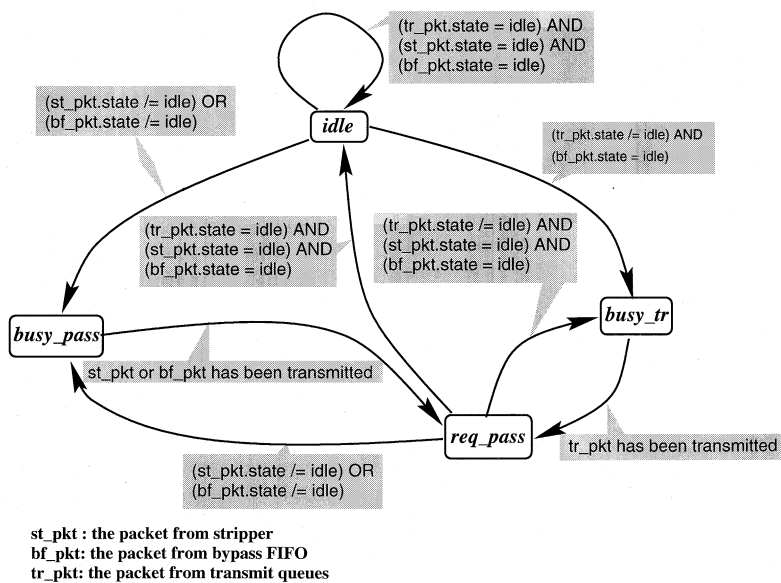

FIGURE 78.15: The state diagram of MUX.

```

MUX_Process : PROCESS(st_pkt, bf_pkt, tr_pkt, MUX_State)

                time_busy := time_busy + SCI_BASE_TIME;
                MUX_State <= req_pass after time_busy;
            ELSE
                MUX_State <= idle;
            END IF;
        END CASE;
    END PROCESS MUX_Process;

```

FIGURE 78.16: The VHDL process of MUX.

where $bw_{\text{transmitting}}$ is the consumed bandwidth of transmitting packets, bw_{passing} is the consumed bandwidth of passing packets, bw_{echo} is the consumed bandwidth of echo packets, and BW_{idle} is the consumed bandwidth of idle symbols. Assuming that the size of the send packets is fixed, we find $bw_{\text{transmitting}}$ is:

$$bw_{\text{transmitting}} = BW_{\text{link}} \cdot \frac{N_{\text{transmitting}} \cdot D_{\text{packet}}}{D_{\text{link}}} \quad (78.10)$$

$$= BW_{\text{link}} \cdot \frac{N_{\text{transmitting}} \cdot D_{\text{packet}}}{(N_{\text{passing}} + N_{\text{transmitting}}) \cdot (D_{\text{packet}} + 16) + N_{\text{echo}} \cdot 8 + N_{\text{idle}} \cdot 2} \quad (78.11)$$

where D_{packet} is the data size of a transmitting packet, D_{link} is the number of bytes passed through the link, $N_{\text{transmitting}}$ is the number of transmitting packets, N_{passing} is the number of passing packets, N_{echo} is the number of echo packets, and N_{idle} is the number of idle symbols. A transmitting packet consists of an unbroken sequence of data symbols with a 16-byte header that contains address, command, transaction identifier, and status information. The echo packet uses an 8-byte subset of the header while idle symbols require only 2 bytes of overhead. Because each packet is followed by at least an idle symbol, the maximum $bw_{\text{transmitting}}$ is:

$$BW_{\text{transmitting}} = BW_{\text{link}} \cdot \frac{N_{\text{transmitting}} \cdot D_{\text{packet}}}{(N_{\text{passing}} + N_{\text{transmitting}}) \cdot (D_{\text{packet}} + 18) + N_{\text{echo}} \cdot 10} \quad (78.12)$$

However, $BW_{\text{transmitting}}$ might be consumed by retry packets; the excessive retry packets will stop sending fresh packets. In general, when the processing rate of arrival packets, $R_{\text{processing}}$, is less than the arrival rate of arrival packets, R_{arrival} , the excessive arrival packets will not be accepted and their retry

packets will be transmitted by the sources. This cause for rejecting an arrival packet is the so-called *queue contention*. The number of retry packets will increase with time because retry packets increase the arrival rate. Once $bw_{\text{transmitting}}$ is saturated with fresh packets and retry packets, the transmission of fresh packets is stopped resulting in an increase in the number of retry packets transmitted.

Besides queue contention, incorrect packets cause the rejection of an arrival packet. This indicates a possible component malfunction. No matter what the cause, the retry packets should not exist in a real-time system in that two primary requirements of real-time DSP are data correctness and guaranteed timing behavior.

78.8.3 DSP Design Case: Single Sensor Multiple Processor (SSMP)

Figure 78.17 shows a DSP system with a sensor and N processing elements (PEs). This system is called the *Single Sensor Multiple Processor*. In this system, the sensor uniformly transmits packets to each PE and the sampling rate of the sensor is R_{input} . For the node i , if the arrival rate, $R_{\text{arrival},i}$, is greater than

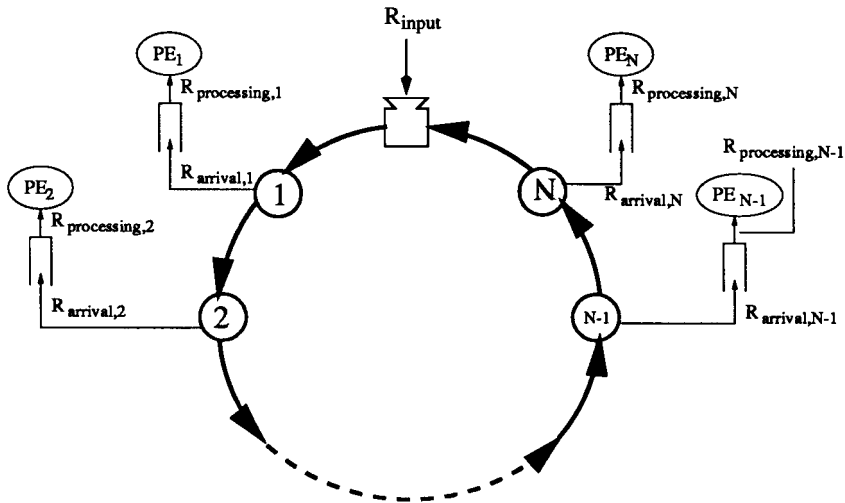

FIGURE 78.17: The SSMP architecture. The sensor uniformly transmits packets to each PE and the sampling rate of sensor is R_{input} ; so, the arrival rate of each node is $\frac{R_{\text{input}}}{N}$.

the processing rate, $R_{\text{processing},i}$, receive queue contention will occur and unacceptable arrival packets will be sent again from the sensor node. Retry packets increase the arrival rate and result in more retry packets transmitted by the sensor node. Since the bandwidth of the retry packets and fresh packets is limited by $BW_{\text{transmitting}}$, the sensor will stop reading input data when the bandwidth is saturated. For a real-time DSP, the input data should not be suspended, thus, the following inequality has to be satisfied to avoid the retry packets:

$$\frac{R_{\text{input}}}{N} \leq R_{\text{processing}} \quad (78.13)$$

Because the output link of the sensor node will only transmit the transmitting packets, the maximum transmitting bandwidth is:

$$BW_{\text{transmitting}} = BW_{\text{link}} \cdot \frac{D_{\text{packet}}}{D_{\text{packet}} + 18} \quad (78.14)$$

and the limitation of R_{input} is:

$$R_{\text{input}} \leq BW_{\text{link}} \cdot \frac{D_{\text{packet}}}{D_{\text{packet}} + 18} \quad (78.15)$$

(a)

(b)

FIGURE 78.18: The simulation of SSMP using *i*860 and SCI ring. (a) The result of SSMP with $R_{\text{input}} = 10$ MBytes/sec. The value of *packet5.retries* shows that there does not exist any request of retry packets. (b) The result of SSMP with $R_{\text{input}} = 100$ MBytes/sec. A retry packet is requested at 25944 ns.

We now assume a SSMP system design with a 10 MBytes/sec sampling rate and five PEs where the computing task of each PE is a 64-point FFT. Since each packet contains 64 32-bit floating-point data, D_{packet} is equal to 256 bytes.

From Eq. (78.13) the processing rate must be greater than 2 MBytes/sec, so the maximum processing time for each packet is equal to 128 μsec . Because an n -point FFT needs $\frac{n}{2} \log_2 n$ butterfly operations and each butterfly needs 10 FLOPs [44], the computing power of each PE should be greater than 15 MFLOPs. From a design library we pick *i*860s to be the processing elements and a single SCI ring to be the communication element in that *i*860 provides 59.63 MFLOPs for 64-point FFT and $BW_{\text{transmitting}}$ of a single SCI ring is 934.3 MBytes/sec which satisfies Eq. (78.15). Using 5 *i*860s, the

total computing power is equal to 298.15 MFLOPS. The simulation result is shown in Fig. 78.18(a). The result shows that retry packets for $R_{\text{input}} = 10$ MBytes/sec do not exist.

As stated earlier, if the processing rate is less than the arrival rate, the retry packets will be generated and the input stream will be stopped. Hence, we changed R_{input} from 10 MBytes/sec to 100 MBytes/sec to test whether the i860 can process a sampling rate as high as 100 MBytes/sec. Upon simulating the performance model, we found that the sensor node received an echo packet which asked for retransmitting a packet at 25944 ns in Fig. 78.18(b); thus, we have to substitute another processor with higher MFLOPS for i860 to avoid the occurrence of the retry packets.

Under the RASSP program, an additional example where performance level models were used to help define the system architecture can be found in [45].

78.9 Fully Functional and Interface Modeling and Hardware Virtual Prototypes

Fully functional and interface models support the concept of a hardware virtual prototype. The hardware virtual prototype is defined as a software representation of a hardware component, board, or system containing sufficient accuracy to guarantee its successful hardware system-level realization [5, 47]. The hardware virtual prototype adopts as its main goals (1) verification of the design correctness by eliminating hardware design errors from the in-cycle design loop, (2) decreasing the design process time through first time correctness, (3) allowing concurrent codevelopment of hardware and software, (4) facilitating rapid HW/SW integration, and (5) generation of models to support future system upgrades and maintenance. This model abstraction captures all the documented functionality and interface timing of the unit under development.

Following architectural trade studies, a high level design of the system is determined. This high level design consists of commercial-off-the-shelf (COTS) parts, in-house design library elements, and/or new application specific designs to be done in-cycle. At this level, it is assumed the COTS parts and in-house designs are represented by previously verified fully functional models of the devices. Fully functional models of in-cycle application specific designs serve as high level models useful for system level simulation. They also serve as *golden* models for verification of the synthesizable RTL level representation and define its testbench. For system level simulations, this high level model can improve simulation speed by an order of magnitude while maintaining component interface timing fidelity.

The support infrastructure required for fully functional models is the existence of a library of component elements and appropriate HDL simulation tools. The types of components contained in the library should include models of processors, buses/interconnects, memories, programmable logic, controllers, and medium and large scale integrated circuits. Without sufficient libraries, the development of complex models within the in-cycle design loop can diminish the usefulness of this design philosophy by increasing the design time. The model fidelity used for hardware virtual prototyping can be classified as listed below:

Internal: {(Gate \rightarrow Clock cycle), (Bit true \rightarrow Token), (All), (Major blocks), (Micro code \rightarrow Assembly)}

External: {(Gate \rightarrow Clock cycle), (Bit true), (All), (Full Structure), (X)}.

Internally and externally, the temporal information of the device should be at least clock cycle accurate. Therefore, internal and external signal events should occur as expected relative to clock edges. For example, if an address line is set to a value after a time of 3 ns from the falling edge of a clock based on the specification for the device, then the model shall capture it. The model shall also contain hooks, via generic parameters, to set the time related parameters. The user selectable generic parameters are

placed in a VHDL package and represent the minimum, typical, and maximum setup times for the component being modeled.

Internal data can be represented by any value on the axis, while the interface must be bit true. For example, in the case of an internal 32-bit register, the value could be represented by an integer or a 32-bit vector. Depending on efficiency issues, one or the other choice is selected. The external data resolution must capture the actual hardware pinout footprint and the data on these lines must be bit true. For example, an internally generated address may be in integer format but when it attempts to access external hardware, binary values must be placed on the output pins of the device. The internal and external functionality is represented fully by definition.

Structurally, because the external pins must match those of the actual device, the external resolution is as high as possible and therefore the device can be inserted as a component into a larger system if it satisfies the interoperability constraints. Internally, the structure is composed of high level blocks rather than detailed gates. This improves efficiency because we minimize the signal communication between processes and/or component elements.

Programmability is concerned with the level of software instructions interpreted by the component model. When developing hardware virtual prototypes, the programmable devices are typically general purpose, digital, or video signal processors. In these devices, the internal model executes either microcode or the binary form of assembly instructions and the fidelity of the model captures all the functionality enabling this. This facilitates hardware/software codevelopment and cosimulation. For example, in [5], a processor model of the Intel *i*860 was used to develop and test over 700 lines of Ada code prior to actual hardware prototyping.

An important requirement for fully functional models to support reuse across designs and rapid systems development is the ability to operate in a seamless fashion with models created by other design teams or external vendors. In order to ensure interoperability, the IEEE standard nine value logic package² is used for all models. This improves technology insertion for future design system upgrades by allowing segments of the design to be replaced with new designs which follow the same interoperability criteria.

Under the RASSP program, various design efforts utilized this stage in the design process to help achieve first pass success in the design of complex signal processing systems. The Lockheed Sanders team developed an infrared search and track (IRST) system [46, 47] consisting of 192 Intel *i*860 processors using a Mercury RACEWAY network along with custom hardware for data input buffering and distribution and video output handling. The hardware virtual prototype (HVP) served to find a number of errors in the original design both in hardware and software. Control code was developed in Ada and executed on the HVP prior to actual hardware development. Another example where hardware virtual prototypes were used can be found in [48].

78.9.1 Design Example: I/O Processor for Handling MPEG Data Stream

In this example, we present the design of an I/O processor for the movement of MPEG-1 encoder data from its origin at the output of the encoder to the memory of the decoder. The encoded data obtained from the source is transferred to the VME-bus through a slave interface module which performs the proper handshaking. Upon receiving a request for data (AS low, WRITE high) and a valid address, the data is presented on the bus in the specified format (the mode of transfer is dictated by the VME signals LWORD, DS0, DS1 and AM[0..5]). The VME DTACK signal is then driven low by the slave indicating that the data is ready on the bus after which the master accepts the data. It repeats this cycle if more data transfer is required, otherwise it releases the bus. In the simulation of

²IEEE 1164-1993 Standard Multi-Value Logic System for VHDL Model Interoperability.

the I/O architecture in Fig. 78.19 a Quad-Byte-Block Transfer (QBBT) was done.

The architecture of the I/O processor is described below. The link ports were chosen for the design since they were an existing element in our design library and contain the same functionality as the link ports on the Analog Devices 21060 digital signal processor. The circuit's ASIC controller is designed to interface to the VME bus, buffer data, and distribute it to the link ports. To achieve a fully pipelined design, it contains a 32-bit register buffer both at the input and outputs. The 32-bit data from the VME is read into the input buffer and transferred to the next empty output register. The output registers send the data by unpacking. The unpacking is described as follows: at every rising edge of the clock (LxCLK) a 4-bit nibble of the output register, starting from the LSB, is sent to the link port data line (LxDAT) if the link port acknowledge (LxACK) signal is high. Link ports that are clocked by LxCLK, running at the twice the core processor's clock rate, read the data from the controller ports with the rising edge of the LxCLK signal. When their internal buffers are full they deassert LxACK to stop the data transfer.

Since we have the option of transferring data to the link ports at twice the processor's clock rate, four link ports were devoted to this data transfer to achieve a fully pipelined architecture and maximize utilization of memory bandwidth. With every rising edge of the processor clock (CLK) a new data can be read into the memory. Figure 78.20 shows the pipelined data transfer to the link ports where DATx represents a 4-bit data nibble. As seen from the table, Port0 can start sending the new 32-bit data immediately after it is done with the previous one. Time multiplexing among the ports is done by the use of a token. The token is transferred to the next port circularly with the rising edge of the processor clock. When the data transfer is complete (buffer is empty), each port of the controller deasserts the corresponding LxCLK which disables the data transfer to the link ports. LxCLKs are again clocked when the transfer of a new frame starts. The slave address, the addressing mode, and the data transfer mode require setups for each transfer. The link ports, IOP registers, DMA control units, and multiport memory models were available in our existing library of elements and they were integrated with the VME bus model library element. However, the ASIC controller was designed in-cycle to perform the interface handshaking. In the design of the ASIC, we made use of the existing library elements, i.e., I/O processor link ports, to improve the design time. To verify the performance and correctness of the design, the comparison mechanism we used is shown in Fig. 78.21. The MPEG-1 encoder data is stored in a file prior to being sent over the VME bus via master-slave handshaking. It passes through the controller design and link ports to local memory. The memory then dumps its contents to a file which is compared to the original data. The comparisons are made by reading the files in VHDL and doing a bit by bit evaluation. Any discrepancies are reported to the designer.

The total simulation time required for the transfer of a complete frame of data (28Kbytes) to the memory was approximately 19 min of CPU time and 1 h of wall clock time. These numbers indicate the usefulness of this abstraction level in the design hierarchy. The goal is to prove correctness of design and not simulate algorithm performance. Algorithm simulations at this level would be time prohibitive and must be moved to the performance level of abstraction.

78.10 Support for Legacy Systems

A well-defined design process capturing systems requirements through iterative design refinement improves system life cycle and supports the reengineering of existing legacy systems. With the system captured using the top-down evolving design methodology, components, boards, and/or subsystems can be replaced and redesigned from the appropriate location within the design flow. Figure 78.22 shows examples of possible scenarios. For example, if a system upgrade requires a change in a major system operating mode (e.g., search/track), then the design process can be reentered at the executable requirements or specification stage with the development of an improved algorithm. The remaining system functionality can serve as the environment test bench for the upgrade. If the system upgrade

consists of a new processor design to reduce board count or packaging size, then the design flow can be reentered at the hardware virtual prototyping phase using fully functional models. The improved hardware is tested using the previous models of its surrounding environment. If an architectural change using an improved interconnect technology is required, the performance modeling stage is entered. In most cases, only a portion of the entire system is affected, therefore, the remainder serves as a testbench for the upgrade. The test vectors developed in the initial design can be reused to verify the current upgrade.

78.11 Conclusions

In this chapter, we have presented a top-down design process based on the RASSP virtual prototyping methodology. The process starts by capturing the system requirements in an executable form and through successive stages of design refinement, and ends with a detailed hardware design. VHDL models are used throughout the design process to both document the design stages and provide a common language environment for which to perform requirements simulation, architecture verification, and hardware virtual prototyping. The fidelity of the models contain the necessary information to describe the design as it develops through successive refinement and review. Examples were presented to illustrate the information captured at each stage in the process. Links between stages were described to clarify the flow of information from requirements to hardware. Case studies were referenced to point the reader to more detail on how the methodology performs in practice. Tools are being developed by RASSP participants to automate the process at each of the design stages and references are provided for more information.

Acknowledgments

This research was supported in part by DARPA ETO (F33615-94C-1493) as part of the RASSP Program 1994-1997. The authors would like to thank all the RASSP program participants for their effort in creating and demonstrating the usefulness of the methodology and its effectiveness in achieving improvements in the overall design process.
